I wish to support Mr. Marshall's views with regard to the importance of taking into account prospective developments when reconstructing a plant, and I consider the cost characteristics and the load factor curves (Fig. 4) an essential help in this respect. For instance, in the example of the reconstruction of a number of London stations, I gave on page 135 the cost characteristics both for the new station (B₄) and the remaining old stations (C₃). To determine the influence of an increased traction load compared with the existing combination of light, power, and traction (Table III, items 17, 18, and 19), I would refer to the load-factor curve in Fig. 4, from which the corresponding improvement of the load factor, and therefore also the approximate improvement of the utility factor, are found. This value substituted in the above equations for the cost characteristics (C₃ and B₄, page 135), determines the new average price to be charged for energy after allowing for a normal return on the capital outlay, eliminating thereby a great deal of guesswork which is generally connected with such calculations for future developments.

The smaller losses in the low-tension network after reconstruction (item 18, Table VI), to which Mr. Marshall refers, are explained by an increase of the utility factor after the reconstruction (item 8, Table VI), which again is due to the smaller reserve (item 7, Table VI) permissible with large plants, as stated in my address at the bottom of page 129. The difference in the cost of the losses (item 19, Table VI), which is obtained by multiplying the losses by the generating costs, is still greater, since the generating costs are also considerably decreased after the reconstruction. With regard to the price which I allowed for the land for the overhead line, I would refer to my reply on page 149 to Mr. Snell's criticism.

Dr. Klingenberg

DISCUSSION ON

"ELECTRIC TRAIN-LIGHTING SYSTEMS." *

MANCHESTER LOCAL SECTION, 27TH JANUARY, 1914.

Dr. E. ROSENBERG: There can be no doubt whatsoever that electric lighting is incomparably safer than gas lighting for trains, and that the tanks containing compressed gas under the carriages do not increase the safety of the travelling public. The most remarkable statements, however, are made in discussions on train lighting. I once heard that compressed gas, instead of igniting, would even blow out a lighted match held in front of a puncture in a tank. I will not combat the possibility of such an experiment, but unfortunately the actual experience of railway collisions shows that the gas not only becomes ignited but also sets fire to the woodwork of the train, and that the fire spreads with great rapidity. After the Aisgill disaster an engineer who took a prominent part in the rescue work gave quite clear and impressive evidence of the part which the gas tanks played in that disaster: he was engaged in gas-engine work, and presumably was therefore not greatly prejudiced in favour of electricity. In the discussions that arose out of that disaster, a very prominent person stated that according to information which he had received, but not checked, there was not a single electrically-lighted coach on either the German or Austrian State Railways. This statement is without any foundation. Although the large majority of the coaches are still lighted with gas, there are hundreds of electrically-lighted coaches on the Prussian railways, as well as on practically every other German railway, and the same remark applies to the Austrian railways. One high official of the Prussian State Railway, namely Geheimrat Wittfeld, was prominently associated with the development of a train-lighting system mentioned in the paper (the Buttner system), which has since made rapid progress and is now also used on a number of other railways. I can speak from first-hand knowledge on that point because my machine, which is described in the paper, is used in that system. The French State Railways have taken up the question of electric lighting on trains very vigorously, and strong action was taken after the recent collision at Melun, where the gas caused a very serious fire.

The author's comparison of constant-voltage and constant-current systems is of great interest. I would say, however, that strictly speaking there is no constant-voltage or constant-current system. The systems of Stone and the author, for instance, are constant-torque systems, and therefore try to give a current in inverse proportion to the momentary voltage of the battery. In the so-called constant-voltage systems the voltage must be made to rise gradually from approximately 2 volts per cell to the charging voltage, say, 2.4 volts per cell. It must also be considered that regulators do not work with perfect accuracy, and that in some systems the inaccuracy of the regulator due to friction, heating of the coils, and other causes, may be so great as to create a difference in the voltage quite comparable with that in the so-called constant-current systems due to the gradual increase of

the voltage during continued charging. The inaccuracy in the so-called constant-current systems, due for instance to varying belt friction and other causes, may also cause greater differences in the current than occur in the so-called constant-voltage systems due to the reduction of the current during the continuous charge. There is one very interesting constant-voltage system designed by Mr. Woodbridge, of the Electric Storage Battery Company of America, which is specially distinguished by the omission of any kind of lamp regulator or resistance between the battery and the lamps. Mr. Woodbridge uses a pressure of only 2.25 volts per cell. He claims that this voltage is high enough to keep the battery well charged and to maintain it in perfect order, and that this voltage, on the other hand, is low enough to prevent the gradual increase in the illumination proving uncomfortable to the eyes of passengers when the battery voltage rises from its normal to this figure. I have not ridden in a car fitted with this system, but the statement seems perfectly feasible, considering how little one notices, when reading in the dusk, the gradual reduction in the illumination, which amounts at that time to many per cent every few minutes.

The Electric Storage Battery Company uses instead of a voltage regulator a very interesting arrangement, which is shown in Fig. A herewith. For the generator a modifi-

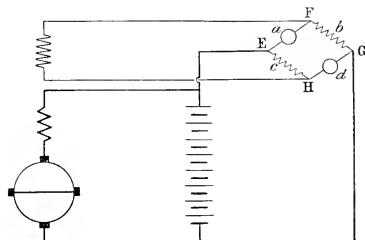

FIG. A.

cation of the Rosenberg machine is used, which the author has mentioned in Messrs. Mather and Platt's system. The field winding comprises a series winding, which is just strong enough to compensate for the armature reaction, and a shunt winding which takes a very small current and is connected as one diagonal of a Wheatstone bridge. Two arms of this bridge, namely *a* and *d* in Fig. A, consist of iron wires in bulbs filled with rarefied hydrogen, while the two other arms, *b* and *c*, are represented by ordinary resistance material. The other diagonal of the bridge is connected to the terminals of the generator (in parallel with the battery). The resistance of iron wire when the latter is near dull-red heat increases enormously

* Paper by Mr. T. Ferguson (see p. 262).

Dr. Rosenberg. as the temperature rises. The iron wire, for instance, can be calibrated for 1 ampere so that it will give, say, a drop in pressure of 2 volts across its terminals when the current falls to 0.99 ampere, and if an attempt is made to increase the current, the resistance will increase so rapidly that the voltage may rise to volts, whilst the current actually returns to 1.0 ampere after momentarily rising slightly above 1.0 ampere. Therefore, if the voltage of the generator is slightly below its normal value, causing the current through the Wheatstone bridge to fall slightly below its calibration value, the voltage drop between the points E and F of the bridge and between the points G and H will be very low, and the exciting voltage for the shunt winding will not be much less than the battery voltage. With the smallest rise of the battery voltage, however, this exciting voltage will be reduced considerably—even down to zero. The machine will therefore not perceptibly change its voltage whatever the increase of speed may be. This system has been used very successfully on the Santa Fé Railway.

The statement on page 264, that "with most double-battery systems the efficiency is probably not more than about 5 to 10 per cent of the current generated," seems to me to be very remarkable, and I cannot possibly believe that it refers to systems which provide a definite current independent of belt slipping and graduated in accordance with the momentary lighting load. With reference to Fig. 4, a statement as to the value of the charging current would be valuable. The dynamo efficiency of 65 per cent mentioned on page 266 seems to be a fair figure if it includes the belt losses in systems which work without belt slipping. In describing his own very interesting system the author refers to an overcharge preventer which breaks the dynamo field. I should like to know whether this procedure is also followed when the lights are on. It is quite possible that on very long non-stop runs the state of the battery might reach the "gassing" point even if the lights were on; breaking the field would then mean that during the remainder of the journey the battery would have to feed the lamps and that the battery might therefore become discharged again. That would be a disadvantage compared with other systems in which the output can be exactly adjusted by changing the excitation, and where the overcharge preventer can be arranged so as to reduce the excitation to such a value that the dynamo current is then just equal to the lamp current.

Mr. J. DENHAM: The author refers to several cases where overcharge preventers are used, but I should like to know if overdischarge preventers are employed at all on the various train-lighting systems now in general use. It is possible to imagine cases where the battery would run right down, i.e. below the generally accepted minimum voltage of 1.8 volts per cell, if carriages were being cleaned and were left all night with all the lights on owing to careless cleaners; or a carriage might be used for many hours on a foggy day and night running slowly and with many stops, so that the battery would receive little charge and would give frequent discharges. It must be very detrimental to the battery in such cases of "running down" to be in any way periodically.

Mr. F. E. COOPER: Speaking from the point of view of the "man in the street," there is no doubt as to the great

danger which arises due to the illumination of trains by gas. It was certainly a revelation to me to learn from this paper what a large number of electric train-lighting systems had been developed, and like Dr. Rosenberg I hope for the complete displacement of gas for train lighting.

Mr. A. POPE: There is one system which the author has not referred to and which I think is a very important one, namely, the straight storage system. From the battery makers' point of view this is probably the best system, and I think that in many cases it is also the best system from the user's point of view. Where trains have to run over a distance of say 12 to 15 miles, and charging facilities can be provided at one or both ends of the line, a small battery only need be used. Whatever may be the state of charge of the two batteries, I think it is impossible for one battery to discharge into the other, since immediately such a current passes the back electromotive force of the low battery will rise and stop the flow of current. On page 264 the author refers to curing a sulphated cell by running it in service. I think a cell when it gets into that state should be taken out of service and put into the shops for proper treatment, which it cannot receive in service. With regard to the small voltage variations on the battery, an increase of 5 per cent in voltage reduces the life by about 50 per cent, and even a 2½ per cent increase in voltage will reduce the life by about 30 per cent. This is a point which the users will probably consider important.

Mr. E. C. McKINNON: I have had at various times to report on numerous systems of train lighting, and one of my pleasantest experiences was a tour in 1906 through Germany and Bavaria to investigate and report on the Rosenberg system. I was impressed at the time by the great difference in the care which was taken of the batteries in Germany—and at a later visit, in Scandinavia—compared with that in this country. In my report I emphasized this point and advanced the opinion that however satisfactory the results of any particular system might be, it did not follow that these results could be repeated in this country owing to the conditions of working. Let me quote from the report:

"In Germany and Bavaria the railways are State controlled, and the careful operation of the batteries is deemed of equal importance with the rest of the plant, all of which is minutely supervised. The batteries are properly examined once a week. In this country, however, batteries so far have been a very neglected part of railway equipment. From our own experience we know that the regulation period for opening up a battery to examine it properly is in some cases six months, and instances are on record where a coach has been lost for several weeks. Then again it is doubtful if the railway companies would agree to incur the expense entailed by the provision of distilled water for topping-up purposes, whereas no other water than distilled is used in Germany and Bavaria."

That is 8 years ago. Since that time the working conditions here, although still very far from ideal, have greatly improved. In a recent catalogue of one of the makers

whose system has been described by the author I find under the section dealing with cells the following statement: "Provision is made for inspection and testing, also for taking the specific gravity and keeping the cells in a fit and proper condition"; but on the other hand the catalogue also states that "Attention at very infrequent intervals only is required to see whether on the whole the battery is over or under charged." This can only be construed into an invitation not to trouble very much about the cells. The catalogue further states that when the coach is running with no lights on, a small charging current is passed through the battery to make up for the polarization losses. This is very bad practice, because it is the small current which is able to attack the positive plates and which by unnecessarily reducing them to lead peroxide shortens their life. A rough comparison of the method of assembling the cells shows the heavy handicap under which they are worked in this country. The British standard is a set of cells each in a lead-lined wooden box fitted with a bolted-down lid, the whole being placed in a wooden case slung under the body of the coach. To obtain access to the cells when in service it is necessary to crawl under the coach, remove the side of the outer case, disconnect the bolted connections, lift out the cells, and unscrew the lids, the whole operation being carried out while in a kneeling position. In Germany, however, the cells are in ebonite boxes which are held in a wooden case in sets of four, the cases being iron-bound at the bottom corners. The boxes are fitted with loose lids resting on the plates. The battery compartment is fixed directly under the body of the coach, and the footboard in front of the compartment swings up and is held in that position by a small bracket. The compartment is fitted with one or more locks; and by unlocking the compartment the front swings out, forming a shelf, on which the containers can be drawn so as to be at once ready for inspection. It should be noted that inspection under these conditions is so easy that the attendant assured me he makes it a practice of examining the battery after every second trip which the various trains make, although his instructions are that he need only do so once per week. In Denmark, axle-driven systems are not in common use owing to the number of ferries on the main routes, and straight battery lighting is employed. The battery is assembled on racks in a special battery compartment on the conductor's coach. Each cell can be examined readily at any moment whilst in ordinary service. On page 267 the author states that any of the constant-current systems can be maintained by comparatively poor-class labour. On page 263 he says that traffic conditions demand that a poor class of labour must be able to maintain the equipment; this I think is the keynote to the question of battery depreciation. In England, rule-of-thumb methods, indifferent attention, and crude switchgear are the custom, and if anything goes wrong the battery is blamed. In Germany we find splendid organization and close attention, and if anything goes wrong the mechanic is blamed. Dr. Rosenberg referred to Mr. Woodbridge's statement that a pressure of 2.25 volts would maintain a cell in proper condition in train-lighting service. I think a point has been missed here, namely, that the cell must be kept healthy. If the cells are once allowed to become sulphated, through

standing idle or discharged for long periods, such a voltage will not restore the cells to a healthy state, and the system would therefore probably be a failure under the ordinary conditions on British railways. I do not agree with the author in his arguments on page 264 against the double-battery system, especially the statement that the fully-charged battery will probably discharge into the empty battery, with consequent double losses.

Mr. W. STANSFIELD: The author in referring to the Dalziel train-lighting system recommends that the special magnetic circuit should be dispensed with and differential coils introduced into the exciter, an iron-wire resistance being inserted in circuit with one of the above coils. I am particularly interested in that suggestion, since in conjunction with Mr. Hatt I developed a train-lighting system on somewhat similar lines and obtained some very promising results with experimental machines. We found that by connecting the exciter to the main machine at one pole, and by connecting the differential coils so that the one with the iron-wire resistance was across the main machine and the coil without the resistance was across the free ends of the main machine and the exciter (see Fig. B herewith).

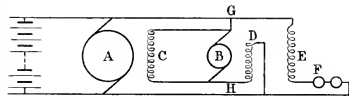

FIG. B.

almost any characteristic could be obtained, from one in which the voltage rose as the speed increased, to a characteristic in which the voltage fell after it had risen to its maximum (Fig. D). Dr. Rosenberg has mentioned

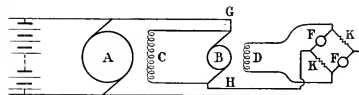

FIG. C.

the combination of the Mather and Platt machine with a special Wheatstone bridge. We also experimented with this special bridge in connection with our machine and obtained some very fair results, but as far as we went the differential coils proved the better arrangement. I might mention that in order to leave us with as free a hand as possible with our coils, in the majority of our experiments we did not use iron wire but ordinary metal-filament lamps, and found that the large increase of resistance from cold to hot (an increase to about 10 or 11 times the cold value) was quite ample for our purpose. Figs. B and C indicate how the special arrangements should be made. In Fig. B, A is the main armature, B the exciter armature, C the main field coil, D and E the differential field coils on the exciter, F the iron-wire (or metal-filament lamp) resistances. On reversal, the connections at G and H should also be reversed. In Fig. C, A, B, and C are the same as in Fig. B, D is the field coil of the exciter, F F are iron-wire or metal-filament lamp resistances, K K are resistances

(such as carbon lamps) having either no variation with temperature or else having a negative variation. The

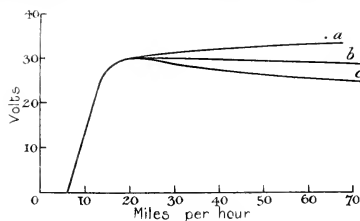

FIG. D.

connections G and H are to be reversed on reversal as in Fig. B.

Fig. D represents three characteristic curves, indicating the possibilities of the arrangement. To obtain these the initial excitation voltage is varied, *a* having a lower initial voltage on the exciter relative to the main voltage than *b*, and *b* a lower one than *c*. Assuming a constant voltage across the main machine an increase of speed demands a reduced excitation voltage, which inevitably gives an increase of voltage difference between the main and exciter machines—the two machines being connected so that the voltage across D or the bridge is the difference between the main and exciter voltages. This increase of voltage is the governing margin required, and it will readily be seen that the larger the proportion that B bears to A, the larger is the proportional variation of voltage for governing, and the characteristic curves change from *a* to *c* (Fig. D). In the majority of our experiments, and in the arrangement which we finally decided upon, we actually connected our load across the two machines A and B in series, but in this case the A and B voltages were added together and the governor coil was connected across A only. By this means the voltage of A was permitted to rise, this slight rise being compensated for by the corresponding drop in the voltage of B. Ultimately we combined A and B in one machine, and on this machine we were able to obtain a perfectly level voltage curve from the lower limit up to the mechanical limit of the machine. A ratio of $2\frac{1}{2}$ to 1 at no load, and 2 to 1 at full load, were the results, the full and no-load voltages being the same. This was without using batteries. Our experiments were carried out on an ordinary 4-pole machine with the armature wound as a 2-pole drum. If any members are interested, I would refer them to Patents Nos. 12,704, 20,704, 22,500, all of 1908, and 4,181 of 1909. Unfortunately, owing to the very unpromising state of the market for electric train-lighting machinery at the time we did not feel justified in maintaining the patents and they have now lapsed.

In his communicated remarks Mr. Newton states that he did not think the action of the machine would be decisive enough in building up on account of the weak field of the exciter. As a matter of fact the machine actually builds up its electromotive force correctly and with much greater promptitude than an ordinary shunt-wound machine. This

will be understood when it is considered that the iron-wire resistance being cold has a similar effect to short-circuiting the field resistance of an ordinary dynamo.

Mr. J. DALZIEL (*communicated*): While the author has made a very useful contribution to train-lighting literature, I think the interest of the paper might have been increased if he had gone a little more fully into details with regard to the various systems. In particular, a more exact description of the principles of operation of the system with which he has been associated—namely, the Leeds Forge Company's system—would have enhanced the value of the matter relating to this system. I deal more fully with this later. The paper gives me the impression of having been written rather from the point of view of the electrical engineer than from that of the railway man, and I think some points which are considered of importance by the latter have been missed by the author. For example, on page 263 it is pointed out quite correctly that the services on which a coach may run often vary considerably in respect to the amount of lighting current demanded; to meet this it is stated, under No. 2 of the list of requirements, that some definite means of adjustment of the output is necessary. Unfortunately, while practically every system provides for some such adjustment, when the service of a coach is changed, on the one hand it is only very rarely that the maintenance staff can be advised of the change of service and thereafter have access to the coach for such adjustment, and on the other hand it is only by guesswork that even an approximately correct adjustment can be made. In actual practice if the change of service is from a light to a heavy current demand, the necessity for adjustment automatically shows itself because the lights go out for lack of dynamo output; whereas if the change is from a heavy to a light demand, no such notice of attention being required is given, and the result is persistent battery overcharge and damage to the cells. As the author has missed this point it is not surprising that he has also missed the sequential one that the preponderating advantage and recommendation of the constant-voltage system are that it removes the whole of the necessity for adjustment, and that it transfers from the battery to the infinitely more robust dynamo the whole of the wear and tear of operation and regulation, and obviates practically all liability to either over- or under-charging.

As the author quite correctly points out, the rise in the counter electromotive force of the battery itself is the over-charge preventer with this system, and since with it the rate of charge of the battery obviously depends entirely on its state of charge, and the charging current is also entirely independent of whether lights are in use or not and of any other conditions of dynamo loading, clearly it is also the best system by which to ensure immunity from undercharging and sulphating. Furthermore the heavy current that passes into a discharged battery ensures a very much more rapid recovery to a condition of healthy charge than can be the case with any constant- or limited-current system. Also as this system ensures, in a way that no other system can ensure, that only such current as is actually required for lighting and charging, and no more, is produced, the power demand on the locomotive is and must be less with this than with any other system. The insertion of resistance, as suggested by the author, is quite a good expedient to limit the initial charging current and

Mr. Stan-
field.

Mr. Dal-
ziel.

give a tailed-off charge effect, but this, though simple, is not necessary with the small battery capacities that are amply sufficient with this system in this country. It is an expedient that is useful on occasion, however, more particularly in America, where capacities of 400 to 600 ampere-hours per coach are used—and necessarily used—and where consequently a tailed-off charging system is not only the one that is best suited to the conditions, but is essential if the generator capacity is not to be excessive. The loss of efficiency in such a resistance is low enough to be practically negligible. The author is hardly fair in attributing the comparatively small use—at present—of constant-voltage systems to a recognition by railway engineers of the inferiority of the principle. He must recollect that until the present writer advocated this principle and designed a regulating method that could be employed in train lighting to give a constant voltage independent of the battery, no such system existed. This was when constant-current systems had been many years in the field and were more or less established, and the new system has had to combat the innate and quite proper conservatism of the British engineer, which for well-understood reasons is nowhere more in evidence than in electric train lighting. Furthermore, in this country the last few years have been no time for developing electric train-lighting systems, old or new.

With regard to gassing, I think the author is mistaken in alleging that gassing does not take place at, say, 2½ volts or even lower voltages per cell. Gassing does take place, though not with the violence which accompanies it at, say, 2½ volts per cell; it is persistent gassing with full charging current at some such voltage as the last mentioned that with constant-current systems boils away the acid and causes the plates to deteriorate. As regards such gassing being necessary to keep the plates healthy, in my view the function of gassing is simply to circulate the acid and maintain it at uniform density throughout its height. The motion of the train in combination with the gassing already mentioned as taking place even with constant-voltage pressures is sufficient to ensure this. As a proof of this contention I may instance that the original equipment on the Dalziel constant-voltage system is running on the Midland Railway to-day with the same battery with which it commenced to run 8 years ago, and this battery though it had to come through all the experimental period with its inevitable troubles is still good for a year or two's life.

With regard to the difficulty in removing the sulphate when a constant voltage is used, this is a perfectly legitimate objection, but owing to the favourable treatment of the battery as above indicated, the occasions when sulphate that requires removal is allowed to form with a constant-voltage system are almost non-existent. As a matter of fact, experience shows that in a day or two the constant-voltage system satisfactorily overcomes sulphating using only the normal voltage; but if desired it is easy of course to raise the voltage slightly. While on this question of sulphating, I should like to ask the author what becomes of the overcharge-preventing relay in his and other constant-current systems while the operation of removing the sulphate is in progress, seeing that such relays are necessarily operated by a rise of voltage? It appears to me that unless this device is put out of action the dynamo

will perpetually cut out, and sulphate will never be removed, which is an infinitely worse state of affairs than with constant-voltage charging and is one of the principal arguments against the use of such overcharge-preventing relays. Most of the latter that I have seen have evidently suffered the same fate as many overload preventers on motor starters, i.e. they have been tied up out of action to prevent them from giving trouble.

Reverting to the Leeds Forge Company's system, I have never been able to understand how the alleged regulating device of this system operated so as to provide even approximately constant-current regulation, and the author's description makes this no clearer to me; if he can elucidate my difficulty in his reply to the discussion I shall be indebted to him. The point is that while it is alleged that regulation is accomplished by means of the torque required to drive the armature—an increase of which forces the armature out of the field and so reduces the flux passing through it—and while obviously the regulation is a constant-torque one, it appears to me that with this means of regulation only it is inevitable that the current must rise very considerably as the speed increases. This is due to the fact that as the flux traversing the armature becomes reduced the torque per ampere must also inevitably be reduced; and following on the constant-torque principle the current must, as stated, considerably increase, as well as the power taken to drive the machine. The only further regulation that I can see is that due to armature reaction, which will increase in effect with the increased lead given to the brushes as the speed rises. I make this point having due regard to the claim made by the author that with this regulation the magnetomotive force in the air-gap increases rather than decreases as the speed rises, which of course contradicts my supposition, but I can see no other alternative. If this really does effect the further regulation it would, I think, be simpler to cut out the mechanical feature and trust to the electrical feature alone, thus giving a fairly simple, purely electrical machine, as, for example, in the Siemens-Wright system.

Though the author in his system has paid me the compliment of imitating my double-switch arrangement for switching in the dynamo of a single-battery system and my arrangement of using the discharge current from the battery to the lamps for holding down the lamp switch until the dynamo is quite ready to take over the duty, I cannot believe that the further additions made to the lamp switch are an improvement. It seems to me that the system must be subject to very considerable sudden variations due to the operation of the lamp switch. Taking place constantly, as apparently they must do at intermediate speeds, these variations are extremely objectionable. This in fact is the experience which I had of the system on the only coach equipped with it that I have ever ridden on; the continuous flickers and jumps caused me to look for the main switch in the corridor to find out whose equipment it was. I am also inclined to think that the end cells will eventually suffer considerably.

With regard to the author's suggestions for improving the constant-voltage system that bears my name, I am afraid that the hot iron-wire resistance has proved too unreliable a piece of apparatus for the proposed exchange to be worth considering; in fact, as the author is probably aware, such resistances have already been used in series

Mr. Dalziel: with the lamps for absorbing excess voltage, and have also been proposed as a means of regulation. I believe that in the first-mentioned use they have not been particularly satisfactory, and I have not heard of the last-mentioned going much beyond the experimental stage as yet. It would of course be possible to use permanent magnets in place of the constant excitation winding, but I hardly think it would be advisable.

I do not wish to discuss any of the other systems except the Grob-Pintsch. It seems to me that if the batteries get run down they have not much chance of ever picking up again, and certainly will not get up at all quickly, which is entirely the reverse condition to that of the Dalziel constant-voltage system. Furthermore, with a very fully-charged battery as a regulator there would appear to be a tendency to overcharge the other battery, with of course the reflex effect on the first-mentioned battery when a change-over takes place. The former is of course considerably the more serious possibility. It is also a great disadvantage that two batteries are required with this system.

Mr. G. C. LUNDBERG (communicated): No reference is made in the paper to providing facilities for the partial control of the light by the passengers. Assuming that the actual switching on or off of the light throughout the train must be under the control of the guard, it is essential on main-line trains that passengers in individual compartments should be able to dim the light when they wish to rest. There is no need, however, to adopt the usual wasteful method of leaving all the lamps full on and obscuring them by means of movable shades. Various tumbler-switch controls have been devised for controlling the amount of light, namely: (a) 2 lamps in parallel or series; (b) 2 lamps in parallel, 1 lamp only, 2 lamps in series; (c) 3 lamps in parallel or series; (d) 3 lamps in parallel, 2 in series, 3 in series; (e) 4 lamps in parallel or series. Methods (a) and (b) are suitable for compartments lighted by 2 lamps, methods (c) and (d) for compartments with 3 lamps, and method (e) for 4 lamps. In each case there is only one tumbler switch of ordinary size per compartment, and this—as has already been stated—can only vary the amount of light, the supply to all compartment switches being controlled by the guard. Methods (b) and (d) have the advantage of giving three degrees of light; and as regards method (e) it may be stated that the light given by 4 metal-filament lamps in series would not be too dim for some people. One or two methods are being used in which the lamps are dimmed by resistances contained in the switches; and although such methods find favour in some quarters, I am inclined to think that the above series-parallel methods constitute good alternatives.

Mr. C. A. NEWTON (communicated): There is no doubt that the careful attention paid to the treatment and maintenance of the battery or batteries used in train-lighting systems is justified, since on this depends to a very large extent the success or otherwise of any train-lighting system. In connection with the author's description of the Dalziel constant-voltage system, and the treatment accorded to the battery in this system, I would point out that provision has already been made for the use of the series resistance mentioned by the author; and this resistance can be connected in such a manner that the regulation of the lamps is in no way affected. This would be effected by con-

necting the series resistance between the top contact of No. 2 switch, directly above the terminal marked B +, and B +. It will be seen that with this connection of the series resistance and a consequent higher charging voltage and increased lamp resistance, the system could be readily adjusted so that the voltage on the lamps would not vary when No. 2 switch cuts in; also the series resistance would be in circuit with the battery while the latter is charging; and with both No. 1 and No. 2 switches cut out, the lamps would be directly connected across the battery as before. I may say, however, that it has been found in practice that the battery treatment is all that could be desired without the use of this resistance. In certain cases, however, where a very large storage capacity is required, compared with the actual lamp current, this resistance would be an advantage by allowing a smaller dynamo to be used; and, as pointed out above, since this resistance would not be in circuit with the lamps when the battery discharges, its inclusion would only affect the overall efficiency to a very slight extent indeed.

With regard to the use of a hot iron-wire resistance and a plain magnetic circuit for the exciter, I should like to draw attention to the fact that such a machine was provisionally patented in this country some four years ago, and as this machine does not appear to have been developed, the natural conclusion is that such a machine is not very practicable. Even if the same degree of regulation could be obtained with the use of a wire resistance as suggested, the absolute certainty of building up with a constant polarity when the machine is rotated in either direction (this is at present an important feature of the Dalziel constant-voltage machine) would be very materially prejudiced, and indeed it is doubtful whether a machine arranged with this method of excitation and without any independent source of excitation could be depended on to build up at all, since the degree of saturation in the magnetic circuit of the exciter would in any case necessarily be of a very small order. In the patent specification of the Dalziel dynamo mention is made of the possibility of using a permanent magnet in place of the highly saturated pole. The objections to this, however, are: (1) the very much decreased magnetomotive force available from such a magnet, and (2) the necessarily much increased weight to obtain the same flux-carrying capacity. In connection with the former objection, I would mention that the relationship between the magnetomotive force expended upon the highly saturated pole and the reluctance of the armature and air-gap portion of the magnetic path is of considerable importance, as affecting the fineness of regulation. I may say that on one of these sets which has been in service for 8 years the original battery is still in use.

Mr. T. FERGUSON (in reply): Dr. Rosenberg refers to the Stone system and the Leeds Forge Company's system as constant-torque systems. I would point out, however, that the former is a constant-torque system but that the Leeds Forge system is a variable-torque one, the torque being inversely proportional to the speed. Both systems should give lower current output toward the completion of the charge as the battery voltage rises; that is to say, the charge is tapered off. This is a very desirable feature, and in this respect both these systems are superior to the electrically-regulated systems described, in which the charging

current increases toward the completion of the battery charge. I quite agree with Dr. Rosenberg that no system really gives constant current or constant voltage. One is apt at first sight to form a partiality for the constant-voltage system, as it would appear to be only common sense that the lamps should burn on a constant-voltage circuit; whereas, as Dr. Rosenberg points out, the variation in any so-called constant-voltage system is probably as great as in the constant-current system.

I am most interested to hear about Mr. Woodbridge's experiments on the Santa Fé Railway, where the charging voltage is limited to 2.25 volts per cell (that is to say $12\frac{1}{2}$ per cent above the normal lamp voltage) and no compensation is used in the lamp circuit. This is a fairly large range of voltage to subject the lamps to, and rather a low pressure to charge batteries at, but I have no doubt that it works satisfactorily. Whether or not it would prove expensive in lamp and battery renewals could only be settled by some railway company having courage enough to adopt it on a sufficiently large scale to give it a fair working trial.

With reference to Fig. 4 in the paper, the charging current is the 8-hour charging rate.

With reference to the Leeds Forge overcharge preventer, I would say to Dr. Rosenberg that the railway companies have the option of arranging to cut the preventer out of service when the lamps are burning. Even if it were not cut out of action, and it operated on a journey, by the battery becoming fully charged, it is not likely that the train would run continuously without a stop or without slowing down for more than one or at the most two hours after the overcharge preventer had operated, so that only part of the charge would be taken out of the battery. The overcharge preventer resets itself when the speed of the train falls below a certain limit. The object of arranging it in this way is for simplicity, and I do not think that any real benefit is sacrificed by so doing.

In reply to Mr. Denham's remarks, so far as I know over-discharge preventers are not in general use either in this country or to any great extent abroad.

The straight storage system referred to by Mr. Pope has been used for a long time past in this country as well as abroad. It certainly has never become popular, and this is probably because of the lack of flexibility of the system. With reference to battery troubles due to sulphating, it is often impossible to remove a battery at once to the shops for treatment, and it is my experience that the trouble can be at least partially cured by running the battery in service under constant-current conditions. With regard to the life of the lamps, my experience with the Leeds Forge Company's system is that one can get from two to three years' life out of modern metal-filament 24-volt lamps, and I doubt also whether any system would keep the voltage much within the limits mentioned by Mr. Pope without undue complication of the system. With so long a life as that mentioned, the maintenance cost for lamps is not a serious matter.

I think that the care and treatment of batteries on British railways has improved greatly in recent years, and hence the contrast between Continental and British practice is not so marked. Mr. McKinnon comments on the reference in the paper to poor-class labour. It is a fact, however, that a system must be able to be maintained and cared for by poor-class labour if it is to be a

commercial success in this country. I quite agree with Mr. McKinnon that Mr. Woodbridge's proposal to use a pressure of 2.25 volts per cell for charging would necessitate that the cells be kept healthy; and if they are allowed to become sulphated, due to standing idle or other cause, this voltage would probably not be sufficient.

Mr. Stansfield's contribution is very interesting. His results reply very fully to several points discussed by Mr. Newton and Mr. Dalziel and need no further elaboration on my part. I am sorry that Mr. Stansfield did not go further into the train-lighting problem and develop the rest of his system. I think he has abandoned a most interesting and fascinating subject.

With reference to Mr. Dalziel's remarks, I quite agree that when the service of the coach is changed it is very seldom that the maintenance staff can be advised in time of the proposed change. However, even if the adjustment is not attended to beforehand, no harm results, and it is an easy matter to adjust the output at the first available opportunity, an operation requiring in modern properly-designed constant-current machines at the most not more than two or three minutes. Theoretically, the constant-voltage system should remove the necessity for adjusting the dynamo, but I doubt very much whether in practice it is possible to operate a constant-voltage system without adjustment of some sort; and such adjustment, as mentioned in the paper, has got to be much more delicate and is by no means so definite as it is in the constant-current system. In fact, as I have pointed out, the constant-current system is the more robust and easily handled of the two. I cannot altogether agree with Mr. Dalziel that the constant-voltage system is the best system to ensure immunity from undercharging and sulphating, especially with a battery which may have been left lying about in a discharged condition for some time. Neither do I agree with him that the power demand on the locomotive must be less with the constant-voltage system than with any other; as obviously when the state of the battery is low the current from the dynamo is very large, which obviously demands considerable power from the locomotive. I am glad that Mr. Dalziel agrees that the insertion of resistance in the charging circuit is a good expedient, as when resistance is inserted a rising charging-voltage characteristic is obtained, somewhat similar to that of a constant-current system, a point on which I laid considerable stress in various parts of my paper. Mr. Dalziel states that he has had his system in operation for eight years, and also that I am hardly fair in attributing the comparatively small use of constant-voltage systems to a recognition by railway engineers of the inferiority of the principle. However, the fact remains that during the last eight years several fresh constant-current systems have been introduced, some of which have been taken up moderately well, whereas had the constant-voltage system been the best, surely that would have been recognized and substantial orders placed during the past few years.

With regard to "gassing," I cannot see that I have stated it does not take place at 2.5 volts per cell, or even at lower voltages. I only said that at least 2.5 volts per cell is necessary in practice to keep the battery in good condition. I cannot agree that the only function of gassing is to circulate the acid, neither do I agree that

Mr. Ferguson.

the motion of the train would do this automatically in train-lighting systems, as the spaces between the plates in most types of train-lighting cells are filled up by wooden separators, which would practically prevent circulation of the acid from the motion of the train.

With reference to the overcharge preventer, this is set at a voltage which is high enough to allow the ordinary current to pass in a sulphated cell, and it has not been my experience that properly-designed overcharge preventers in constant-current systems are useless.

Mr. Dalziel says that he cannot understand how the "alleged" regulating device in the Leeds Forge system operates; he also states that obviously the regulation is a "constant-torque" one, and that he can only account for the regulation by the armature reaction. If this were so, Mr. Dalziel would be quite right in assuming that it would be preferable to cut out the mechanical feature and use a normal machine. However, the regulation is a "variable-torque" one, and so both the current and the power are kept constant. In fact, by suitably shaping the cam a drooping characteristic can easily be obtained. I think this will now make the action perfectly clear to him. It is a very simple matter to calculate the variable slope of the cam, the formula being—

$$\tan \theta = \frac{63000 \times \text{h.p.}}{\text{r.p.m.} \times R \times r},$$

where θ = the angle of the cam corresponding to the r.p.m.,

R = the resisting or controlling force of the spring, and r = the radius of the cam.

There is nothing arbitrary in this formula; it is a simple question of mechanics, and checks out correctly in practice.

I must confess to being quite innocent of imitating Mr. Dalziel's double-switch arrangement. According to my earliest experience of train-lighting apparatus, dating back a long time before Mr. Dalziel described his system, two such switches were used, and it has always been quite common practice in single-battery systems. Further, I would point out that I do not hold down the lamp switch by a solenoid or magnet of which the winding carries the discharge current from

the battery, as in the case of Mr. Dalziel's system. I cannot understand either Mr. Dalziel's theory or his experience in connection with the frequent jumps and flickers in the light. It has not been my own experience and I have heard of no such complaint from the various railway companies both at home and abroad who are using the system.

I understand that hot-wire resistances are found quite successful where they are used. They certainly complicate a system and produce a loss of power where they are employed as lamp regulators, as I pointed out.

I quite agree with Mr. Dalziel that if the batteries in the Grob system become run down they have a poor chance of picking up again.

As regards Mr. Lundberg's statements, I would mention that the control of individual lamps by passengers is quite usual in first-class compartments, sleeping-cars, etc., but it is not usual for railway companies to provide means for dimming the lights. This is purely a question of expense in additional wiring, switches, lamps, etc., and, as Mr. Lundberg says, it presents no particular difficulty. The possibility of switching individual lamps in and out is referred to in several places in the paper, and it has not been assumed that the switching on or off of the lamps throughout a train must be under the control of the guards.

I am interested to learn from Mr. Newton's communication that he makes provision for a series resistance in the charging circuit of the battery, and I would add that I am a firm believer in the use of resistances in the charging circuit when charging from constant-potential mains, whether it be in train-lighting systems or for charging portable batteries from the ordinary electric supply mains in a house. I consider that the benefit received more than counterbalances the slight loss involved. With regard to Mr. Newton's remarks as to the modification of the exciter which I suggested in the paper, I may say that Mr. Stansfield appears to have obtained excellent results from this device. I was unaware of Mr. Stansfield's experiments when I wrote my paper, and the results of those experiments as described in his remarks provide a complete reply to the latter half of Mr. Newton's communication.

BIRMINGHAM LOCAL SECTION, 28TH JANUARY, 1914.

Mr. Taylor.

Mr. A. M. TAYLOR: I should like to draw attention to the low efficiency of the batteries used for train lighting, especially when a double-battery system is employed. Having regard to the low efficiency of train-lighting systems, it is not surprising that there is such a large increase in the draw-bar pull or decrease in the speed of the train when the lighting apparatus comes into operation.

Mr. Fennell.

Mr. W. FENNELL: I should be glad if the author would state whether it is still the custom of railway companies to judge the suitability of a battery for train-lighting purposes by its capacity for withstanding persistent over-charging. In this connection I may mention that I knew of a case some years ago in which the merits of a battery that was submitted to a railway company were decided by such a test, and this seems to confirm the very low efficiency of train-lighting systems.

Dr. J. D. COALES: Would not the installation of a battery in each coach and generators only in the guards' vans meet the ordinary traffic conditions on a railway? Such a plan is obviously much simpler and cheaper than that in which a train-lighting dynamo and the accompanying switchgear are provided in each coach. When a carriage had to be slipped at a junction the battery would look after its lighting for the time being in the usual way, and the battery would receive its charge during the time the carriage formed part of a complete train. Such coaches could not of course be included for any lengthy period in, say, a local gas-lighted train, but that difficulty would disappear when electric lighting on any system became general.

Dr. C. C. GARRARD: In my opinion modern train-lighting systems appear to be unnecessarily complicated.

Mr. J. D. MORGAN: The development of the principal train-lighting systems appears to be characterized by an excessive accumulation of corrective accessories. A defect in the dynamo or battery is corrected by the addition of some device designed to prevent that defect from operating adversely in the lighting circuit. Frequently the accessory introduces a further defect, and this is rectified by another accessory, thereby bringing about the accumulation of corrective accessories. I wish to emphasize the necessity of the designer's reviewing the fundamental requirements of the problem and endeavouring rather to develop systems inherently satisfactory than to gain perfection by complicating a system which is fundamentally defective. In connection with the question whether the ideal generator system should provide constant voltage or constant current, I wish to point out that the requirements of the lamp circuit demand a constant voltage and variable current. Unfortunately this is not capable of attainment by ordinary means, because the requirements of the battery are incompatible with this condition. The designers of train-lighting systems have become so obsessed by the difficulties arising from the use of a battery that the problem is no longer how to light a train but how to charge a battery. It is for this reason the constant-current system has been generally adopted. The unsuitability of the constant-current system is becoming more and more widely recognized, and serious efforts are being made in a number of directions to realize an ideal constant-voltage system.

Mr. T. FERGUSON (*in reply*): In reply to Mr. Taylor's remarks, I would say that the storage batteries used in train-lighting systems are not in themselves inefficient, and need not be a greater source of loss than the ordinary power-station or sub-station battery in an electricity supply system. Double-battery systems may certainly become a considerable source of loss, especially when one of the batteries becomes short-circuited by dirt, loose paste, or due to other causes. It is occasionally noticed in electrically-lighted trains that the light decreases in brilliancy while the train is running, and increases, for a short time at

least, while the train is standing. This is what occurs when the No. 2 or lighting battery contains a faulty cell. When the train stops the two batteries are connected in parallel, and the lamps get the benefit of the good battery. The extra draw-bar pull due to the dynamos in the case cited and illustrated in Fig. 5 in the paper is only about 4 per cent of the total locomotive draw-bar pull in the case of the constant-efficiency system, and would be less if the train was run at all during the hours of daylight. With the belt-slipping system the draw-bar pull is considerably greater, as explained in the paper.

In reply to Mr. Fennell's remarks, I do not know of any special storage-battery tests that are generally adopted by the railway companies, other than a prolonged trial in service.

I quite agree with Dr. Coates' statements, but the system which he mentions does not appear to have found favour with the railway companies owing to the subdivision of trains for different services. The connectors between the carriages would involve extra work in uncoupling, and practically every guard's van in the system would have to be fitted with generating plant. There are also various other reasons too numerous to be discussed in detail, which would prevent this system becoming popular.

In connection with Dr. Garrard's remarks, it has been the aim of every designer of train-lighting apparatus to simplify the system without impairing its reliability, regulation, and efficiency.

With reference to Mr. Morgan's remarks, I think he is unnecessarily severe in condemning the present systems as being "fundamentally defective." Mr. Morgan states that the "unsuitability of the constant-current system is becoming more and more widely recognized." If this be so, then why is it that the modern constant-current systems are being adopted in greater numbers than the constant-voltage systems? Possibly the answer is to be found in Mr. Morgan's own remark that the requirements of the battery are incompatible with that of the constant-voltage system.

DISCUSSION ON

"SOME RAILWAY CONDITIONS GOVERNING ELECTRIFICATION." *

BEFORE THE INSTITUTION, 12TH FEBRUARY, 1914.

Mr. Firth

Mr. H. W. FIRTH: I am so much in agreement with the author that I find little to criticize in this paper, which has been written from the railway point of view. There are, however, a few points to which I should like to call attention. In the first place, the author emphasized what is the greatest drawback to electrification in this country, *i.e.* the low return for passenger transportation. That is a matter which cannot apparently be dealt with by the railway companies themselves. Fares have gone down, and are now at an extremely low figure, many of these low fares being statutory obligations upon the companies. The position is this, that the railway companies are expected to provide, for precisely the same revenue as that which they are now obtaining, the higher acceleration, the better schedule speed, and the superior comfort that are features of electrical services. If 100 per cent load factor were obtainable on suburban services, it would be possible to get an adequate return from electrification, but unfortunately by far the greater part of the suburban business is dormitory business, in fact peak-load business. It is not necessary in speaking to members of this Institution to emphasize what that means in regard to the economics of the position. To provide a very large capital for peak-loads, *i.e.* rush-hour traffic, and to have that capital lying more or less idle during the rest of the day, is not good business. Electrification has frequently been shown to increase greatly the number of passengers carried, but some of the figures which have been published in regard to the results of electrification must, I think, be taken with a certain amount of caution. Where there is a good steam suburban service it is not possible for electrification to show such good results as in some cases where a comparatively poor steam suburban service has been electrified. Then, again, the character of the district very materially affects the return which can be obtained from electrification.

There is one point which the author has referred to and where I think he is not quite correct as regards suburban services; he says that "with electrification a maximum of 48 trains per hour can, if required, be run each way during the rush hours while employing existing stations and tracks." I myself do not think there is any general trunk-line railway system in this country which will accommodate 48 trains per hour each way while employing existing stations and tracks. The limiting factors, as the author said, are not engineering factors; they are well known. The limiting factors in suburban electrical working are the question of finance, to which I have just referred, and the question of traffic working. As many as 48 trains per hour could certainly not be worked over the majority of the flat junctions or into most of the termini in this country; and certainly not in the case of London. In that connection the author says on page 295: "Most of the suburban services into and out of London already provided or in process of being provided are run on tracks distinct from the main line." If that is so, a very frequent service can be worked, but I do not

think 48 trains per hour can be run continuously, even Mr. under conditions like that. That rate may be obtained for a quarter of an hour or so, but I do not think it can be kept up continuously under the conditions of a trunk line. Very often there are heavy gradients; in many cases speed restrictions round curves; and in the majority of cases, even if the line can be more or less set aside for suburban work, it is bound at some point or another to conflict with main-line trains or with goods trains or other services, and I think that such a figure as 48 trains per hour will not be attained in practice under the ordinary conditions on trunk lines. In my opinion there is one very important point, not only as regards main-line working—in which connection the author has referred to it—but also as regards suburban working, and that is the point which he makes as to the necessity of obtaining a motor with a speed characteristic different from that of the series motor. That point is very important indeed for this reason: it is not possible to restrict certain rolling stock always to certain definite services. It may be necessary one day for the rolling stock to be worked on a schedule which requires station stops 0·8 or 0·9 of a mile apart; but the next day it may be necessary for that train to run at 60 miles an hour on a semi-express trip. Unless it is proposed to duplicate the rolling stock that point requires attention. As regards many of the lines running into London which have a very heavy seaside traffic in the summer and a very heavy suburban business as well, it will be found that on Bank Holidays and on Sundays in the summer a very large proportion of seaside traffic has to be dealt with by suburban stock, and if that stock is to be electrified and if it is proposed to electrify sufficiently far out to accommodate any of these services, the problem will have to be faced of obtaining a motor which will work adequately on both those services. I think it is very important that more attention should be given to the problem of either separately exciting the field or devising some method of giving a more flexible speed characteristic to the motor. I am sure that is very important in many cases, even as regards suburban traffic.

There is one other point in regard to dealing with heavy traffic on which I think the author is not quite correct, namely, where he mentions as among the advantages multiple-unit-controlled motor-coach trains. He says that among the other advantages are "first the doubling of terminal accommodation by halving the number of signal and locomotive movements." I do not think that is quite right. A number of locomotive movements are done away with altogether, and the signal movements are halved or perhaps even more than halved, but the accommodation is not thereby doubled, although no doubt it is largely increased. I saw some figures the other day with regard to the Berlin Stadtbahn line in which it was shown that under electric working the number of trains possible on the clear section of the line not complicated by junctions or terminals was 40 per hour in each direction with electric traction, and 32 per hour in each direction with

* Paper by Mr. Roger T. Smith (see p. 293).

steam; but at the terminus it was found that 33 electric trains per hour and 21 steam trains per hour were all that could be worked. What may be called the "terminus factor," that is to say the relative number of trains which can be dealt with at the terminus compared with those which can be dealt with on the through line, is for electrical working about 0.825, and for steam 0.656, taking the above figures. Thus it is impossible to double the number of trains that can be worked into a terminus by adopting the multiple-unit equipment or in any other way; in fact, it is, as I say, the terminus working and the flat junction working which nullify against running the number of trains per hour which one would like in order to increase the suburban business as it should be increased.

As regards long-distance traffic—passenger traffic particularly—I think the author has shown very plainly that, for the time being at any rate, the problem is not one which we can hope to tackle. He has shown that, even if we obtained the locomotive with the necessary characteristics, we are still faced with the problem that, as far as can be seen under the present conditions as regards the cost of coal, the cost of electrical energy, and, what is perhaps equally important, the cost of money, there is very little likelihood of being able to save in operating expenses, and it is not likely much advantage will be obtained.

With regard to goods working, there again I think some of the points made by the author must be taken with a little reserve. He points out what is obvious, that the electric locomotive can give a very much greater train mileage per annum in service than the steam locomotive can. He refers, however, to the fact that an increase in the size of the goods trains may be impossible until the lay-by sidings, etc., have been increased; but I think it ought to be emphasized also that it is no use providing a locomotive which is capable of running, say, 50,000 miles per annum unless the service conditions and the track conditions allow of that being obtained. There are many traffic schedules in operation in this country—necessarily in operation because of other services and because of the lay-out of the lines—which do not call for a greater mileage of engines than can be done by a steam engine under present conditions. Of course the electric locomotive is going to be much more economical; it will not have any stand-by costs while it is idle. But I do not think it will be found to be possible always to get in general goods service the amount of mileage out of a locomotive which is theoretically possible; and that will affect the cost per train-mile which is given in the paper. I do not say it will affect it very much, but I think in some cases it will be a factor which has to be considered. I think that the author's summing up of the position as regards goods working is quite accurate, with the above exceptions, but I do not imagine that heavy goods working will come into operation in this country at the present time except in places such as on the North-East Coast where the conditions are exceptional. The mineral traffic on the North-East Coast is, as no doubt the majority of members know, a thing which is quite apart from general railway working in this country. In a position like that it is quite possible that electrification will come about in a very short time. But I think general goods electrification is in the same category as general passenger electrification,

and that neither of those branches of the work is a matter with which we are likely to deal at the moment. On the whole, as I say, I am in agreement with the author's remarks, and I think it is a very good thing indeed that the members of this Institution should have the opportunity of discussing a paper which does not deal with the matter from any controversial electrical point of view, but purely from the point of view of the general broad policy of the electrification of railways.

Mr. J. B. SPARKS: When we contrast the rather unfavourable remarks of the author and of Mr. Firth with the electrification work now in progress in London and elsewhere, we can only come to one conclusion: that electric traction and steam traction for suburban work cannot be compared directly as regards operating expenses. Electric traction gives something which steam traction cannot give, and in order, therefore, to compete successfully with tramways and omnibuses or to increase the capacity of any given line, it may be absolutely necessary to adopt electric traction. In the first part of the paper the author refers to the possibility of using one system of electrification for suburban lines and another system for the main-line traffic. Surely it would be very difficult to work a railway under those conditions, with locomotives of two different electrical systems and two different kinds of supply. In the case of the supply, for example, there would have to be two separate power stations, or alternatively rotary transformers for single-phase supply in addition to the rotary converter plant for the continuous-current supply. With regard to the relative importance of the cost of electrical energy, the author takes the fixed charges of railway operation at 60 per cent and the variable charges at 40 per cent, and states that of this 40 per cent electric energy in a particular case formed three-fourths, i.e. 30 per cent, of the whole. But decreasing the cost of electrical energy by one-half surely reduces the total working costs by 15 per cent only, and not 25 per cent as he suggests. At any rate I should like to know to what that 25 per cent refers. Further, I think the figure of 75 per cent, i.e. the ratio of the electrical energy to the total variable costs, is too high. In the case of the Central London Railway it is only 40 per cent; and in the author's own estimate for main-line working the 3d. per train-mile given is only 40 per cent of the total of 7½d. per train-mile. In that case reducing the cost of energy by one-half would reduce the total operating costs by only 8 per cent. It is important that one should appreciate the correct proportion of the energy cost, as in all probability railways will not be able to purchase electrical energy at much less than 0.4d. per unit with present methods of generation. The author's figure of 0.33d. is certainly within the range of possibility, but I do not think his 0.25d. is. The 1913 contract of the Commonwealth Edison Company of Chicago with the Chicago Railways for a supply of some 60 million units, with a maximum demand of 20,000 kw., is equivalent to 0.45d. per unit; and even if the maximum demand reaches the enormous figure of 120,000 kw., or say 300 million units per annum, the price falls only to 0.35d. That is for a very large station with a 40 per cent load factor.

With regard to main-line working, the author takes the example of a line with an annual traffic of 10 million train-miles over 1,000 miles of route. Assuming double

Mr. Sparks. track, or 2,000 miles of track, this represents an average of 5,000 trains per annum over any section of the track. Taking the full 8,760 hours per annum as the number of hours of running, this gives an average service of one train every $1\frac{1}{2}$ hours over a 24-hour day, or one train every $1\frac{1}{2}$ hours over an 18-hour day. That is surely a very poor service, and one would hardly expect to obtain much economy by adopting electric traction for such a service. Taking his estimated saving of 3d. per train-mile, the author concludes that with this service the saving is sufficient to pay 6 per cent on a capital expenditure of £2,100 per mile of route. For a continuous-current equipment of 2,400 volts, I estimate that an amount sufficient to pay the cost of the track equipment and sub-stations for, say, a train service every half-hour would be about £5,500 per mile of route. If the author's total of 10,000,000 train-miles is multiplied by the ratio of £5,500 to £2,100, we get the number of train-miles which, at 3d. saved per train-mile, will provide sufficient to pay interest on that amount. The result is 26,400,000, which corresponds to a train every 40 minutes over a 24-hour day, or a train every 30 minutes over an 18-hour day, which is approximately the present service over the Brighton line. With this train frequency, therefore, electrification would just pay for itself. Mr. Philip Dawson has stated that by placing all the Portsmouth trains on the Brighton line he would get a service of one train about every 15 minutes. On the basis of the above figures it would appear that there would be a saving in that case, because if one train every 40 minutes over a 24-hour day just pays for electrification, a train every 15 minutes would probably give a reasonable profit, providing, of course, that the traffic demands such a train frequency.

There is one point which I do not see mentioned in the paper, namely, that if electrification is carried out there is a saving due to the elimination of coal haulage. In the paper by Mr. Kahler before the American Institute of Electrical Engineers, which is mentioned by Mr. Roger Smith, it is assumed that there is a reduction by electrification of 46 per cent in the number of ton-miles per annum, due solely to the absence of coal haulage over the system. Mr. Kahler takes the number of train-miles per annum for electrical working as only 75 per cent of the number in the case of steam working, partly on this account and partly due to the increase in the weight of the trains which is rendered possible by the ability of the locomotive to haul heavier trains over the ruling grades. With regard to the author's ratio for the mileage of steam and electric locomotives, I find that he takes 27,000 miles for the steam and 40,000 miles for the electric locomotive, *i.e.* approximately a 50 per cent greater mileage in the case of the electric locomotive. Mr. Hobart assumes the same ratio in his paper, to which the author's refers, but I find that Mr. Kahler in the case of passenger locomotives takes 55,700 miles for steam and 107,000 miles—nearly twice as much—for electric locomotives.

With regard to Mr. Firth's remarks, surely it is admitted that the electric locomotive will spend only a short time in the shops, and that there will be comparatively no cleaning to do; further, the cleaning that is required need not necessarily be done in the engine-house. In that case, for a given service, considerably fewer locomotives would be required. In most cases the number of electric loco-

motives would be less than 75 per cent of the number required for the same service with steam locomotives, and so the number of train-miles for the electric locomotive would be at least 30 per cent greater than the number for the steam locomotive. The actual records which have been published for the electric locomotives on the Pennsylvania Railroad and the New York Central lines, both terminal electrifications, are very disappointing, however. The 1912 average for the 33 Pennsylvania Railroad locomotives is only 30,000 miles, while the average for the New York Central Railroad with 47 locomotives is 28,800 miles. These poor results are, I think, due to the traffic conditions on those lines. There is a short run of only 9 miles in the first case, and a shorter run still in the second. The passenger locomotives in the case of the Pennsylvania Railroad, however, gave in some cases 54,000 miles per annum.

There is one question which I should like to ask the author; how does he obtain the figure of 7½d. per train-mile? Assuming that the cost of electrical energy represents 3d. per train-mile, and with repairs at £200, or 1½d. per train-mile—which is very low, since it is 1½d. in the case of the Pennsylvania and New York Central lines—and with interest and depreciation at 6 per cent, which on a £5,000 locomotive represents £300, or 1½d. per train-mile, it leaves only 1½d. per train-mile for wages and administration, which is much too low a figure.

Dr. S. P. SMITH: In this paper the author has brought Dr. Smith very fair criticism to bear upon many of the problems connected with the electrification of railways. There are some points, however, that might well have been touched upon, to enable us to form a judgment somewhat more easily. For example, the reasons that have led certain railways to adopt electrification are among the most important questions which we have to consider. It is certainly not an economic question in every case. Even if economic advantages are expected, they are in some cases a secondary matter. In a country like ours, rich in coal and without the opposing influences of water power, it might be a strong argument that, unless it was economically sound to electrify a railway, electrification should not be considered. On the other hand, from what the author has told us, it is certainly not economical advantages alone that are bringing about the electrification of many suburban lines. It would be well if we could have a synopsis of the reasons that have led other countries to adopt electrification. For instance, the reason for the equipping of the experimental line at Dessau-Bitterfeld in Germany was stated to be not so much a question of economics as the necessity for dealing with the increasing traffic on that particular section, which reduced itself to a choice between doubling the track and speeding up the traffic; the latter could only be done electrically. In other cases where there are heavy gradients and long tunnels, such as are met with in Switzerland and Italy, the question is not primarily an economic one, because electrification is really the only solution of the problem at the present day. It is only necessary to mention the Givi Tunnel in Italy, where the air became practically unbreathable; but now that the railway has been electrified it is possible to deal with the traffic in a satisfactory manner. Again, there is the recent case of the Lötschberg Tunnel, which was constructed from the outset as an electric railway.

In our own particular case, it seems to me that one of the greatest needs in the future will be the terminal electrification of the lines around great cities, and I am sorry the author does not mention this subject specially. It is quite possible that in the near future many of or all the main lines will haul all their long-distance trains electrically into London. At a certain point outside London where the suburban electrified lines start, the steam locomotive will probably be taken off and an electric locomotive attached. It may be that in time railways will be compelled to do this by law, or on account of the fines for allowing engines to emit smoke becoming so excessive. Or, indeed, the companies themselves may find it beneficial to electrify termini where the upkeep of the tunnels due to the effect of the smoke and the corrosion of the rails and steelwork are excessive, and valuable space is required for coaling, etc. This seems to me to be one of the things that is bound to come, just as the electrification of suburban lines is bound to come.

There is another point that I should like to have seen brought forward, and which I think ought to be strongly impressed on all who are interested in the electrification of railways, namely, that the argument for the self-contained unit is one of the strongest reasons in favour of the existing method of operating trains. When it is only a question of a few miles in and around London this may not be so important, because if the service can be supplemented by an existing steam service an alternative is at hand. But if we do away with the self-contained unit, it seems to me that we may be lowering the factor of safety of working to an undesirable extent. Though one of the strongest arguments at present for the retention of the steam locomotive is doubtless the fact that it already holds the field, we have nevertheless to remember that a line that is electrified can easily be put out of service. This strategic argument is one that has been considered for a long time on the Continent, for a sharpshooter aiming at one of the insulators could put a whole section out of work; or, in a country where there are strikes and industrial unrest, it is only necessary for one of the insulators to be damaged to interfere with a lot of traffic. All these things have to be considered in connection with the factor of safety of working. It may be that under normal conditions the system would be quite sound; but we are not living under Utopian conditions. To my mind, this matter should be mentioned in a paper dealing with the conditions governing electrification.

The only other point to which I wish to refer is in connection with the limits of the electric locomotive. Whether it is a sound economic proposition to use the electric locomotive for long-distance work I am not concerned with, because I am not competent to speak on this side, but the author makes the statement that he does not think it is possible to develop 1,100 h.p. from an electric locomotive at 70 miles per hour. In order to see if this is so I have made some comparisons with the Lötschberg Railway locomotives, which I think are some of the finest and most successful electric locomotives that have ever been built. The first question is: Can one get the required power at the desired speed electrically? Now in a single-phase commutator motor this is only a question of voltage control. By merely adjusting the pressure the motor can be made to work at any speed that may be required. The

starting torque is also purely a matter of control, and there is no need to make the motor exert a starting torque that will break the drawgear. I think that everything could be arranged quite satisfactorily electrically by merely controlling the voltage in the proper manner. Turning now to mechanical details. I took the dimensions of the two 1,250-h.p. motors, the gears and the diameter of the driving wheels, and then worked out two corresponding 350-h.p. motors intended to drive the locomotive by helical gearing at the required speed of 70 miles an hour. I first increased the size of the driving wheels from 4 ft. 6 in. to 6 ft. 9 in., which is, I think, about the normal size on British express locomotives. The gear ratio on the existing locomotive is 1:2.23—this I reduced to 1:2, and thus increased the speed of the gearing by 10 per cent, which I thought permissible, for the present gearing is working quite satisfactorily at 3,000 ft. per minute, with a maximum peripheral speed 50 per cent above this. The new motor was also designed to run at 4 times synchronous speed. As a result, I found that the diameter of the motor was such that it just enabled me to get the gears between the axle of the motor and the counter axle. That was quite a straightforward calculation, and it seemed to me there would be no trouble whatever in making such a locomotive run at 70 miles an hour and develop 1,100 h.p. The question of the bogies does not concern me, nor am I able to say how much adhesive weight could be allotted to the driving wheels at this speed; these are questions for the mechanical engineer.

With regard to a question discussed by the author in connection with the economical side, I have to acknowledge the courtesy of Professor Dalby in permitting me to show two interesting slides on the screen. The one illustrates the efficiency that can be obtained from a steam locomotive and the other that from an electric locomotive. From 100 heat units obtained from the coal, it is seen that in the steam locomotive only 5 per cent of the heat units are converted into mechanical energy. Of this, 1 per cent is needed to overcome the friction of the locomotive, and 4 per cent remains for hauling the train. The other slide shows the electrical case where the 100 heat units are provided at the central station. The efficiency of 10 per cent given by the engine would probably be objected to by most engineers of large stations at the present day. The system is practically the same as we have on our underground railways, and shows that here again we get some 4 per cent of the energy available for traction. That means, according to this rather pessimistic comparison, that the electric train would be no more efficient from the point of view of energy than the steam train. Accepting this basis, we have now to see what it means. It is just a question of what has to be paid to get the 100 units of energy. The author tells us that on the locomotive they have to pay twice as much for the coal as the central station has to pay; so that, according to this figure, if the calorific value is the same, the electric train is getting its energy at half the price the steam train gets it at. This of course is only a rough comparison and takes no capital charges into account, but as far as the cost of energy alone is concerned, it may be interesting.

Mr. W. M. MORDEY: As affecting the prospects of electrification of railways the author emphasizes two requirements—one that locomotives should be cheaper—

Mr. Morley: that is a question of capital cost—the other that energy should be cheaper—that is a question of working cost. I want to confine myself to the second of these points; but regarding the first of them I would ask the author in his reply to give some figures showing what proportion of the total capital cost of electrification must be allocated to the locomotives, so that we may see what difference it would make to the total expense if he got his locomotives at half the present price. The author's demand for cheap energy—he mentions 1/8d. per unit—is getting very familiar to us. No doubt cheap energy is very desirable, but perhaps too much attention may be given to it. I suggest it might be as well to go a little further back and see what is done with the energy when it is obtained. Could not the author attain his object of reducing the total cost of energy by making better use of the energy when he gets it? An examination of the curve in Fig. 1 may be useful in explaining what I mean. It shows that the number of watt-hours per ton-mile increases very much as the stations get nearer together. What does this curve mean if we express it in terms of efficiency? Allowing for the not unreasonable assumption of say 10 lb. per ton friction loss on railways, then the best figure in the curve, namely, 40 watt-hours per ton-mile with stations one mile apart, means an efficiency of 50 per cent, and the lowest figure in the curve, 93 watt-hours per ton-mile with stations one-third of a mile apart, means about 19 per cent efficiency. I do not know where these lowest figures in the curve come from, but I do know that on carefully working out the results some years ago for the Liverpool Overhead Railway I found the same sort of thing. There they had frequent stations, and high positive and negative acceleration. The loss in starting resistances was about 20 per cent, and the loss in braking about 50 per cent. These losses did not include any line or transmission losses. Energy is poured into the train to get it up to speed as fast as possible and is then shut off, and the brakes are applied and the train stopped as quickly as possible—very difficult conditions to meet of course, but we may hope that the author and others who have opportunities may find some way of avoiding this very serious loss of energy. Improvement is to be obtained by some method of regeneration. The Central London Railway is a case in point. Mr. Greathead, who was responsible for this line, adopted the switchback principle, and trains are partly braked by going up hill and partly started by running down hill. The result is that in spite of its frequent stations and high average speed it is more than twice as efficient as the Liverpool Overhead Railway. Of the proportion of energy reaching the train I found that nearly 50 per cent was spent in useful work—about 20 per cent in braking, and another 20 per cent in starting resistances. One cannot help feeling that this principle of regeneration for braking and some form of inductive or other electrical variable-ratio method during acceleration contain promise of better results than those shown in the author's curve. I would suggest that renewed attention should be given to this question of saving energy on railways as more likely to yield an immediate practical result than any attempts, however praiseworthy, to get the supply authority to provide energy at such low prices as those which the author suggests. Whilst fully alive to the difficulties of the subject, I cannot help thinking that

the curve in Fig. 1 amounts to a condemnation of the Mr. Morley present methods of using energy on the urban railways of London.

Mr. H. M. SAYERS: I wish to emphasize and welcome Mr. Sayers the fact that the author has stated that the goods traffic and the shunting traffic on railways under present conditions can be economically worked electrically. That is an important fact, which has been known to a number of railway electrical engineers for some years, but I think this is only the second time that I have heard it stated publicly. We may hope to find some practical result from that statement and from the figures which back it up. With reference to fast passenger services, I think we can agree with the author that such services will be the last to be electrified; but I do not admit that the position is quite so hopeless, even under present conditions, as he assumes. He says that an electric locomotive has not been built to maintain its draw-bar pull at 70 miles per hour; but there are probably half a dozen competent motor designers present at this meeting who would be ready to provide him with any number of such motors. For high-speed heavy work the possibility of using the whole of the weight of the load for adhesion is a very great advantage. It is one which steam cannot possibly give, and it is one which, as soon as it is necessary to increase the working capacity of a line beyond the limits of steam, gives electricity the first place and the only place. It should be noted that the author's railway conditions are present conditions. The future effects of electrification are not considered at all in this paper, and are also left out of account by a great many railway authorities. The effect of electrifying a railway in this country is not, as a rule, to reduce working expenses—either the actual working expenses or the total expenses including capital charges. The effect must be to improve the service which the railway can give, and thus to increase the earning capacity. A very large proportion of the capital expenditure on a railway is due to acquiring land, constructing the permanent way, building stations, and providing terminal facilities. The amount of revenue which can be obtained from the track with steam conditions is limited. If a larger revenue is required, such revenue can only be obtained by electrification or by its equivalent. Many railways in this country have incurred heavy expenses for doubling their lines, increasing the station facilities, and improving the gradients, in order to increase their capacity for dealing with the traffic that is offering; but they are adhering to steam working. I venture to say that in most of those cases to-day the extra facility and the extra earning capacity could be provided at a lower total working cost by electrifying the present lines. There is one example in London to-day of the effect of electrification which has been brought to my notice very forcibly. The electrification of the London, Brighton, and South Coast Railway Company's lines between Victoria and the Crystal Palace has been accompanied by a large increase in the service of trains, and that has induced a great increase in the traffic. It is not only "rush-hour" traffic. At any time of the day, between 11 o'clock in the morning and 5 o'clock in the afternoon—the hours which, under steam conditions, were "dead" hours—the trains on the line are full. It seems to me that railway companies have to look in that direction for remuneration for their expenditure on electrical working.

Although it does not perhaps appear to the average person that a very large increase of service on the long distances would pay, I should not be at all surprised if it were found that it does pay and will pay, and that at some not very distant future time it will be possible to go to Euston or St. Pancras for a train to Manchester without consulting the time-table and without having to wait very many minutes.

(Communicated): To the author's statements of what steam does, and electric traction must do at least equally well so as to be substituted for steam, it would be well to add some of the things which steam traction fails to do, and which electric traction would evidently facilitate. None of the great English railways gives a reasonably good passenger service to the small towns and villages on its trunk lines. The difficulties in doing so with steam trains, and at the same time keeping clear roads for the fast long-distance traffic, are obvious. The higher acceleration and deceleration associated with electric working are needed for such local trains. The author's views as to working goods traffic electrically suggest that by the same equipment good local passenger services can be made available. Such improvements in frequency and speed of the passenger service will rapidly develop a large amount of additional traffic, or all past experience will be falsified. The author's statements as to the position of suburban railways in competition with road-borne traffic, tramways, and motor omnibuses, cannot be admitted as either complete or well founded. The free use of the highways by pedestrians and passengers generally is a civil right, antedating the railways by many centuries.

Mr. J. M. KENNEDY (communicated): There appear to be two reasons for the electrification of suburban railways on which the author has not laid sufficient stress. First, the public are becoming gradually accustomed to faster and more luxurious methods of travel, and those districts which are best served will undoubtedly attract the largest population. We no longer tolerate the style of travelling that was in vogue 20 years ago, and it is a fair assumption that even 10 years hence a still greater degree of comfort will be demanded. This is no doubt due in part to the wave of prosperity which has been passing over the country, and it seems only right that the railway companies should be able to charge increased fares for the better facilities that are provided. Secondly, there is the question of smoke nuisance, both as regards the general cleanliness and health of the towns, but more especially with reference to the peace and comfort of big terminal stations. In connection with the curve in Fig. 1, it would be interesting to know how the schedule speeds between adjacent stations are calculated on different lines. In the case of a line on which the distance between the stations varies considerably, if the schedule speed is calculated to give a fairly constant energy consumption per train-mile on each section, there should be an improvement in the all-over efficiency and load factor. As regards the generation of electricity, one cannot help feeling that the author's argument against a railway company's generating its own electrical energy might equally apply against the use and maintenance of the electrical equipment of the rolling stock; this in itself necessitates an organization quite different from any already possessed by a steam line, except where a railway has an electrical

engineer and staff already prepared for the work. In this case, however, one often finds an electrical generating station for station lighting and other purposes. Apart, however, from the organization, there is the more important question of finance. In one or two very exceptional cases it may be found that an outside authority can give a supply of electrical energy as cheaply (or possibly at a lower price) than the railway company can generate it; but in the great majority of cases this seems most unlikely. A load of 15,000 kw. may be required for, say, 50 miles of route, and it must be remembered that in installing its own plant (when its lines are electrified) a railway company would be able to install the latest and most economical type of machinery. Unless the supply authority install exactly similar plant, its generating costs will be higher, and in addition there will be capital charges on the necessary high-tension cables, which might easily cost £80,000 to £100,000 more than in the case of the railway company's own supply. There is also the question of capital charges on the generating plant, which will be higher in the case of an outside supply than for the railway company, owing to the higher rate of interest required. A railway load has not of course a very good load factor, but it is an open question, depending on individual circumstances, whether it will or will not improve materially the load factor of any other undertaking. With generating units of suitable size the plant load factor can, however, be kept at a fairly high figure throughout the day, and this of course has a most important bearing on economical production.

Mr. A. W. E. HARRIS (communicated): With reference to the draw-bar pull of steam and electric locomotives, similar curves to those reproduced in Fig. 2 were included

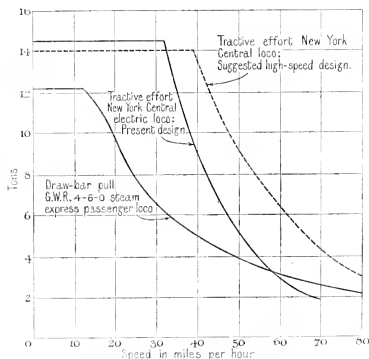

FIG. A.—Curves of Draw-bar Pull and Maximum Tractive Effort at Tread of Wheels.

in the railway electrification discussion at the Paris meeting last year,* but there was then little opportunity of criticizing them. The author uses these curves in support of the assertion that no electric locomotive yet built can give

* *Journal I.E.E.*, vol. 51, p. 611, 1913.

Mr. Harris results equal to those of the steam locomotive at a speed of, say, 70 miles per hour. Though this is literally true yet by a simple alteration in the design any of the electric locomotives referred to could be made to give a draw-bar pull considerably in excess of the British steam-locomotive pull. This has not been done because in America the tendency has been towards the haulage of heavy passenger trains up to 1,000 tons in weight at moderate speeds, rather than trains of half that weight at higher speeds. The modification of the design necessary to give an increased draw-bar pull would consist in altering the ratio between the speed of the train and the speed of the motors. By increasing the size of the driving wheels, say, the motor would run more slowly for a given speed of the train; but the lower speed would cause the motor to take more current and hence to exert a greater tractive effort. As an illustration of this principle I would refer to Figs. A and B herewith. The full-line curves of Fig. A have

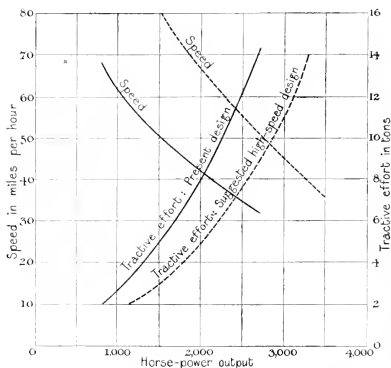

FIG. B.—Curves of Speed and Tractive Effort plotted against Horse-power.

been reproduced from Fig. 2 of the paper for the Great Western steam passenger locomotive and the New York Central electric locomotive. If now the curve of the electric locomotive is plotted in Fig. B with speed and tractive effort as ordinates, and horse-power as abscissae, the ordinary series-motor curve is obtained, except that the output instead of the input is shown. Suppose, now, the size of the driving wheel were increased by 60 per cent or the motor were re-wound for a proportionately higher speed, the effect would be that for a given horse-power the speed would be increased by 60 per cent and the pull would be reduced by 60 per cent as shown by the dotted curves. But for any given speed both the horse-power and the pull are increased; and if the pull is plotted against the speed in Fig. A again, the curve shown by the dotted line will result. At a speed of 70 miles per hour the new design would give a total tractive effort of 4.33 tons, which should be more than equivalent to

the 2½-ton draw-bar pull of the Great Western Railway locomotive. By further increasing the gear ratio still greater pulls may be obtained at the higher speeds, the only limits being the heating of the motors and the permissible overload at starting. It thus becomes a question of whether the required motor capacity can be installed within the limits of weight imposed by the conditions of the line. In this connection the particulars of the latest electric locomotives being built for the New York Central Railroad may be of interest. These locomotives have been designed for a continuous output of 2,000 h.p. on a total weight of 68½ British tons and with an overload capacity of 4,000 or 5,000 h.p. at starting. At 75 miles per hour 2,000 h.p. is equivalent to a tractive effort of 4.47 tons, giving a draw-bar pull of say 3½ tons. Mr. Lydall's requirement, which was agreed to by Mr. Roger Smith, was 3½ tons at this speed. The first problem to be faced in competition with the steam locomotive would therefore appear to be capable of solution. Perhaps also the financial problems of main-line electrification, when considered as an addition to already existing suburban electrification, may not appear so insurmountable.

Mr. W. B. WOODHOUSE (*communicated*): The relationship between the energy consumption per train-mile and the frequency of stopping shown by Fig. 1 of the paper may be emphasized by plotting as ordinates the reciprocals of those chosen, or "stops per mile"; there is then indicated a relationship of the first degree, shown approximately by the equation:—

$$\text{Watt-hours per ton-mile} = 21 + 22 (\text{stops per mile}).$$

For the conditions considered by the author it takes as much energy to start the train from rest as to run it one mile. The author's remarks as to the cost of energy are interesting, but on this point there should be no difficulty in arriving at the price at which energy could be generated by a station used only for traction supply, and therefore at the price at which it will pay to buy electrical energy from a public supply. There is no mystery about the cost of generating electrical energy, and the figure is not difficult to arrive at for any given conditions. In view of the rapid progress that is being made in the economical production of electrical energy by public supply authorities, and the inevitable early obsolescence of present-day generating machinery, one can only regret that so much capital is being spent by railway companies on electric generating plant in preference to purchasing electrical energy from a public supply.

Mr. ROGER T. SMITH (*in reply*): It is satisfactory to find Mr. Firth in agreement with what is said in the paper as to the poor return for passenger service. He emphasizes the point for passenger service in general and for suburban service in particular owing primarily to the reduction of fares by competition with other means of transport, and draws especial attention to the fact, appealing at once to the electrical engineer, that the business is a peak-load business. The bulk of the traffic is during a few rush hours morning and evening, so that the transport load factor is as poor as a lighting load factor. With regard to the maximum number of trains per hour that can be run during these rush hours, 41 trains per hour are being run each way on

Smith.

the District Railway to-day, and 50 trains per hour has been laid down as a maximum in the Parliamentary Committee rooms. It is not quite certain whether 48 trains have yet been run per hour in an actual service, but there is no doubt that they could be run on lines unhampered by crossings on the level. Flying junctions are essential for such traffic density. The necessity for an electric motor with a variable speed characteristic, even for suburban service, has been very well put by Mr. Firth, who emphasizes the fact that rolling stock cannot be confined to certain definite services. The need for an improvement in an equipment which has only two running speeds was further brought out by Mr. Mordey on the grounds of higher efficiency in the transformation of electrical to mechanical energy on the train. It is to be hoped that this will receive the serious attention of designers. Mr. Firth also points out that it is not right to say that the terminal accommodation is doubled by halving the locomotive and signal movements. This statement is based on the fact that every time a locomotive train comes in and goes out there are four platform operations and eight signal operations. Every time a multiple-unit train goes in and comes out there are two platform operations and four signal operations. In that case accommodation is doubled unless external obstructions interfere.

It is satisfactory to have Mr. Firth's agreement with the argument that on engineering and economic grounds the advantages of electric traction for fast passenger traffic have not yet been shown. With regard to goods working, he also points out that the argument for electric working on the economic side largely depends on whether the increased train mileage worked by the electric as compared with the steam locomotive is possible. This is a most important point and must always be worked out for every particular case. But on the engineering side it must also be remembered that there are cases of mineral and heavy goods traffic in hilly districts where the average speed with steam is only 5 or 6 miles per hour. Even if circumstances did not allow of a reduction in the number of locomotives, an increase of the average speed to 12 or 15 miles per hour might alone justify electrification.

In dealing with the paper Mr. Sparks has not always kept to the distinction there made between urban and suburban and other types of service. The author is not only in agreement with Mr. Sparks that for urban service there is no question of the superiority of electric traction, but says so on page 204. Mr. Shaw's paper on "The Mersey Railway under Steam and under Electric Traction" gives quantitative and economic results, and although no paper has been read collecting the comparison between the steam and electric services on such parts on the London Underground Railway services as were formerly worked by steam, there is no doubt that in both these cases steam had come to the end of its tether. The only drawback is the lowness of the fares. The results of suburban working are not so indisputably successful. It is quite agreed that to recover traffic lost to tramways and omnibuses the only thing for a suburban railway system to do is to electrify, but the economic result may be far from satisfactory to the railway. Mr. Sparks is quite right in pointing out a mistake in the figure given for the reduction

in working costs on page 206. Halving the cost of electricity reduces the total cost by 15 per cent and not by 25 per cent. Mr. Sparks's criticism of the sparseness of the service assumed for fast passenger service is welcomed, but it really confirms the argument. A railway having not less than 2,000 miles of route had been purposely assumed. If the other figures assumed are correct, the railway would lose money heavily by electrification. The Brighton Railway is a particular case in which the traffic is far more dense than in the illustration, the figure being about 15,000 train-miles per mile of route averaged over the whole line. The figures given by Mr. Sparks show the effect of density in the problem in the increased money available for electrical equipment of the line per mile of route. Incidentally it suggests that the form of analysis used by the author has some convenience in showing the limiting density of service which would not result in a loss. It is to be remembered that if the figures given in the paper for the annual cost of a locomotive, the train mileage it runs, the cost of locomotive coal and the cost of electricity, are accepted, there would be a dead loss in changing from steam to electric working with a traffic density of only 10,000,000 passenger train-miles per 1,000 miles of route.

Mr. Sparks referred to the saving in locomotive coal haulage. Usually haulage for railway purposes is balanced as between one department and another, but haulage of the coal used in a generating station must not be lost sight of. If the railway generates electrical energy, or if electrical energy is purchased, coal haulage equally appears in the bill; but it is convenient to allow for this in the extra train mileage run by the electric locomotive rather than in the annual cost of a locomotive. Mr. Kahler's figures, quoted by Mr. Sparks, for the reduction in train mileage were for a particular case in the mountain ranges of Western America. They would not apply to British conditions. Similarly the locomotive mileage quoted by Mr. Sparks from Mr. Kahler's paper is not an average but a particular hypothetical case, and is not applicable to the argument for British practice. It is quite safe to say that on the average the electric locomotive ought to be able to haul 50 per cent more train-miles than the steam locomotive, but in any individual division or even on a whole railway, as pointed out by Mr. Firth, this may not be possible. A very good example is the main line of the Metropolitan Railway which is electrified as far as Harrow and is used for steam traction from there to Verney. In this case the annual mileage run by steam engines is about double the mileage run by electric engines. This ratio will be altered when the extension of the electrification contemplated by the Metropolitan Railway is complete. At present the electric service is of the nature of a rather extended terminal service which, as pointed out by Mr. Sparks, must give a poor mileage per locomotive.

Mr. Sparks criticizes the figure of 7½d. per train-mile on 40,000 train-miles. He forgets again that the paper deals with average conditions over 2,000 miles of route, including small locomotives for local and branch traffic. This figure is based on an average of 200 tons for the train, including locomotive, and 50 watt-hours per ton-mile. The Pennsylvania trains weigh 1,000 tons. In any case the figures in the paper show that for fast passenger service the case for electricity is hopeless; but I believe

Mr. Smith.

* Minutes of Proceedings of the Institution of Civil Engineers, vol. 179, p. 19, 1909-10.

Dr. S. P. Smith, the annual cost of £1,250 per electric locomotive to be correct on the average for all sorts of service over 2,000 miles of route.

Dr. S. P. Smith supplied several conditions governing electrification which the paper omitted. It only claimed to refer to some of them, and others were specifically left out because they were to have been dealt with in one or other of the following papers. With regard to the reasons for electrification, Mr. Aspinall has stated that his railway electrified not to save money but to make more. It is the only managerial pronouncement of which the author is aware, and it puts the case admirably.

Dr. Smith rightly calls attention to the importance of the independent unit in the shape of the steam locomotive. If all lines had been electrified and the steam locomotive were then invented, it is conceivable that as a new thing it might be hailed as an immense convenience and improvement. Dr. Smith reconstructed the single-phase locomotive in use for the Lötschberg Tunnel and showed that it could run at 70 miles per hour. No doubt the motors could be designed to give 1,100 h.p. at between 70 and 80 miles per hour, but the speaker did not then say what starting pull it would give. The steam locomotive is a constant-output machine. No electric locomotive yet made is a constant-output machine, but Dr. Smith seemed to assume that it was, and without his diagram to refer to it does not necessarily follow that the locomotive will give its rated horse-power of 1,250 at any speed. The paper does not say—and this equally refers to a criticism by Mr. Sayers—that an electric locomotive suiting British limitations of drawgear cannot be made to give the same pull at maximum speed as a fast passenger steam locomotive; but that such a locomotive has never yet been made, and until it has been made and run successfully we cannot discuss it.

Professor Dalby's diagrams of overall efficiency between the heat in the coal and the work done agree fairly well with the figures given in the paper on page 299, namely 33 per cent for the steam locomotive and 0 per cent for the electric locomotive.

Mr. Mordey's criticism was very much to the point. He showed that for suburban service an improvement in the use of the energy, by reduction or elimination of the losses, was wanted rather than a decrease in the cost of electrical energy and in the first cost of the locomotive. It is useful to remember that 1 lb.-per-ton train resistance is equal to 2 watt-hours per ton-mile at 100 per cent efficiency, so that for the service considered on page 300 and in Fig. 1, where the measured train resistance averages 16 lb. per ton, the number of watt-hours per ton-mile at 100 per cent efficiency to overcome resistances only is 32. This allows nothing for imparting momentum which is afterwards destroyed, but although the efficiency is not quite so bad as that given by Mr. Mordey, who assumed to lb.-per-ton train resistance, it is bad enough. The improvement must come from the designer, and it is probable that the railway engineer has not worked with him sufficiently. It is satisfactory that Mr. Mordey has drawn special attention to this point and especially to the question of regeneration. Mechanical regeneration, as on the Central London Railway, is perfect where obtainable and for trains that stop at every station. Electrical regeneration so far seems only to be completely under control with three-phase motors. All

accounts that have been published of single-phase and continuous-current regeneration seem to show that the voltage is so little under control that it is more trouble than it is worth. It needs careful consideration not only for mountain railways but for suburban working, and if obtainable under complete control it would be of great importance.

Mr. Mordey asked for the proportion of the total capital cost of the electrification that must be allocated to the locomotives. Each individual case is different, and it was because of this difficulty that the form of analysis used in the paper was put forward. In this the locomotive annual capital, working, and renewal costs are averaged over the whole line. Granted certain assumptions as to the cost of locomotive coal, the cost of electrical energy, and the resulting train mileage, any difference in favour of the electric locomotive is available for the electrical equipment of the line, when capitalized, and for profit. Of the annual costs, capital charges at 6 per cent for the locomotive form 13 per cent in the case of the steam and 18 per cent in the case of the electric locomotive. If the cost of the electric locomotive is halved the capital charges drop to 12 per cent of the annual costs.

Mr. Sayers gave excellent engineering reasons for the electrification of passenger services, pointing out that the conditions taken by the author were present conditions. It is important for electrical engineers to realize that steam locomotive engineers are not standing still. At Mr. Fowler's paper on the superheating of steam locomotives which was read and discussed for three nights last month before the Institution of Civil Engineers, the superheating of locomotives was described as the greatest advance that had been made within recent years. The curves for steam locomotives given in Fig. 2 are for saturated steam. They would be considerably better for superheated steam, and especially is that the case at high speeds. Mr. Sayers' remarks all point to the fact that electrification of railways comes in when steam has reached the end of its tether. With that statement the author is in hearty agreement, the point being to decide when steam has come to the end of its tether. There is no question about underground working or dense urban and suburban working, but it is a great mistake to suppose that steam locomotive improvement is at a standstill. The increase in the Brighton traffic due to electrification is referred to on page 295.

Mr. Sayers's communicated remarks as to improvement in the services for branch lines by electric working suggest the system which it is believed will be used on the suburban system of the French State Railways. On its electrified sections every coach is to be a motor coach, seating 100 passengers and with standing room for 100 more. Coaches can run coupled as trains, driven by multiple-unit control, and be shed singly at junctions for branch traffic, joining the train again for the return main-line journey. Such traffic working can only be done electrically. Mr. Sayers no doubt thinks it just that for 25 municipal tramway concerns which in 1912 received support from the rates, the larger part of that support should come from the railways with which they compete, but which are not represented municipally. The moral is: "Happy is the railway without an urban and suburban service."

Smith.

It is refreshing to find a member of the travelling public, if I may so call Mr. J. M. Kennedy, acknowledging the justice of the argument that the demand for faster, more frequent, and more luxurious railway service entitles the railway to higher fares. Were it possible for that view not only to be acknowledged but acted upon, the present difficulties of the railway companies in improving their suburban services by electrification would cease. At present the handicap in favour of the railway's competitors stated on pages 295 and 296 of the paper, as well as statutory obligations as to fares, stand in the way. If only suburban traffic could be made to pay, instead of being, as is often the case, a burden on the long-distance and goods traffic, it would be possible for all the railways to give the public increased facilities for living at distances up to 30 miles away from their work. Mr. Kennedy combats the view that it is better for the railway to buy electrical energy than to generate it. The railway can only invite offers to supply, and if none of them is worth accepting it must generate electrical energy for itself. Mr. Kennedy suggests that it is easier for the railway than for the supply authority to buy so-called up-to-date machinery; but is it easier for the railway to scrap obsolete machinery? The principles on which most railways work with regard to their machinery, in accordance with the system of accounting imposed on them by the Board of Trade, is to maintain and renew out of revenue. If any money is put aside for obsolescence the amount is small and will only reproduce the capital in a long period of years, as it is against the spirit and practice of railway accounting to provide for rapid obsolescence. Experience has shown how necessary it may be to scrap electric generating plant after a short life, but the imposed form of railway accounts makes no provision for this except as a lump sum out of revenue for that particular year, and the temptation to a railway company to allow plant to become obsolete is considerable. In addition to this, electrification costs so much, and capital is wanted for so many other purposes, that the saving of the money necessary for the land, buildings, and machinery for generating electrical energy may make all the difference to the

acceptability of a scheme. When the power required is Mr. Smith, well under 20,000 kw. the cost to the railway of a complete power station should in general be greater than the cost to a supply authority of increasing its existing plant. London with its multiplicity of small stations is at present as bad a place as can be found for buying electrical energy for railway purposes. As to the view that the maintenance of electric equipment on rolling stock is equally a new business to the railway as electric supply, the railway must maintain its electric equipment whether it wants to or not, while it need not supply electricity if it can buy it on favourable terms. It is not to be lost sight of that there is much more chance with a diversity of supply for prices to become more favourable with time if electrical energy is bought, than if it is generated by a railway company in a power station that is debarron from selling energy to anybody else other than a railway, and may have no chance of increasing its output.

Mr. Harris has reconstructed the characteristic curves of the New York Central electric locomotive shown in Fig. 2 (which is not the latest design) to run at over 70 miles per hour. This he does by installing larger motors and gearing them up by increasing the diameter of the driving wheels. This gives appreciably more than the horse-power output and draw-bar pull of the 2-6-0 steam locomotive at 70 miles per hour. Between 10 and 20 miles per hour the steam locomotive only needs to develop some 1,250 h.p. The geared-up electric locomotive can apparently develop more than 4,000 h.p.; and as a continuous-current equipped machine the waste in rheostatic control would more than justify Mr. Mordey's strictures on the inefficiency of electric traction. Something better than the installation of more than 4,000 h.p. to develop 1,200 h.p. seems needed before it can be said that a continuous-current locomotive has been designed capable of competing with the modern high-speed steam locomotive.

Mr. Woodhouse very neatly shows the meaning of the curve in Fig. 1 by plotting the number of watt-hours with stops per mile, and his equation has far more meaning than if the curve itself be expressed as a logarithmic equation.

BIRMINGHAM LOCAL SECTION, 11TH FEBRUARY, 1914.

Taylor.

Mr. A. M. TAYLOR: The curves in Fig. 2 of the paper are very instructive, and quite emphasize the point which the author has put forward, namely, that at the high speeds suitable for fast passenger traffic, electric locomotives as hitherto constructed have been deficient in draw-bar pull as compared with steam locomotives. I understand that this is still more the case if they are compared with the latest forms of superheated steam locomotives. The two types which are selected for comparison in Fig. 2, viz. the 2-8-0 Great Western steam goods locomotive and the 4-6-0 Great Western steam passenger locomotive, illustrate the different performances of the steam locomotive very well. It will be noticed that while the curve representing the performance of the former falls rapidly after a speed of about 27 miles per hour has been reached (that is to say the draw-bar pull falls off rapidly with an increase of speed), yet on the other hand the curve representing the performance of the latter maintains a high value for

the tractive effort right up to a speed of 50 miles per hour, only diminishing slowly after that point. In fact, the curve lies very nearly upon the constant-horse-power curve for 1,000 h.p. But the two Pennsylvania electric locomotives give a draw-bar pull which decreases very rapidly when the speed exceeds 40 miles per hour, and the curve passes across the constant-horse-power curves, as also does the curve of the New York Central electric locomotive. The curve of the New York, Newhaven, and Hartford electric locomotive, on the other hand, shows a somewhat better performance. It is, of course, well known that the continuous-current series motor, although it has excellent characteristics as regards the initial stages of acceleration which render it highly suitable for local suburban lines, falls off considerably in its pull as it reaches a steady running speed corresponding to that in which all the resistance is taken out. Series-parallel control, if it were workable, would give improved results, but between the

two final speeds there would be a large gap over which efficient running could not be maintained. Some means is needed for meeting this condition. The author has pointed out that a single-phase locomotive can partly be adapted to these conditions by absorbing voltage in reactances at the lower speeds. What, therefore, is wanted appears to be an electric locomotive which for a given expenditure in copper and iron will give a very large draw-bar pull at high speeds. This may be obtained apparently at the expense of diminished acceleration at the low speeds, although on the other hand there is a large margin of draw-bar pull available at the lower speeds for acceleration on account of the fact that the pull increases as the $5/3$ rd power of the speed. I cannot believe that it is outside the capacity of electric railway engineers, when once they know the conditions that have to be met, to design a locomotive suitable for high-speed passenger service, and I feel confident that now Mr. Roger Smith has propounded the conditions it will not be long before designers are able to comply with these. On the other hand, I understand that the author considers the capital outlay and the cost of working to be no less than with steam for this particular class of service, and therefore to offer no great inducement to the introduction of electric traction. As regards the cost of the locomotive itself, I think this depends largely upon the standardization of designs and the building of a considerable number of locomotives. The initial cost, however, must necessarily be very heavy. As regards the cost of running, the author hints that the railway companies do not care to undertake such a big experiment as the generation of electrical energy for railway work on a large scale, which they feel would require a large staff for its introduction and operation, and might be better undertaken by those who have been accustomed to supplying electrical energy on a large scale. Here, again, I cannot help thinking that if it is once known that this is the attitude of the railway companies, the large suppliers of electric power will not hold back; but of course the railway companies must not expect them to undertake the supply of energy at prices which are unremunerative in order merely to introduce electric traction. The author mentions getting current at $\frac{1}{4}$ d. per unit. I do not think there is any probability of his obtaining that happy result at present, and I do not think the railway company at any rate could generate energy at

that figure or even near it. It would be interesting to know something more about the designs of the locomotives which gave the draw-bar pulls shown in the curves in Fig. 2, and whether any of them were other than continuous-current locomotives. Mr. Taylor.

The author has apparently made out a good case for the electric goods locomotive, and I can see no reason why, if this be so, electrical engineers should not concentrate their energies on introducing electric locomotives for this class of work. It would appear to be the "thin end of the wedge" for long-distance work and would probably bear the cost of the electrification of the line, which need not then be debited to the high-speed passenger service when electric locomotives for this were introduced later. In conclusion, I feel sure that this paper will serve good purpose in laying before electrical engineers the reasons for the slow progress hitherto made in railway electrification and the lines on which future developments should be shaped.

Mr. R. T. SMITH (*in reply*): Mr. Taylor emphasizes the fact, clearly shown in Fig. 2, that for the high speeds required in fast passenger service the steam locomotive—which is a constant-output machine over almost its whole range of speed—seems to meet the case, while the series-motor electric locomotive is so far from being a constant-output machine that at high speeds its power falls off very rapidly. It must not be forgotten that even for high-speed services spare power at low speeds for acceleration is most useful, enabling the maximum speed to be lowered, and providing for hauling up grades at increased speed. Mr. Smith.

We do not want to turn the electric locomotive, even for fast passenger service, into a constant-output machine, as the greater the power available at starting, over and above that required to overcome resistances, the sooner will the train reach average speed. What is wanted, however, is a design in which the falling off of power with speed is not so marked as it is at present with motors having a series characteristic.

For goods service and for suburban services the limitations of speed are for the most part within the limitations of the series characteristic, but the want of flexibility of a one-speed motor for any one load is a very serious drawback as compared with the steam locomotive. It is satisfactory that Mr. Taylor should have drawn special attention to that part of the problem.

ANNUAL DINNER, 1914.

The Annual Dinner of the Institution was held in the Grand Hall of the Hotel Cecil on Thursday, 5th February, 1914. The President, Mr. W. Duddell, F.R.S., presided over a gathering numbering about 300 persons. Among those present were: The Hon. Sir C. A. Parsons, K.C.B., F.R.S. (*Honorary Member*), Sir Thomas Barlow, Bart., K.C.V.O. (*President of the Royal College of Physicians*), Sir George R. Askwith, K.C.B. (*Chief Industrial Commissioner*), Sir H. F. Donaldson, K.C.B. (*President of the Institution of Mechanical Engineers*), Sir W. Graham Greene, K.C.B. (*Permanent Secretary to the Admiralty*), Sir John Bradford, K.C.M.G. (*Secretary to the Royal Society*), Colonel Sir T. H. Holdich, K.C.M.G. (*Chairman of the Royal Society of Arts*),

Sir John Gavey, C.B. (*Past President*), Sir J. Crichton-Browne, LL.D., F.R.S. (*Treasurer to the Royal Institution*), Sir Alfred Kempe, F.R.S., D.C.L. (*Treasurer to the Royal Society*), Sir J. McClure, LL.D., Sir H. Trueman Wood, M.A. (*Secretary to the Royal Society of Arts*), Major-General S. B. Von Donop, C.B. (*Master General of Ordnance, War Office*), Dr. R. T. Glazebrook, C.B., F.R.S. (*Past President*), Mr. W. F. Marwood, C.B. (*Assistant Secretary to the Railways Department, Board of Trade*), Dr. F. G. Ogilvie, C.B. (*Adviser to the Science Department, Board of Education*), Mr. A. M. J. Ogilvie, C.B. (*Member of Council*), Mr. F. Pullinger, C.B., Rear-Admiral E. F. B. Charlton (*Assistant Director of Torpedoes*), Colonel G. M. W. MacDonogh

(*General Staff Officer, Imperial General Staff*), Lieut.-Colonel P. G. Von Donop, R.E. (*Chief Inspector of Railways, Board of Trade*), Captain E. O. Henrici, R.E. (*Member of Council*), Mr. A. B. Anderson (*Member of Council*), Mr. F. E. Berry (*Member of Council*), Mr. R. A. Chattock (*President of the Incorporated Municipal Electrical Association*), Mr. E. Russell Clarke (*Member of Council*), Mr. E. G. Dawber (*Vice-President of the Royal Institute of British Architects*), Dr. S. Z. de Ferranti (*Past President*), Mr. F. Gill (*Member of Council*), Mr. R. Hammond (*Hon. Treasurer*), Mr. W. Hartnell (*Past Chairman of the Yorkshire Local Section*), Mr. J. S. Highfield (*Member of Council*), Mr. H. Hirst (*Member of Council*), Mr. G. W. Humphreys (*Chief Engineer to the London County Council*), Mr. W. Judd (*Vice-President*), Mr. J. E. Kingsbury (*Member of Council*), Professor T. Mather, F.R.S., Mr. W. M. Mordey (*Past President*), Mr. H. A. Payne (*Comptroller of Companies Department, Board of Trade*), Professor A. W. Porter, F.R.S. (*President of the Königen Society*), Mr. Garnham Roper (*Assistant Secretary to the Harbour Department, Board of Trade*), Dr. A. Russell (*Member of Council*), Mr. W. Rutherford (*Member of Council*), Mr. A. H. Seabrook (*Member of Council*), Dr. W. N. Shaw, F.R.S. (*Director of the Meteorological Office*), Mr. A. Siemens (*Secretary to the Royal Institution, and Past President I.E.E.*), Mr. R. T. Smith (*Member of Council*), Mr. J. F. C. Snell (*Vice-President*), Mr. J. Swinburne, F.R.S. (*Past President*), Mr. A. M. Taylor (*Chairman of the Birmingham Local Section*), Professor S. P. Thompson, F.R.S. (*Past President*), Mr. H. E. Wimperis, M.A. (*Member of Council*), and Mr. P. F. Rowell (*Secretary*).

The President gave the toasts of "His Majesty the King," and of "Her Majesty the Queen, Queen Alexandra, His Royal Highness the Prince of Wales, and other Members of the Royal Family."

SIR JAMES CRICHTON-BROWNE, LL.D., F.R.S. (Treasurer to the Royal Institution), in proposing the toast of "The Institution of Electrical Engineers," said: In the regrettable absence of Lord Moulton, regretted by no one more than by me, I am suddenly called upon to propose this important toast. But as a medical man I am gratified to have this duty assigned to me, for medical men feel a constant pride in the advance of electricity. It was a medical man, Dr. William Gilbert, who gave us the word "electricity" and laid down the foundations of electric and magnetic science on sound experimental and inductive lines. Galvani, the inventor of the metallic arc, whose observations led to Volta's epoch-making discovery, was a medical man. Sir Thomas Young, who first affirmed the identity of electricity and galvanism, was a medical man. Meyer, who first propounded not only the mechanical theory of heat, but the doctrine of the conservation of energy which lies at the basis of so much electrical work, was a medical man. Helmholtz, who stimulated Hertz to those researches that led up to wireless telegraphy, was a medical man. Besides these great and shining stars in the electrical firmament I could mention others of minor, but still of considerable, magnitude of medical affinities, but that I fear it would be thought I was going to appropriate all the merits of the electrical engineers to my own profession. Medical men have recognized that there is a curative value in electricity, and have freely availed themselves of it in

those engineering operations which they have to perform on the human body in cases of paralysis and other diseases. Not merely as a medical man but as a representative of the Royal Institution of Great Britain I am gratified in having to propose this toast, for it was in the laboratory of the Royal Institution that there was planted that mustard seed of electricity which has grown and become the greatest of herbs and a tree in which is lodged this immense flock of birds of sombre plumage but of cheerful song whom I see assembled here this evening. It was in the laboratory of the Royal Institution, if I recollect rightly on the 29th August, 1831, that Faraday performed an experiment with an iron ring and a bit of copper wire which was the foundation of the electrical studies that led to the electro-magnetic and dynamo-electric machines. Electrical engineers perhaps hardly realize how far their influence reaches. I can assure them I have found it in every lunatic asylum in the country, not as electric lighting but as mental observations. The commonest forms of insane delusions in these days are connected with electricity. Thousands of unhappy beings have their night's rest constantly broken by electric shocks; thousands are constantly receiving wireless messages of an insulting and objectionable character. Thousands have their brains kept in an incandescent state by confounded electrical apparatus of one kind and another. I do not know whether we shall shortly have in our lunatic asylums those etheric impressions which have been recently discussed in *The Times*, and which have been thought to be a proper explanation of spooks and ghosts of all kinds. But at any rate at this moment it is electricity that holds the field. I recall one interesting experiment performed by Faraday. He was able to produce gold leaves of such thinness that it would take thousands of them to make the thickness of an ordinary sheet of notepaper; and these leaves were transparent and of a dull green colour. It occurs to me that while all electrical engineers may admire Faraday in his electrical relations, they do not follow him in his experiments upon those gold leaves. The gold that passes through their hands is much thicker, and there is no green about it. I hope there is plenty of it, and that boundless wealth is in store for all the members of this distinguished Institution, whose health I am proposing. It is a great pleasure to propose the toast of an Institution which has shown such remarkable growth, and which is of such immense public utility. I have to couple with this toast the name of the President, Mr. Duddell, who looks so young and is so wise. I will not pass any judgment upon his electrical labours, but this I will say from my own knowledge, that he has the power of clear and of brilliant exposition, and that his experiments never fail. I have the pleasure of proposing the toast of "The Institution of Electrical Engineers," coupled with the name of the President, Mr. Duddell.

The President (Mr. W. Duddell) in responding to the toast said: I am rather at a loss to know what to say, but in the first place I must thank Sir James for the exceedingly kind way in which he has proposed this toast, and those present for the hearty manner in which they have received it. The toast is a double-barrelled one; it couples the Institution of Electrical Engineers with my name. In proposing the toast Sir James has referred to those medical men who have helped electrical engineers and who were

in fact the pioneers of electrical science. He has also made such a complimentary speech that I hardly know how to reply. There is one thing, however, that I must say. I have recently been suggesting to the Institution that we ought to extend our fields of usefulness, and that we ought to take up all kinds of new developments. Another field has now been suggested: that the Institution of Electrical Engineers should try and help the medical profession in applying electricity to the amelioration of the ills of the human race. I thank Sir James for making this suggestion, and I hope we may be able to act upon it.

This is the second Annual Dinner at which I have had the honour of presiding; I therefore do not think I need say very much about the work of the Institution. The proposer of the toast is, as we all know, the Treasurer of the Royal Institution, and he has referred to the work that Faraday did there. I think there is no other Institution in this country which recognizes so well as we do our indebtedness to that great man, Faraday, for laying the

foundations of our science. But I do not think our indebtedness to the Royal Institution ends there. Year by year valuable work is carried out in its laboratories; nearly every new invention is described in its Lectures, and we have the privilege of hearing what is going on in that most valuable Institution, which dates back a whole century or more. As the representative of one of the younger societies I should like to express our indebtedness to the Royal Institution for the valuable work which it carries out. Sir James has suggested that electrical engineers are on the point of receiving a large amount of thick gold. I only hope it may be true. I will conclude by again thanking, on my own behalf and on behalf of the Institution, Sir James and those present for the hearty way in which this toast has been received.

Dr. S. Z. DE FERRANTI then proposed the toast of "Our Guests," to which Sir George Askwith, K.C.B., K.C., responded.

A re-union was subsequently held in the Victoria Hall of the Hotel.

ELECTRIC LOCOMOTIVES.

(SUPPLEMENTARY PAPER.)

By F. LYDALL, Member.

(Paper first received 29th January, and in final form 16th February, 1914.)

Since the author's paper on "Electric Locomotives" published in No. 222, Volume 51, of the *Journal* was completed, a few new designs have been developed and a certain amount of fresh experience has been gained. It may be of interest to bring forward these new designs with a brief reference to each, in order to complete the list, and also state, so far as is possible under the circumstances, the present position in regard to locomotive design in general. It will of course be understood that information as to the results obtained with locomotives of different kinds is not readily available, such experience being frequently acquired at great expense, and therefore being usually regarded as confidential. Messrs. Siemens Schuckert of Berlin have, however, been good enough to place at the author's disposal some hitherto unpublished information with regard to the working of one of their latest types of locomotive, from which certain general conclusions can be drawn. This is referred to below.

NEW DESIGNS.

Four new designs are illustrated in Figs. 1 to 4, two having been brought out by the Bergmann Elektricitätswerke Aktien-Gesellschaft for the Silesian Railways, one by the Maschinenfabrik Oerlikon for the Lötschberg Tunnel Railway, and one by the General Electric Company of America for the New York Central Railroad. Particulars of the motors with which these locomotives are equipped are given in the author's paper on "Motor and Control Equipments for Electric Locomotives."*

1. *Type 2—D—1 by the Bergmann Elektricitätswerke A.G.*—The general arrangement is shown in Fig. 1, the special feature being the provision of two jack shafts coupled by inclined connecting rods to the armature shaft of the single motor. The obvious advantage of this design is that the torque produced by the one powerful motor is

divided between two jack shafts. The locomotive is at present in course of construction.

2. *Type 2—B+B—1 by the Bergmann Elektricitätswerke A.G.*—The general arrangement is shown in Fig. 2. The rating of the two motors on this articulated locomotive is the same as that of the single motor in the foregoing 2—D—1; the mechanical arrangement is, however, entirely different, the jack shaft in each half being geared to the corresponding motor shaft. This locomotive is also at present in course of construction.

Messrs. Siemens Schuckert are also building a locomotive with gear-wheel drive on to jack shafts for the Silesian Railways.

3. *Type 1—E—1 by the Maschinenfabrik Oerlikon.*—The general arrangement is shown in Fig. 3; the two motors are geared to two jack shafts which drive on to the middle of the five driving axles by Scotch jokes. This locomotive has already been running for some time on the Lötschberg Tunnel Railway.

4. *Type B+B+B+B by the General Electric Company of America.*—The general arrangement, as shown in Fig. 4, consists of four articulated trucks each equipped with two bipolar motors of similar construction to, but smaller in size than, those on the original New York Central locomotives. The trucks are grouped together in pairs by two frames, these frames carrying the body.

The first of these locomotives was delivered for experimental running about 18 months ago, as a result of which further locomotives of the same design were ordered. The duty for which they have been designed is to haul trains of 900 tons (American) at express speeds, that is, up to about 60 miles per hour; but Mr. Katté has informed the author that the motor armatures are to be enlarged to enable trains of 1,100 tons (American) to be hauled. Mr. Katté also states that the riding qualities of the locomotive are excellent.

* See p. 384.

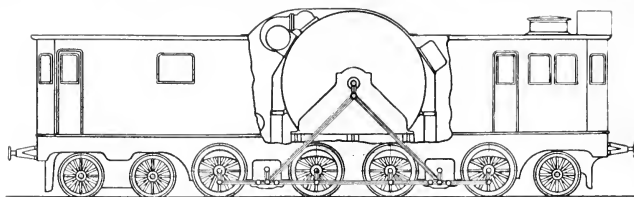

FIG. 1.

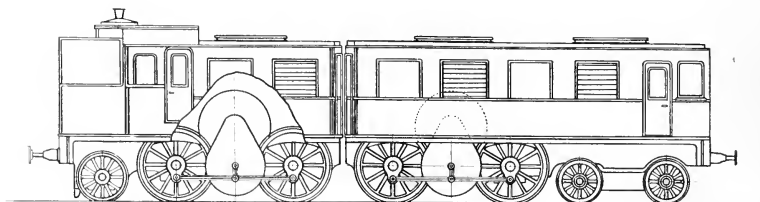

FIG. 2.

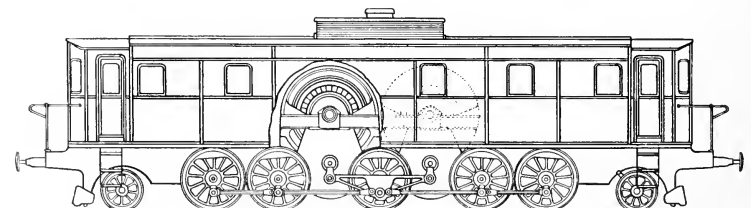

FIG. 3.

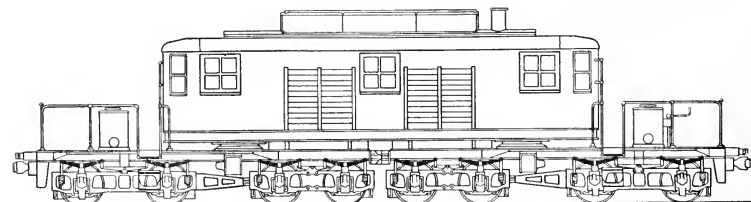

FIG. 4.

Before leaving the subject of new designs, mention must be made of the so-called "two-rod drive" developed by Messrs. Brown Boveri. Two locomotives of the general type 1-C—1 have been ordered from this firm by the Baden State Railway Administration for service on the Wiesenthal line. Up to the end of last year only one had been delivered.

The special feature of this design is that the two motors which are mounted near the centre of the body and well above the centres of the driving axles drive direct on to the central driving axle without the intermediary of any jack shaft. The arrangement follows the lines of the Scotch yoke system in that the bearing on the crank-pin of the driving axle is free to move up or down in a vertical slot in the connecting rod which connects this crank with the corresponding crank of one of the motors. It differs, however, from the Scotch yoke in that the two connecting rods from the cranks of the two motors are pivoted together at the bottom angle instead of being rigidly connected so as to form a frame. The general arrangement is shown in Fig. 5.

The object of this design is to eliminate the heavy and expensive jack shafts with their cranks and bearings, etc., and at the same time to provide an arrangement in which great accuracy of adjustment (of motor axle and jack shaft positions) is unnecessary. It is too soon to say definitely whether this design is successful in practice or not, as from one cause or another the locomotive has so far seen little service.

Turning now to the general experience with electric locomotives of various designs, it appears to be fairly well established that for railways equipped on the continuous-current system, either high-tension or low-tension, shunting locomotives and those intended for hauling heavy goods and mineral trains at the speeds customary in this country are best made on the articulated bogie principle with four geared motors suspended on the bogies in the ordinary way.

For railways on which the electrical supply is on the three-phase or single-phase alternating-current system, the choice of drive is perhaps rather more open. There is a tendency towards concentrating the motive power in one or two motors, and these must necessarily be connected to the driving axles by connecting rods on one system or another, so as to utilize the total weight of the locomotive for purposes of adhesion. This introduces at once the consideration of coupling-rod drive in the light of recent experience.

Attention has been drawn in the technical press on one or two occasions during the last six months to the difficulties experienced on the Wiesenthal Railway with the locomotives supplied by Messrs. Siemens Schuckert. These locomotives are of the 1-C—1 type with two single-phase motors driving down by connecting rods on to a single jack shaft between two of the three coupled driving axles. Nine of these locomotives were delivered during last year, and during the first month of working a number of mishaps occurred, some trifling and others more serious. The occurrences of minor importance were due to difficulties with the four-part motor bearings, troubles with the sand pipes, and other small details. These matters were attended to and put right without any serious disturbance or any substantial modifications of the

general design. Such small difficulties are to be expected whenever locomotives of a new type and with new equipments are first put into operation.

The more serious mishaps were not to be explained in the same way, and were apparently due to some fundamental cause. After a great deal of observation it was found that at a certain speed the connecting rods and coupling rods on both sides of any of these locomotives started to vibrate, and that this vibration gradually increased as the speed rose, until at a speed of about 36 kilometres per hour it reached a maximum of considerable amplitude. At this speed there seemed to be the equivalent of resonance, as the vibration practically disappeared as soon as the speed had risen to 40 kilometres per hour.

It is of special interest to remark that this peculiar performance of coupling-rod systems is observable on

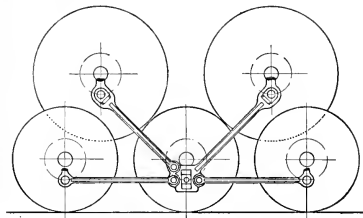

Fig. 5.—Brown Boveri 2-rod drive.

practically all locomotives in which the effort of the motor or motors is transmitted to the driving axles by means of connecting rods. It is especially noticeable in those cases in which a pair of motors is coupled to a single jack shaft, or are rigidly coupled together by any arrangement of connecting rods, and is not confined to the construction adopted for the Wiesenthal locomotives, but is also observable with Scotch yokes, as on the 1-E—1 locomotive for the Lötschberg Tunnel Railway, on which breakages of the yokes have taken place. The same experience, although to a less extent, is found on locomotives in which each motor, if there are more than one, drives on to a single jack shaft, such as the 1-C—1 for the Prussian State Railways. The same effect has also been observed on the 2-B+B—2 locomotives of the Pennsylvania Railroad, although in this case the vibration is very slight.

Having recognized this as the fundamental cause of the breakages referred to above, Messrs. Siemens Schuckert devised a new arrangement—particulars of which the author is not at liberty to publish—which, so far as can be seen after several months' working, eliminates the trouble. The new arrangement does not require any far-reaching alteration to the general design, the jack shaft being used as before with the two connecting rods and the coupling rods on each side. The alterations have been already carried out on all the nine locomotives. It should be mentioned, however, that the new design is not that of the two-rod system alluded to above and shown diagram-

matically in Fig. 5. The statements that have recently appeared in the technical press to this effect are incorrect.

The experience mentioned above may with advantage be taken into account in considering the most suitable design of locomotive for a given class of service. Partly for this reason, and also on other grounds connected with the first cost, there is a tendency at present on the Continent towards the use of gearing rather than connecting rods for transmitting the torque to the jack shaft or direct to the driving axles. If the author is not mistaken, this is also the general conclusion in the United States, where the connecting-rod drive does not find much favour.

For express passenger service, however, there still remains the difficulty of excessive gear velocity if gear drive is employed. For speeds which would be required in this country, say, 75 miles per hour, it would hardly be practicable to run without some kind of forced lubrication for the gears, as, for example, by jets of oil directed against the surfaces of the gears in contact. It may be, however, that a locomotive designed on this principle would have some advantages in comparison with a connecting-rod locomotive for the same service; but a careful study of all the requirements and conditions of any particular case would be necessary before any conclusion could be reached.

MOTOR AND CONTROL EQUIPMENTS FOR ELECTRIC LOCOMOTIVES.

By F. LYDALL, Member.

(Paper first received 20th November, 1913, and in final form 3rd February, 1914; read before THE INSTITUTION 26th February, before the BIRMINGHAM LOCAL SECTION 25th February, and before the MANCHESTER LOCAL SECTION 10th March, 1914.)

General questions relating to the design of electric locomotives having already been discussed in a paper submitted to the Institution and printed in the *Journal*,² it may be of interest in the same connection to draw attention to some considerations relating to the electrical equipments alone.

It is not proposed to go at all deeply into the many questions of motor design that must be carefully dealt with by the designer of the equipment, as these are matters for specialists; even if the author were competent to do justice to these questions, which he does not profess to be, it would be better in his opinion to accord them separate treatment in a paper addressed principally to dynamo designers. Neither is it proposed here to go into the constructional details of the various pieces of apparatus constituting the control equipment. Putting aside these matters, however, it may be of interest to refer to a few general considerations which are applicable more especially to electric locomotives as distinguished from electrically equipped vehicles in general.

MOTORS.

Dealing first with motors for locomotives, it will be convenient to divide them into two classes, viz. geared and gearless motors. The suitability of one class in preference to the other in any particular case has already been discussed at some length in the paper mentioned above. The conclusions arrived at are that the sphere of utility of the geared motor is practically confined to locomotives of moderate speed, as, for instance, locomotives whose maximum speed never exceeds 60 to 65 miles per hour; whereas for express passenger locomotives, with which speeds up to 80 or 85 miles per hour may be reached, the gearless motor practically holds the field.

Various methods of utilizing motors in locomotives, that is of transmitting the effort exerted by them to the driving axles, have also been referred to in the same paper and

need not be repeated. It is proposed only to draw attention to questions of motor capacity in relation to (a) gauge, (b) electrical system, (c) voltage, (d) diameter of driving wheel, (e) method of transmission, and (f) forced ventilation. A list given below also contains a certain amount of information about several locomotive motors built by various electrical firms or companies, which may perhaps be convenient for reference.

(a) *Gauge*.—It will be readily understood that a narrow gauge hampers the designer very seriously. If it is intended to adopt the ordinary form of transmission, viz. by single reduction gearing with the "wheelbarrow" type of suspension, the space available for the motor and the gearing is equal in one direction to the distance between the wheel tyres, less the necessary clearance. If with the normal-sized driving wheel the space available is insufficient to accommodate a motor of the required capacity, the only alternatives are to increase the wheel diameter or to adopt some other form of transmission. The latter of these two alternatives leads to a more expensive construction, but nevertheless it may be unavoidable.

The point is well illustrated by two locomotives both equipped by Messrs. Siemens Schuckert, one for a colliery in the North of England, the other for the metre-gauge railway line belonging to the Rombacher Hütte in Alsace. In the latter the motors are suspended on the bogies in the ordinary way, and the only departure from the usual arrangement is in respect of the wheel diameter which is greater than customary for motors of 160 h.p. capacity. This instance is of particular interest owing to the fact that each motor is designed for a voltage of 1,000 and is insulated sufficiently to withstand a pressure of 2,000 volts to earth, the supply being at 2,000 volts continuous current.

In the former locomotive, which was designed for a gauge of 26 in., the problem was to provide an equipment with a total capacity of about 175 h.p. For this purpose an 88-h.p. motor was mounted on each of the two bogies in such a position that it was not restricted in an axial

* F. LYDALL, "Electric Locomotives." *Journal I.E.E.*, vol. 51, p. 739, 1913.

direction by the wheel tyres. A jack shaft was also provided geared to the motor and coupled to the driving axes by side coupling rods. In this way a motor which with the ordinary suspension could not be got into any gauge less than 1 metre was fitted on to a truck built for 26 in. The two constructions are shown to the same scale in Fig. 1.

Another example may be mentioned, viz. the 250-h.p. single-phase motor of the 760-mm. (2 ft. 6 in.) gauge locomotive for the St. Polten-Mariazell line in Austria. In this case the motor is mounted on the top of the bogie and is geared to a jack shaft immediately below it, this shaft being connected to the three driving axes by Scotch yokes or slotted coupling rods. In this way space restrictions are eliminated.

The restrictions of gauge are of less importance in a locomotive in which gearless motors are used mounted in the body of the locomotive and driving by connecting rods and jack shafts. With this construction the motor can be made as large in diameter as desired consistent with the

Space in an axial direction being in general restricted, the tendency will naturally be towards an increase in the diameter, corresponding to an increase in the working voltage, as has already been noticed in the case of the Rombacher Hütte locomotive mentioned above.

For motors of moderate capacity, there seems no difficulty in raising the supply voltage to 2,400, as in the case of the locomotives for the Butte and Anaconda Railroad, each of which is equipped with four 300-h.p. single-reduction twin-gear forced-draught motors suspended in the ordinary way with 48-in. driving wheels. A step in advance of this is being tested on the Lancashire and Yorkshire Railway, where motor-coach equipments are being supplied by Messrs. Dick, Kerr & Co., each consisting of four 250-h.p. 1,650-volt single-reduction single-g geared motors with driving wheels of 44-in. diameter, the supply voltage being 3,300. These equipments are said to work perfectly satisfactorily, but it is self-evident that in some places inside the motor the clearances between live parts and the frame

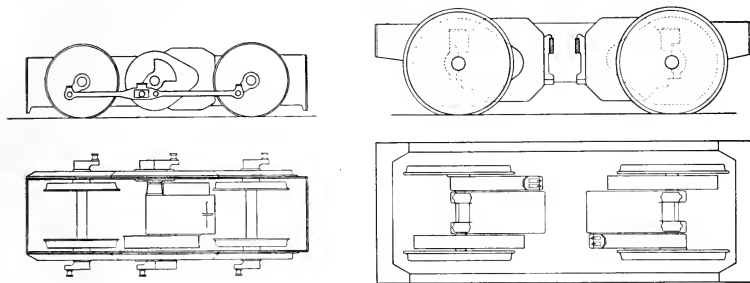

FIG. 1.

limits of armature peripheral velocity, but in an axial direction it is limited by the distance between the centres of the crank pins at the two ends of the jack shaft. With outside bearings, however, the cranks being on extensions of the journals, this is not a severe restriction.

(b) and (c) *Electrical system and voltage*.—Four alternative systems may be mentioned: continuous current low-tension, continuous current high-tension, three-phase alternating current, single-phase alternating current.

For continuous current, low tension may be regarded as any voltage up to 750 or 800, high tension 1,000 volts upwards, there being no cases that the author is aware of in which the voltage is between 800 and 1,000. It will be obvious that for the same capacity a high-tension motor will be larger and heavier than a low-tension motor. There is less space for armature conductors, and therefore the armature must be bigger for the same volume of copper. The commutator may be shorter if the motor is designed for a high terminal voltage, and not merely insulated for connection in series with another low-voltage motor on a high-tension supply; but this advantage is counterbalanced by the longer creeping surfaces required and the greater clearances between live parts and the frame.

must be comparatively small. But whatever the results of this experiment may be, it is certain that in the case of a locomotive where there is no objection to the motors projecting above the floor-level, the electrical designer would feel happier in making the motor with ample internal clearances, and this could only be done by freeing the motor, by one or other of the various methods available, from the restrictions of the gauge and the wheel diameter.

In considering the two alternating-current systems, the question of frequency is important. For three-phase locomotive motors, especially those operating in cascade, a low frequency is desirable. In the new locomotives for the Norfolk and Western Railway 25-frequency motors are to be used, but this is probably on account of the general tendency in the United States to adopt this frequency as the lowest standard for railway work in order to utilize the supply for other purposes at the same time.

So far as capacity in relation to weight and bulk is concerned, polyphase induction motors make a very good showing, as may be seen from several examples in the table annexed. It must be remembered, however, in comparing induction motors with motors having series characteristics, whether continuous current or single-phase alternating

current, that the induction motor is rated at its maximum speed, that is at a speed which may correspond to the maximum permissible peripheral velocity of the rotor, whereas the series motor is rated on the basis of a speed which may be, and often is, not more than half the maximum. If series motors were especially designed to give their output on the one-hour rating at their maximum speeds, they would compare very favourably with induction motors; at least the continuous-current series motor would give astonishing figures for weight per horse-power.

In practice, the single-phase motor, even at the low frequency adopted as the standard on the Continent (16½ or 15) is undoubtedly more bulky than the continuous-current motor. As an illustration of this, the 2,000-h.p. 600-volt motor of the Pennsylvania Railroad locomotives may be

the locomotive where they can be inspected at any time. Reference may perhaps be made in this connection to the paper by Professor Reichel,² in which the whole question of ventilation for locomotives is fully discussed.

CONTROL EQUIPMENTS.

The problems inherent in the design of a control system suitable for an electric locomotive are bound to depend upon the purpose which the locomotive is intended to serve. It may be said at once that apart from special cases an electric locomotive differs essentially from a motor coach both as to its function and as to its constitution. A motor coach, as generally understood, is a passenger vehicle with an electrical equipment. This equipment is usually designed to enable the train to be

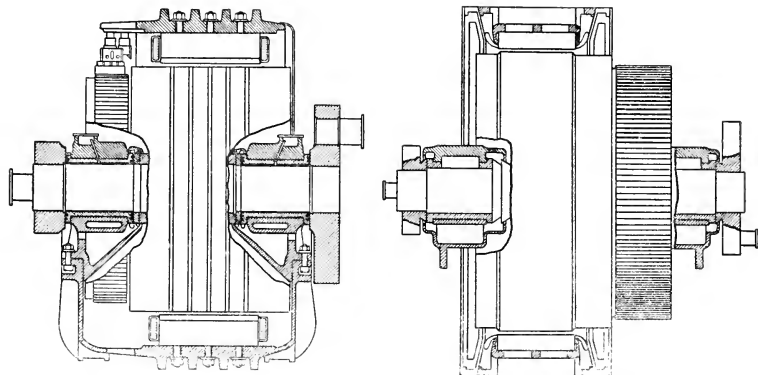

FIG. 2.

2,000-h.p. 600-volt Motor for Pennsylvania Locomotives.

800-h.p. Single-phase Motor of 1-B+B-1 Locomotive for Lötschberg Railway.

compared with the 800-h.p. single-phase motor of the Lötschberg locomotive equipped by the Allgemeine Elektrizitäts Gesellschaft. The comparison is shown in Fig. 2, the two motors being drawn to the same scale.

(d) and (e) *Diameter of driving wheel and method of transmission.*—The influence of these two factors on motor capacity has already been touched upon above.

(f) *Forced ventilation.*—The advantage of forced ventilation in increasing the continuous capacity is so great that it is becoming general to introduce it in locomotives of all classes except small industrial locomotives. A few figures are given in the table showing the gain in capacity due to forced ventilation as compared with radiation from the external surface of the closed motor, shown more particularly in the relation between the continuous and the one-hour ratings. The complication of apparatus involved in the provision of the blowers is not great, and no trouble in regard to maintenance need be anticipated, as the blowers and their motors can be fixed in the interior of

started with a high acceleration, so high in fact that it does not depend to any great extent on the gradients such as are ordinarily met with on English railways. The weight of the motor coach is determined principally by structural considerations with regard to the passenger accommodation, and partly by the weight of the electrical equipment itself, and is kept down to the lowest limit consistent with strength and the requisite capacity.

The design of an electric locomotive, on the other hand, depends on quite different considerations. In the first place, the weight is arbitrarily chosen independently of the structural strength and to a certain extent of the capacity of the equipment; on the contrary, the principal deciding factors are the adhesion necessary to enable the required tractive effort to be exerted, and the speed of travel. The first of these factors determines the weight carried by the driving wheels; the second the number and arrangement of non-driving wheels. In many cases loco-

² *Elektrische Kraftbetriebe und Bahnen*, vol. 11, p. 100, 1913.

motives are ballasted in order to bring up the total weight to the required value.

In the second place, electric locomotives are not usually intended for service in which high acceleration is required. Rapid starting is not a matter of great importance for freight trains or for long-distance passenger trains. In consequence the proportion of the weight on the driving wheels to the total weight of the train is usually much lower in the case of trains hauled by electric locomotives

Now the variations of the tractive effort exerted by the motors during the progress of the controller obviously depend on the number of steps in which the controlling resistances are switched out with motors in series and in parallel. Whatever the variation may be, the current on each position of the controller must be allowed to fall so far that when the next step of resistance is switched out the current does not increase beyond the value corresponding to the maximum permissible tractive effort. If the load

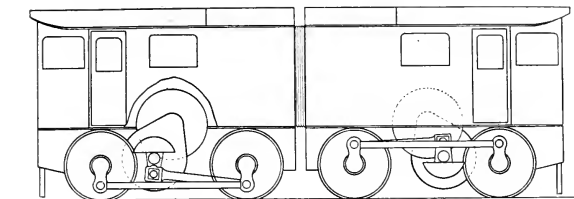

FIG. 3.

than in the case of multiple-unit motor- and trailer-coach trains.

For example, for freight trains the ratio might perhaps be as low as 1 to 20; whereas for multiple-unit trains it would seldom be less than 1 to 2½, or 1 to 3.

This difference in the ratio of adhesion weight to total weight has a marked influence on the control system, as will be seen the moment the question of starting on gradients is considered.

The following general statements with regard to heavy traction by steam or by electric locomotives will be admitted by railway engineers.

(a) The weight on a pair of driving wheels is generally not far from the maximum permissible weight as determined by the strength of the track, bridges, etc.

(b) A locomotive is utilized to the greatest advantage when it is coupled to the heaviest train with which it is able to deal; that is, haul at the regulation speed on the line selected, start on the steepest rising gradient, and stop on the maximum falling gradient.

It will perhaps be best to explain the influence of these points on the control system by considering a simple example.

Let it be assumed that the maximum weight per axle of the locomotive is 16 tons; and take the case of an articulated 4-axle 64-ton locomotive, each half of which is equipped with one continuous-current motor, driving through single-reduction gearing and coupling rods. Suppose also that the steepest gradient on the line is 1 in 90. Fig. 3 shows the outline of the locomotive, and Fig. 4 gives the performance curves of each motor.

In order to study the capabilities of the locomotive it is necessary to make some reasonable assumption as to the maximum value of the coefficient of adhesion. Let it be assumed that this value is 1 to 4, in other words that the greatest tractive effort that can be exerted by the motors without causing the wheels to slip is 6¼ tons (= 16 tons) measured at the tread of the driving wheels (not at the draw-bar).

behind the locomotive when travelling up the specified gradient is too great, the current will never fall sufficiently to permit the controller to progress without causing the wheels to slip. It is of course well known that when the wheels slip the tractive effort is much less than while the wheels adhere to the rails. If, therefore, the load is excessive, the locomotive will be unable to start the train and gather speed on the gradient, although it may be perfectly capable of maintaining full speed up the gradient if

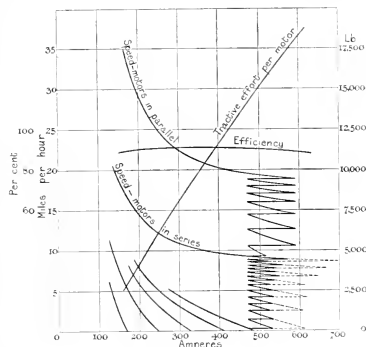

FIG. 4.—Performance Curves of 550-h.p. 1,300-volt C.C. Motor

the train has already been started on the level or on an easier gradient.

Thus suppose the locomotive mentioned above is coupled to a train weighing W tons, and assume that the tractive resistance of the whole train during the start is 7 lb. per

ton, then the tractive effort required to maintain speed on the gradient of 1 in 90 without acceleration will be—

$$\begin{aligned} & (W + 64) \left[\frac{2240}{90} + 7 \right] \\ &= (W + 64) 32 \text{ lb.} \\ &= \frac{W}{70} + 0.915 \text{ ton.} \end{aligned}$$

This then will be the theoretical lower limit of the variation of tractive effort during the start.

For example, supposing the number of steps in the control system is such that with an upper limit of 16 tons the lower limit is 12.5 tons, then the maximum train weight permissible will be given by the equation—

$$\frac{W}{70} + 0.915 = 12.5,$$

from which $W = 810$ tons.

It is hardly practicable, however, on the assumptions made above, to work with a trailing load as high as this. If this load were coupled to the engine and an attempt were made to start up on the specified gradient, each step of the control would occupy an inordinate time before the motor current fell far enough to permit the controller to advance to the next step. This is fairly obvious from the speed time curve in Fig. 5, which shows how the acceleration varies from a fairly high value down to almost zero on each position of the controller. If then the maximum theoretical load is attached to the locomotive, the acceleration must actually reach zero on each position of the controller, which is of course impracticable. In practice, therefore, the load must be limited to something less than the theoretical maximum value. For the following reason the reduction will depend on the gradient. If the tractive

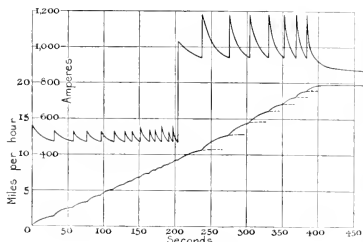

FIG. 5.—Acceleration Curve of 804-ton Train. 1 in 100.

resistance is small compared with the force of gravity on the gradient, the pull required to maintain speed on the gradient can be calculated with fair accuracy. If not, the calculation will depend to a large extent on a correct forecast of the tractive resistance. Even a correct forecast, however, is not sufficient, since the tractive resistance differs between wide limits under varying conditions.

For example, suppose the gradient in question is 1 in 50,

and the estimated tractive resistance is 7 lb. per ton. Then the pull corresponding to steady speed will be

$$\frac{2240}{50} + 7 \text{ lb. per ton} = 51.8 \text{ lb. per ton.}$$

An error of 10 per cent in the tractive resistance will only involve an error of 1.25 per cent in the total.

If, however, the gradient were 1 in 200, an error of 10

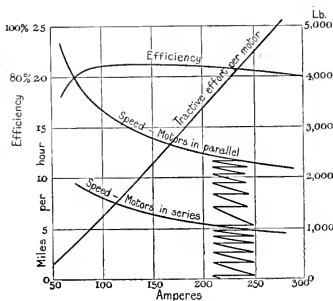

FIG. 6.—Performance Curves of 100-h.p. 500-volt C.C. Motor.

per cent in the tractive resistance would lead to an error in the total of 3.8 per cent.

The only safe way then is to estimate the tractive resistance on the high side and allow a margin beyond the calculated value to ensure that the starting period is not unduly prolonged.

For example, in the case illustrated in Fig. 5, the theoretical maximum value is 810 tons, and the actual value on the basis of which the curves have been drawn is only 740 tons.

The number of steps in the controller or control system will depend on the characteristics of the motor in question. If the magnetic circuit of the motor is not highly saturated on that part of its range which is used during starting, and if the resistance of the motor is relatively high, the number of steps necessary to keep the torque variation within moderate limits is not likely to be excessive. The greater the saturation and the lower the internal resistance, the greater will be the number of steps.

These two factors can be combined in one, viz. the slope of the speed curve at the working range. The greater the slope, the smaller the number of steps.

This slope being the resultant of the two factors will vary with different motors. In a general way one may say that the bigger the motors, the lower will be the internal resistance, and therefore the less the slope and the greater the number of steps. This is illustrated by the comparison in Figs. 4 and 6, the former of which shows the starting curves for a 550-h.p. motor and the latter those for a 100-h.p. motor, the same percentage variation of torque being permitted in both cases.

This comparison is perhaps worth consideration when

determining the most favourable motor equipment for a given locomotive. If a single large motor be chosen instead of, say, four small motors of the same aggregate capacity, in order to arrive at the same value of the maximum permissible load a more elaborate control system must be installed. This is, however, comparatively a small point.

It is also worth remarking that the question of self-induction in the motor windings does not enter into the consideration of the problem. In the case of a tramcar starting on the level, under ordinary circumstances the entire starting period may not last more than 6 seconds, and therefore the time spent on each notch of the controller is so short that the variations of the motor current may be considerably influenced by self-induction. In the case of a locomotive starting with its maximum load on a steep gradient, the accelerating period may last from 5 to 10 minutes, so that the influence of self-induction may be ignored. It is therefore necessary to consider the matter carefully, as no help can be expected from this source.

On the other hand there are two factors which make for some uncertainty as to the precise fluctuations of the torque during the accelerating period, viz. the variation of the supply voltage on the overhead line, or on the third rail as the case may be, and the variations in the resistance values of the controlling resistances due to the rise in temperature. The first of these tends to reduce the fluctuations, as the supply voltage will generally fall slightly as more current flows through the motors. The second is very uncertain, the temperature of the resistances depending on the working conditions, etc.

So far the question has been discussed only in relation to continuous-current motors controlled in the well-known way by means of inserted resistances cut out in successive steps. To a certain extent the same problem is met with when alternating-current motors are employed either with rheostatic control or with voltage control obtained by drawing current from successive tappings of a transformer. The actual variation of motor torque from step to step will, however, depend upon a factor which is absent in continuous-current working, viz. the effect of the self-induction of the motor windings on the motor characteristics. This effect, so far as the speed-current curve is concerned, is similar to that of a large increase in the internal resistance of the motor, and therefore greatly reduces the fluctuation of the torque for any given number of steps.

As an example of this effect, the speed curves in Fig. 7 may be compared with those in Fig. 4. The difference in the number of steps for the same fluctuation of torque in the two cases is obvious.

Going back to the general question, it is evident that the irregularity of the effort exerted by the motor equipment of an electric locomotive is a disadvantage which under certain circumstances reduces the usefulness of the locomotive. It may be compared with a very similar characteristic of the steam locomotive, the tractive effort of which varies with the positions of the cranks. There is, however, this difference between the two cases: the tractive effort of the steam locomotive fluctuates under all conditions, whereas that of the electric locomotive is uniform on any single step of the controller whether intermediate or final so long as the speed remains constant, and there-

fore at the worst fluctuates only during the actual starting period.

The question may be raised as to whether this disadvantage in the electric locomotive cannot be overcome by means which are commercially practicable. For continuous-current equipments variable voltage must be obtained by some form of motor-generator, the motor taking current from the power supply, and the generator delivering current at a suitable voltage to the driving motors, the voltage being varied as required by the excitation of the generator.

This method is open to the great objection that the motor-generator is practically a sub-station installed in the

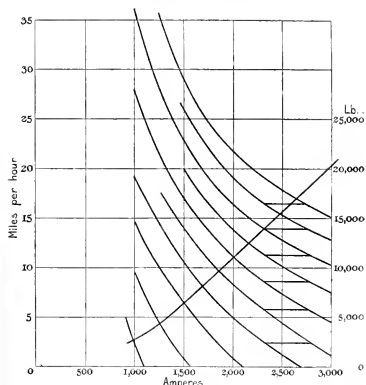

FIG. 7.—Speed Curves of 700-h.p. Single-phase Railway Motor.

locomotive, and is extremely bulky and expensive, and costly to maintain.

The capacities of the machines may be considerably reduced, however, by employing them only during the starting period, both machines running idle or being switched out altogether during the continued working of the locomotive. For example, the motors may be arranged for series and parallel connection in the ordinary way, and the motor-generator may be used to reduce the line pressure by interposing in the circuit between the motors and the line a gradually decreasing back electromotive force. With this arrangement the size of the motor-generator will be determined largely by its heat capacity in relation to the output required for the comparatively very short time of starting and accelerating.

In any case, however, it is highly probable that this solution of the difficulty is more expensive and complicated than the simple expedient of multiplying the number of resistance steps and the corresponding contactors so far as may be necessary.

The case is quite different, however, with large locomotives equipped on the single-phase alternating-current system. Voltage variation can be very conveniently pro-

vided without using rotating machinery in the case of alternating current. Definite steps of voltage can be obtained simply by providing taps on the secondary winding of the step-down transformer, and there are various well-known methods at present in use whereby the maximum number of voltage steps is obtained with the minimum number of contactors.

In spite of the advantages of these different schemes, however, it is not practicable to go very far in the direction of fine graduation. In practice, owing to the requirements of single-phase motor design, the voltage even at full speed is seldom more than about 300. It is also customary to employ large motors for these locomotives, and consequently the motor current which must be dealt with by the controlling contactors may be very heavy.

For example, the 1-C-1 locomotive equipped by Messrs. Siemens Schuckert for the Prussian State Railway, contains a single 1,800-h.p. motor. The one-hour current of this motor, assuming the terminal pressure to be 300 volts, will be in the neighbourhood of 6,000 amperes. The indefinite multiplication of contactors suitable for dealing with this current, even if the control is so arranged that the current is equally divided between four contactors, is not a prospect that possesses any attraction for the designer, and it is only natural that he should look round for an alternative scheme which will provide the desired fine adjustment of speed and tractive effort without the necessity of a large number of parts all of which require attention from the maintenance staff.

The alternative is to use an induction regulator or variable transformer in which the primary winding is mounted on a movable core arranged so that it can be turned round into any position relative to the fixed secondary winding, the mutual inductance and therefore the ratio of transformation being varied as gradually as desired from zero to a positive or negative maximum.

This method has the great advantage of simplicity, as it entirely eliminates the contactors and theappings on the low-tension side of the main transformer. It has, however, also the serious disadvantage of introducing into the locomotive a bulky and heavy additional piece of apparatus which adversely affects the efficiency and the power factor of the equipment.

For example, take the case of a locomotive equipped with two motors each rated at 1,250 h.p. at 300 volts (one-hour rating).

The corresponding current taken by the two motors is about 7,700 amperes. Suppose the voltage regulation required for the proper working of the locomotive is from 120 to 300. Then the main transformer must be wound for 210 volts, and the induction regulator must be wound for 90 volts. That is to say, the capacity of the regulator must be approximately—

$$\frac{7700 \times 90}{1000} \text{ kw. or nearly } 700 \text{ kw. (one-hour rating).}$$

A regulator of this capacity must necessarily weigh a good deal and occupy a considerable space, and it must be observed that its introduction into the equipment does not lead to any reduction in the size or capacity of the main transformer unless a combined transformer and induction regulator is used, as the whole of the energy taken from the high-tension line must be transformed down to the low voltage however the motors are controlled.

An alternative method, which is in reality a combination of the contactor system and the induction-regulator system, was worked out by the present writer about 8 years ago, and has been adopted on several of the single-phase locomotives equipped by Messrs. Siemens Schuckert for the Prussian State Railways.

This method consists in the employment of a small induction regulator combined with a number of contactors which control the connections from the motors to theappings of the low-tension winding of the main transformer. The function of the regulator is to increase the voltage at the terminals of the main motor or motors as gradually as may be required until the voltage corresponding to the next higher tapping of the transformer is reached. At this point a change is made in the circuit connections by closing a fresh contactor and opening the one previously closed, which operation can be effected without giving rise to any local short-circuits or serious sparking or difficulties of any kind. If the number of contactors employed is, for example, four, the capacity of the regulator is reduced to one-quarter; if six, it is reduced to one-sixth. Whatever the number and the consequent reduction in size, however, it is possible and easy to ensure that the voltage variation shall be as gradual as may be desired.

There are various ways of carrying out this method, but probably the simplest is shown, quite diagrammatically, in Fig. 8. In this diagram sixappings and six contactors are shown. The voltage of the secondary winding of the

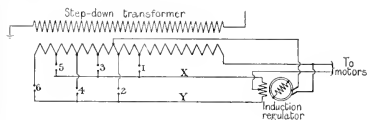

FIG. 8.

regulator through which the main current flows is exactly equal to the voltage between any two adjacentappings. Current passes into the secondary winding at either end according to which end is connected to a closed contactor and passes out from the middle point to the motors. Theappings are connected through the contactors alternately to two leads *x* and *y*; 1, 3, and 5 being connected to *x*, and 2, 4, and 6 to *y*. The ends of the regulator secondary are permanently connected to these leads *x* and *y*. For the minimum voltage, contactor 1 is closed, the primary of the regulator being in such a position that the voltage induced in the secondary opposes the voltage of the main transformer. To increase the voltage, the regulator is turned round until the voltage induced in its secondary is added to the voltage of the main transformer. At this point contactor 2 is closed, and contactor 1 opened, and the circuit is in this way re-arranged so that the regulator voltage opposes the main transformer voltage corresponding to the second tapping. The regulator is then turned round again as before and the process repeated until the full voltage is reached.

Control diagrams of this and other systems are given below.

Referring once more to continuous-current locomotives, the importance of avoiding shocks also has its influence on

the control equipment. During the starting period there are at least two occasions when shocks of greater or less severity are possible and are to be avoided, so far as may be, in the interest of the couplings between wagons. The first occasion is when the current is first switched on to the driving motors. If all the couplings were taut it would not matter very much if the full starting effort of the motors were exerted immediately. But if, as is very frequently the case with goods and mineral trains, the couplings are slack, it is strongly advisable that the initial pull of the locomotive should be only sufficient to take up the slack in the couplings before the train is accelerated. In this connection it must be observed that trains may be made up with the full number of wagons or with very few, and in both cases care must be taken to avoid a shock. The control equipment must therefore be arranged so that the tractive effort on the first notch or step of the controller is relatively quite small.

It should also be remembered that if the starting acceleration of the locomotive when working light is too great it may be difficult for the locomotive driver and his mate to keep their feet. For example, suppose a 64-ton locomotive is designed to exert an average tractive effort during the start of 23,000 lb., the acceleration which this effort would produce with the locomotive alone would be something over 3 miles per hour per second. It would be almost impossible for a man to stand up against this acceleration if it were applied suddenly. It would therefore be necessary to install sufficient resistance in the locomotive to reduce the tractive effort on the first step to something like 5,000 lb., which would produce an initial acceleration of about 0.6 mile per hour per second.

The other occasion on which a shock is to be avoided is during the transition in the grouping of the motors from series to parallel. This can be effected by employing the well-known bridge system of control, in which the full torque is maintained by the driving motors right through the transition stage, subject of course to the fluctuations that occur to the same extent during the whole of the starting period.

Provided only two motors or two groups of motors are used in a single equipment, the two being connected successively in series and in parallel, there is no difficulty at all in arranging the control equipment on the bridge system. It is otherwise, however, when there are four motors to be arranged in three groupings, viz. series, series-parallel, and parallel. It is a simple matter to arrange one of the transitions on the bridge method, but for the other it is hardly practicable, though theoretically quite possible, to pass through the transition without a momentary reduction of the tractive effort to quite a low value. An example is given below in Fig. 9 which shows the control diagram of the 4-motor equipment of the New York Central continuous-current locomotives.

Dealing now with the arrangement of the controlling resistances, it is to be observed that with the same number of steps the fluctuations of torque are much greater in the series than in the parallel grouping. To put it in another way, in order to keep the fluctuations within given limits as mentioned in the beginning of this paper, it is necessary to provide more steps for cutting out resistance in the series grouping than in the parallel.

This can be done most conveniently, and without

involving the provision of any more contactors, by arranging the equipment on the bridge system, in which each motor or group of motors has its own set of resistances and contactors for cutting out these resistances in steps, and by cutting out one section of resistance from each of the two sets alternately while operating in series and cutting out the same sections simultaneously when operating in parallel. A good example of this is provided by the control equipment of the 2-B+B-2 double locomotives of the Pennsylvania Railroad, the diagram of which is given in Fig. 10.

The various points mentioned above include most of the considerations to which attention may be drawn in connection with what may be called the theoretical side of locomotive control. The subject is of course by no means exhausted, but it has been the author's wish to bring forward the principal points in which locomotive control differs from the fairly well-known systems of multiple-unit motor-car train control.

Turning now to the practical side, there is not a great deal that can be said without entering upon many questions of detailed design which would be out of place in this paper. The author is not in a position to give working drawings of the various items of locomotive control equipments, and he does not think they would be of very wide interest if they were published, as comparatively few firms at present undertake the manufacture of such apparatus.

The points that may be mentioned and discussed include the following: Main controlling resistances, contactors, reversers, circuit-breakers, apparatus for automatic working, and induction regulators.

The material most generally used for the main controlling resistances in continuous-current locomotives is cast iron. This can be either plain grey cast iron, or an alloy which contains certain ingredients giving qualities of elasticity and high resistance. For small currents one of the alloys is generally employed, but for large currents simple cast iron may be used, provided care is taken in selecting thoroughly sound castings.

There is no difficulty in obtaining grids having a specific resistance of about 80×10^{-6} ohms per cubic centimetre, and capable of carrying intermittently currents from 30 amperes to 400 amperes or higher still if necessary.

The grids are usually left plain without any rust preventive. In some cases they are tinned or coated with aluminium paint; but such coating reduces considerably the radiating capability of the grids. The paint, moreover, seldom lasts very long, as it tends to flake off under the influence of the heat and the vibration. Further, if the locomotive is kept in service there is little tendency for the grids to rust, as any moisture which may settle on them very quickly dries off as soon as current passes.

The determination of the resistance values in any particular case is not very difficult if the motor characteristics are known. On the other hand it is extremely difficult to decide on the capacity of the resistances for a locomotive unless the conditions of service are very precisely stated. As a general rule it is impossible to lay down a set of conditions such as can easily be given for multiple-unit trains in urban or suburban service. A locomotive can be most irregular in its working. It may start from rest and reach half speed, the wheels may then slip and the acceleration period may be indefinitely prolonged,

or other circumstances may arise which will prove still more severe on the resistances.

The only rule which will provide for perfect security against overheating is to make the resistances so large that continuous running on any step of the controller is possible without giving rise to excessive temperatures.

There is no difficulty in meeting this condition in the case of a low-power locomotive, and there is everything in its favour. Ballast to a greater or less extent is almost always lifted in such locomotives to obtain sufficient adhesion, and no harm is done if some of this is in the form of resistance grids.

For high-power locomotives it is practically impossible to attain to this ideal on account of the space required. Blocks of resistance cannot be piled up in several layers, otherwise the heated air from the lower blocks prevents

On the Continent liquid rheostats have been used in one or two cases, principally for three-phase locomotives. Such an arrangement will probably not appeal to English engineers, although it possesses some definite advantages, principally in the facility with which the resistance can be varied under air pressure, and in the absence of a large number of connecting wires, contactors, etc. It has, however, disadvantages which offset these features, viz. that the resistance depends on the strength of the solution, which may alter considerably in a short time if the rheostat is worked hard due to evaporation of the solvent; and further, that after the resistance has once been cut out by filling the chamber with the fluid quite an appreciable time is required to empty the chamber again in order to prepare the rheostat for further use. For continuous-current locomotives it would be difficult to utilize such an

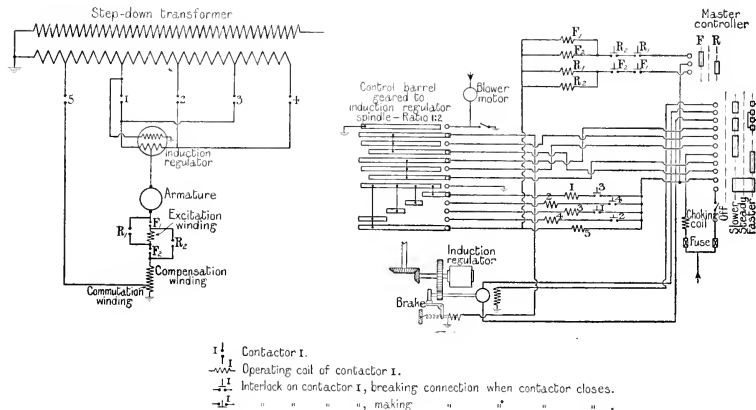

FIG. 11—Control Diagram, Siemens 2-B-1 Locomotive. Dessau-Bitterfeld.

the cooling of the upper layers. It is also important that easy access is provided to all the grids so as to facilitate inspection and maintenance. It is possible that a grid may very occasionally break and in so doing open the main circuit. It should be an easy matter to locate the breakage and replace the damaged grid. It is also advisable to blow off occasionally the dust and dirt that collect on the insulating surfaces of the supports, otherwise there will be a breakdown of insulation sooner or later.

For such locomotives the only thing to be done is to examine each case separately and insert as much resistance as can be conveniently disposed in the space available. It may also be necessary to take into consideration the question of forced ventilation for the resistances. This is of course a complication, and the question whether it is justified cannot be settled without a full knowledge of the circumstances.

arrangement, and for single-phase locomotives a rheostat finds no place.

With regard to control apparatus proper, such as contactors, reversers, circuit-breakers, etc., there is this to be said, that whereas in equipments for motor coaches the designs are practically determined by the requirements of multiple-unit working, no such condition necessarily applies to locomotive control-apparatus. In motor coaches all the apparatus is operated by remote control through the agency of the master controller and possibly one or two auxiliary switches. In electric locomotives, although in the first instance it is often thought best to make provision for multiple-unit working, it frequently happens that such provision is abandoned or dispensed with. For example, on the New York Central locomotives, which were originally arranged with all necessary appliances for coupling two together and controlling both from a single controller, it was found that the possibility of working in this way was

not taken advantage of, and the electrical couplers were permanently disconnected.

There are, of course, cases in which this provision cannot be dispensed with, for example on the 1-C+1 freight locomotives for the Kiruna-Riksgränsen line in the North of Sweden. These locomotives are intended for hauling mineral trains weighing 2,000 tons, there being one double locomotive in front and another at the rear of the train. Under these conditions it is important that the two locomotives should not work independently, otherwise there would be frequent cases of breakage of couplings. The control equipments are therefore specially designed so that both can be operated absolutely synchronously from the master controller in the leading locomotive, electrical connections being provided by a control cable with the usual couplers from front to back of the train.

This condition is, however, up to the present somewhat

connected by a chain with a crank arm pivoted on the front wall of the locomotive.

In the 2-B-1 locomotive equipped by the Allgemeine Elektrizitäts Gesellschaft for the same line, the main switch is operated in a similar manner, and there is a single master controller in the centre of the locomotive operated by means of a hand wheel in either of the two driver's cabs through rods and bevel gearing.

Numerous other examples could be quoted, but it is sufficient to draw attention to the fact that advantage has been taken of the conditions under which locomotives work to break away from stereotyped methods of designing control equipments in the direction of simplicity and directness of operation.

Turning now to a rather more detailed consideration of locomotive control-apparatus, it must be admitted that in many cases there is nothing to distinguish the various items

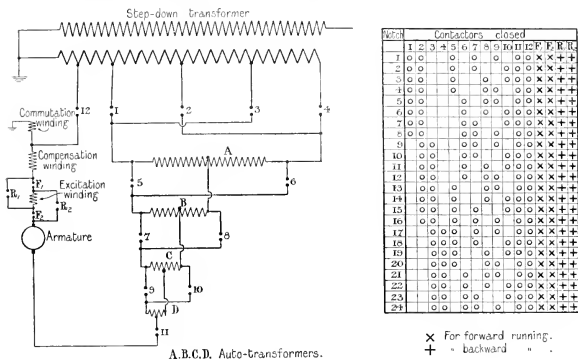

FIG. 12.—Control Scheme originally proposed for Siemens 1-C+1 Locomotive. Kiruna-Riksgränsen.

exceptional, the more usual arrangement being that the electric locomotive is a single unit suitable for hauling trains of specified weights in the same way as steam locomotives. Under these circumstances the necessity for remote control for all switchgear and apparatus constituting the control equipment is not apparent. In many cases advantage can be taken of this to arrange the main circuit-breaker and perhaps the reversers for hand operation by means of levers, hand wheels, and geared shafts. When very large units have to be dealt with, this possibility may sometimes greatly facilitate the design and construction of the apparatus.

Several of the single-phase locomotives built on the Continent have been designed on this principle. For example, in some of the locomotives equipped by Messrs. Siemens Schuckert for the Dessau-Bitterfeld line, the main high-tension oil switch is operated by a lever which passes through the partition dividing the high-tension chamber from the driver's compartment, and the reverser is moved into one position or the other by means of a shaft con-

in the equipment from similar items in the control equipments of multiple-unit trains except size and quantity. The contactors are more numerous and are larger as is necessary to deal with the higher current. The circuit-breakers, fuses, etc., are designed on well-known lines, merely adapted to altered conditions.

Various changes may, however, be noticed, particularly in the locomotives built in the United States. For example, reversers are commonly eliminated and replaced by the necessary number of contactors. In one way this is a simplification, as it is not usually thought necessary to interlock the reversing contactors with the series, bridge, and parallel contactors as is generally the case with barrel-type reversers; on the other hand, the number of contactors is considerably increased. Except on the score of expense, the modification has much to recommend it.

Circuit-breakers for continuous-current locomotives do not call for any special remark except that on high-voltage systems the circuit-breaker must not only be substantial

but should also be allowed plenty of room in which the arc may spread. Where the high-voltage continuous-current supply is distributed by means of an overhead line, it is advisable that the arc formed on breaking a heavy overload or a short-circuit should not be violently disrupted by means of a strong magnetic blow-out, otherwise there is a liability for surges to be set up in the overhead line. In order to provide for plenty of space in which the arc may be gradually extinguished, the circuit-breaker may be fixed on the roof of the locomotive. If there is plenty of room in the body of the locomotive, the circuit-breaker may be housed in an insulated chimney with an opening through the roof covered by a hood. The latter plan, if it can be arranged, is more convenient, as it obviates the necessity of getting on the roof to examine or clean up the switch contacts.

On alternating-current locomotives, the circuit-breakers are usually oil switches similar to those used in generating stations, but adapted to fit into the locomotive.

In the past there has been very little automatic control apparatus in this country. Whatever its merits or demerits in connection with multiple unit trains, it seems to the author that for locomotives, especially freight locomotives, there can be no question as to the benefits to be gained from taking the regulation of the tractive effort at starting out of the hands of the driver. The foregoing consideration of the starting conditions will make this evident. It seems, therefore, rather remarkable that practically nothing has been done in this direction either in the United States or on the Continent. So far as the author is aware, the only cases where automatic control is employed are on the three-phase locomotives for the Simplon tunnel and the Italian railways.

The author is strongly of the opinion that if the limit switches are adjustable, and if the control equipment can be changed over without difficulty or complication from automatic to hand control whenever circumstances require such a change, there is everything to be gained by relieving the driver of the necessity of watching the ammeter and setting him free to attend to the signals and to his other duties.

Coming now to induction regulators for controlling single-phase railway motors, the main point to which attention may be drawn is the necessity for very substantial construction. Except when the relative positions of the primary and secondary windings are such that the mutual induction is zero, there is a very considerable torque produced by the action of the magnetic field and the current in the secondary winding. Moreover this is neither a continuous nor a uniform torque. On the contrary, as there is only a single phase in the magnetic field, the force fluctuates at twice the frequency of the supply between zero and maximum values. It is clear, therefore, that a fairly powerful motor is needed to operate the regulator; and the reduction gearing between the motor and the regulator must be of a very substantial nature.

Some trouble has been experienced with regulators of this type due to breakage of the gears which were designed before the effect of the powerful fluctuating torque was fully realized. Any sudden overload or short-circuit in the main motors is bound to set up a tremendous force in the induction regulator, and the whole of this is transmitted to the teeth of the gear wheel.

The advantages and disadvantages of induction regulators as compared with contactors has recently been considered very thoroughly on the Continent in the light of the experience acquired with the locomotives already in service for some time. The general tendency seems now to be setting towards the use of contactors exclusively for locomotives however large. This has been the practice all along in the United States and has much to recommend it. In case of a bad short-circuit, protection is afforded by the main circuit-breaker, the contactors being unaffected if the circuit-breaker is capable of dealing with the short-circuit immediately and effectively. In the case of an induction regulator equipment there is in addition to the demand on the powers of the circuit-breaker a very severe shock on the mechanical parts of the regulator.

Apart from this argument the time element must also be taken into consideration. The action of a contactor may be regarded as practically instantaneous, and in case of momentary failure of the supply all the contactors will open, and the control system can easily be arranged in such a way that they will not close again except by notching up from the first position of the master controller. In this way protection is provided against sudden rushes of current. With the induction regulator, or indeed with any other controlling mechanism operated by an auxiliary motor, such as for example the drum-type controller of the new Lötschberg single-phase locomotive, similar protection can be provided, but the process is comparatively slow and cumbersome.

On the other hand, the induction regulator undoubtedly possesses the advantage already mentioned of fine gradation in the regulation of the speed and tractive effort of the locomotive, which can only be obtained with contactors by multiplying the number of contactors and operating circuits and by enlarging the master controller.

Opinions have been expressed in favour of replacing contactors as far as possible with motor-driven drum switches, on the score of the high cost of maintaining the contacts and operating parts of the contactors. The use of a drum controller for heavy locomotives is only made possible, however, by removing from the drum all possibility of arcing at the contacts and concentrating the arcs on one or more special switches operated by some means or other in synchronism with the rotation of the drum. It would appear, however, that if a given number of arcs have to be dealt with, there is no great disadvantage in spreading them over a number of special contacts designed for that purpose. These contacts are bound to require less frequent attention and renewing than a single switch which does the whole of the work. There is also the auxiliary motor to be considered as against the operating coils of the contactors.

Most engineers will agree that the fewer auxiliary motors there are in a locomotive the better. So far as single-phase locomotives are concerned, the supply of current at a voltage suitable for small motors is quite a simple matter, as there is usually an auxiliary transformer which can be tapped as required. With continuous-current locomotives, however, especially when the supply voltage is higher than 600 volts, the auxiliary motors must be fed either from the main supply direct, or from the dynamotor or motor-generator. In either case the voltage is probably incon-

Approximate.

1 Electrical input at continuous rating

1 At continuous rating.

veniently high for small motors. On the other hand there is no great difficulty in insulating master controllers and contactor-operating coils for 600 or 750 volts, or in reducing the voltage on each coil by means of control rheostats.

It would be a mistake, however, to press forward too much in the direction of a rigid standardization until the

general requirements of electric locomotives and their operating conditions are better known. By that time it is possible that outstanding differences of opinions in regard to various questions of locomotive control may have been settled, and standardization may be taken in hand to the advantage of purchaser and manufacturer alike.

DISCUSSION BEFORE THE INSTITUTION ON 26TH FEBRUARY, 1914.

Smith.

Mr. ROGER T. SMITH: In the author's exhaustive paper on "Electric Locomotives," published in Volume 51 of the *Journal*, it is pointed out that in America electric locomotives were in the first place adopted for hauling very heavy loads either through tunnels or into termini with fairly dense traffic, while on the Continent their first use was for main-line work, chiefly on steep gradients and through tunnels, but with a comparatively sparse traffic. I would suggest—which I think the author's paper bears out—that the reason for this is largely due to the relative price of coal in America and in Europe. With coal at over 20s. per ton, and with water power available, as is the case in many countries in Central Europe, electric main-line working may be quite economical compared with steam working. The same remark applies to the Argentine Republic and other parts of South America. In the United States, however, with coal at from 2½ to 3 dollars (10s. to 12s.) per ton, or in this country with coal at from 10s. to 14s. per ton, other reasons than economy in working, I think, lead to electrification. I want to emphasize the word "working," because the coal of course only affects the working costs. There may be, however, many other economies that result from electric traction. In the United States the smoke problem and the physical circumstances of the tunnels entering New York, and elsewhere, have very largely forced the terminal electrification of railways. In England this has not occurred. It must be quite understood that we are not discussing suburban traffic, carried on with multiple-unit-controlled motor-coach trains, but only traffic, either passenger or goods, which demands a locomotive for hauling purposes. I venture to suggest that the electric locomotive will be used in Great Britain for some time to come, not from the point of view of any economy of working, but to secure such economies as may result from circumstances under which the electric locomotive can do what the steam locomotive cannot do. Such conditions occur in a number of places where mineral traffic is carried down from the hinterland—if one may use this term in such a small country as ours—a few hundred feet above the level of the sea. Where mineral traffic is carried to the sea, often happens, when it comes to returning with the empties, that it is necessary to divide the train into two or more parts, taking half the empty train up first and then returning for the other half. For busy mineral and colliery districts of this character the electric locomotive is actually being made to-day, with a maximum speed of, say, 35 miles per hour, appreciably lighter for the same adhesive weight and with a less load per axle than the corresponding steam locomotive; and it can haul whole trains of empties up gradients of 1 in 100, and even of 1 in 50, after taking down fully loaded trains.

* *Journal I.E.E.*, vol. 51, p. 730, 1913.

Mr. Smith.

I gather from the first part of Mr. Lydall's paper in Volume 51 of the *Journal* that it is easy enough to design an electric locomotive to deal with one class of traffic, but that the difficulties begin when several classes of traffic have to be dealt with by the same locomotive, and especially at several different speeds. For instance, on page 746 of that volume the author suggests a goods locomotive giving a pull of some 12 tons at 25 miles per hour. I should like to ask him if he contemplated doing this with continuous-current series motors. The output would be 2,000 h.p. at this pull and speed, and, if the adhesion allowed, could give a maximum starting pull of something like 30 tons. Now for nearly everything a locomotive of that power would have to do if equipped with series continuous-current motors, it would be running with the resistances in series, except when it had to pull its maximum load at almost the maximum or half the maximum speed. Another point as to which I should like to ask the author for information is this: I notice he implies that the difference between tractive effort and draw-bar effort is, in general, equivalent to about 700 lb. draw-bar pull. I would suggest that this is really somewhere about half what it ought to be. Little information has been published as far as I am aware on the tractive effort required to haul the locomotive itself. Experiments have been published with steam locomotives on the Orleans Railway, and taking those results as applicable to electric locomotives for such speeds as are dealt with in this paper, the resistance of the locomotive is something like 20 to 30 lb. per ton. If that figure is applicable it would mean that merely to haul the locomotive we should want a pull of about 1,500 lb. instead of about 700 lb. The author also suggested on page 747 of Volume 51 a passenger locomotive able to haul 200 tons up a gradient of 1 in 100 at 60 miles per hour. Now this is a draw-bar pull of just under 3 tons, and if the locomotive were fitted with continuous-current series motors it would give the maximum permissible draw-bar pull of 12 tons at nearly 40 miles per hour. For speeds below 40 miles per hour resistances would have to be used in series with the motors in order to prevent the wheels slipping. I would ask the author if he contemplated that this locomotive could be equipped with continuous-current motors.

He shows very clearly on page 749 (Volume 51) that economy in first cost depends on the highest permissible peripheral speed which can be given to the active material on the commutator, and that this speed is tied by the maximum permissible speed that can be given to the pitch line of the gearing. May I take it from what is inferred, though not perhaps directly stated, in the paper, that about 45 metres per second is the maximum armature peripheral speed which is allowable, while the maximum permissible speed of the pitch line of the gearing is about

Smith. 20 metres per second? I think the author makes out a case that for the higher speeds in electric locomotive working the use of gearing combined with couplings and connecting rods is a mistake because it leads to an uneconomically low peripheral speed of the motor armature; and that, for high speeds, gearless motors either with motor armatures concentric on the axles or with coupling and connecting rods must be used. This, however, seems to be modified by the experience quoted in the supplementary paper,^{*} and I should like to know if the author's general conclusion now is that on the whole it is better to use gearing combined with coupling rods.

With regard to the paper on "Motor and Control Equipments for Electric Locomotives,"† the author shows very clearly the effect of adhesion in determining the control equipment for either continuous-current or alternating-current commutator-motor locomotives. He points out how the lower limit of current and hence of torque during the notching period when the locomotive and train are being accelerated up a gradient really determines the maximum weight of the train. This is most important, and although it should be quite obvious I have never seen it clearly stated before. Figs. 4, 5, and 7 will repay study by all engaged in this problem, and one cannot but be impressed in this connection with some of the advantages of the alternating-current commutator motor as compared with the continuous-current motor for slow hauling of heavy trains up grades. Not only does Fig. 7 show how with single-phase working the acceleration is obtained with one-third of the number of notches required for a continuous-current motor of about the same power, but the author very clearly shows that with continuous current, if the actual train load is too near the minimum torque exerted by the motors during the notching period, it may happen that the current on any notch does not decrease sufficiently to get on to the next notch without slipping the wheel. Should any slipping occur it may be necessary to stop and begin the acceleration all over again. With the alternating-current motor every notch is a running notch, and the driver can continue running on that notch without any waste of energy or overheating of resistances until the gradient conditions change and he can get on to the next notch.

The author's arrangement, described on page 390, for using his inductive regulator to raise the voltage gradually between one transformer tapping and the next, is ideal in theory, and I should very much like to ask if in practice the only trouble is the one to which he has referred, namely, the extraordinary fluctuations in torque on this induction regulator. As far as the design of electric locomotives has gone already, if the number of types for the various services is to be kept down, unless the Ward-Leonard or some equivalent system of voltage variation control is used, it seems to me that it will be very difficult for the continuous-current locomotive to meet the case. The difficulty of course occurs only during the accelerating period. If the author could say anything about the experience in that respect with Continental locomotives I should be glad. The difficulty of rheostatic control for varied conditions is a real one, for the author has pointed out the impossibility of designing the values of the resist-

ances for continuous-current motors to meet all the Mr. Smith. varied conditions.

One other matter that the author brings out is the advantage of automatic control during the accelerating period. The predetermined lowest point to which the current should fall between one step and the next determines automatically when the controller passes on to the next notch, this being quite out of the control of the driver. It is rather curious, as the author points out, how little automatic notching has been used in this country; but on the North-Eastern Railway they use nothing else—the driver merely pulls his controller handle right round and the controller notches up automatically. The advantage of this was clearly shown in the late railway strike. During the strike the North-Eastern Railway Company's electric traction was satisfactorily maintained, because it was found possible to draft in men as drivers from the substations and elsewhere who had a little knowledge of electricity. They had only to be taught all that was essential about the signals on the line, and as far as driving went they had merely to pull the controller handle right round and the automatic arrangements did the rest.

Mr. F. W. CARTER: Referring particularly to the author's Mr. Carter. paper that was published in Volume 51 of the *Journal*, it appears to me that though it has much to commend it, it suffers from a serious defect, namely, that it is not critical enough, and even where it is slightly critical it is apt to be a little partial. We are at present in the early stages of the art of electric locomotive design, and it is quite inevitable that a number of unsatisfactory forms should be developed which will not be heard of in a few years' time. There is not necessarily any discredit to the makers in this, for they are simply gaining experience which will enable them to evolve the satisfactory types. One would, however, expect the author of a paper on the subject to do something to compare the different forms, and point out the weaknesses and objections to each. Mr. Lydall's paper gives such particulars of various types as the manufacturers supply to the technical press, and would lead one to suppose that types are more or less equal to one another in desirability, and that the construction that settles which type is most desirable is the peripheral speed of the motors, or something of that nature. Actually, many of the types that the author describes have given a great deal of trouble, and are open to grave objections. As an instance, I may refer to his Fig. 13 [Vol. 51, facing page 752], which shows a locomotive with three coupled wheels, two jack shafts, and outwardly sloping connecting rods, the motors being under the sloping ends of the locomotive cab. I believe a diagram of the same locomotive was introduced in Messrs. Storer and Eaton's paper on electric locomotives read before the American Institute of Electrical Engineers in June, 1910,^{*} and there it appears to be used by way of an example of what a locomotive should not be, the objection to it being that the large masses of the motors at the ends of the locomotive give it a large moment of inertia about the vertical—this has always been recognized as causing nosing, and tending to spread the rails at the entrance to curves if it is run at any consider-

* See Vol. 52, p. 381.

Carter

able speed. Mr. Lydall says of this locomotive: "Ten locomotives were ordered, but the one shown in Fig. 13 was built first in order that the design might be thoroughly tested before the others were put in hand. The tests were carried out on the electrified line between Dessau and Bitterfeld with very good results. The remaining nine locomotives are now being built to a slightly modified design referred to below, and shown in Fig. 21." I have been long enough with a manufacturing company to recognize this statement as the manufacturer's way of expressing somewhat the same opinion as Messrs. Storer and Eaton, for Fig. 21 is a totally different design, in which the two motors have been brought together at the centre of the locomotive. I gather, however, from Mr. Lydall's supplementary remarks that the modified type has also proved unsuccessful.

As another instance, I may refer to the Lötschberg locomotive [shown in Mr. Lydall's Fig. 14], which was in fact supplied on approbation by a German firm to the Lötschberg Railway, and after having been thoroughly tried, was rejected. I think we may assume that this was not on account of its having been found satisfactory and suitable for its work. In order that it may be clear that I am not alone in considering that some of the types that Mr. Lydall has described are thoroughly unsatisfactory, and that the troubles that have occurred in connection with them are fairly well known, I will give extracts from an article by Mr. R. E. Hellmund, a well-known American authority on the subject, which appeared in the *Electric Journal* for last October.* Mr. Hellmund says:† "The mechanical design of the locomotives at Dessau-Bitterfeld cannot, in general, be considered very successful. Several reasons seem to be responsible for this. First, the Government practically dictated the policy of using one or two very large motors per locomotive and side-rod drive, and eliminated schemes for applying gears together, thereby limiting the possibilities to a design which brings with it a number of inherent difficulties." Referring to a passenger type of locomotive with vertical side rods, Mr. Hellmund says:† "Most of these locomotives have only one large motor. Only one locomotive which was originally built by the A.E.G. for the Lötschberg electrification [Mr. Lydall's Fig. 14], and was there rejected on account of not meeting requirements, and subsequently bought by the Prussian Government, has two motors and practically vertical side rods. All these locomotives with one big motor [shown in Mr. Lydall's Fig. 17] have sooner or later given trouble, due to the breaking of the cranks and crank pins. The mechanical parts have since been strengthened considerably, but have not been in service long enough to show that they are now sufficient to do the work." Referring to a freight locomotive with four drivers and a jack shaft, driven by one big motor by means of side rods inclined about 45 degrees [shown in Mr. Lydall's Fig. 18] Mr. Hellmund remarks, "These locomotives have so far given best satisfaction in service, although they are subject to rather pronounced vibrations. There is little doubt, however, that some type of geared locomotive would have been a better solution for this ser-

vice." Of a third type he says,‡ "Quite recently a number of locomotives of a heavier type have been tried. These locomotives have two large motors, driving a common jack-shaft by a side rod inclined about 45 degrees [this is shown in Mr. Lydall's Fig. 19]. This design seems to be altogether a failure. One locomotive was tried on experimental runs, and began to vibrate very severely at a speed of about 40 miles per hour. Subsequently, there was a big noise followed by smooth running. After the locomotive had been brought to rest, it was found that the crank pin of the jack shaft was missing. A second locomotive of the same type behaved quite similarly, with the exception that the crank pin of the jack shaft and both of the inclined side rods were broken." In his general summary of the subject, Mr. Hellmund says,† "The only European locomotives that have been successful from a mechanical point of view, and which give at the same time reasonable weights, use either gear arrangements or the Scotch yoke construction, or both, and even in Germany it seems that the gear arrangement will be used in spite of much opposition." This is a Westinghouse view, and I think in the main a sound one.

There are very good reasons which render the side-rod type of locomotive a very difficult one to make satisfactorily; reasons, in fact, sufficiently strong to proclaim this a type to be avoided wherever practicable. For one thing very fine adjustment is required, without which the case would be hopeless; much more difficult mechanical fitting is necessary than anything connected with the steam locomotive. The chief trouble is that the uniform torque of a motor can only be converted into a pair of reciprocating forces in the direction of the side rods by subjecting the frame of the locomotive to very severe stresses.

If T is the maximum tension in a connecting rod, and θ is the angle of the crank measured from the line of centres, the tension in the connecting rod is $T \sin \theta$, and that in the connecting rod on the other side of the locomotive, where the crank is at right angles, is $T \cos \theta$. These forces can be written—

$$T \sin \theta = \frac{T}{\sqrt{2}} \left[\sin \left(\theta + \frac{\pi}{4} \right) + \sin \left(\theta - \frac{\pi}{4} \right) \right]$$

$$T \cos \theta = \frac{T}{\sqrt{2}} \left[\sin \left(\theta + \frac{\pi}{4} \right) - \sin \left(\theta - \frac{\pi}{4} \right) \right]$$

Thus the forces exerted by the connecting rods, besides balancing the torque of the motor, impose on the locomotive frame a system of forces composed of a reciprocating force of maximum value $T/\sqrt{2}$ in the direction of the connecting rods and an alternating couple of maximum turning moment $Ta/\sqrt{2}$ in the plane of the coupled axles, where a is the horizontal distance between the connecting rods. The couple is the troublesome element, as it is of large magnitude. If b is the length of the crank, Tb will be the torque of the motor, so that the ratio of the turning moment of the couple to the torque of the motor is $a/b\sqrt{2}$. For a full gauge locomotive, a is of the order of 80 in., and b of the order of 8 in., so that the above ratio is about 7, i.e. the turning moment of the couple is about seven times the torque of the motor.

† Page 982.

* Page 983.

† Page 997.

Mr. Carter.

Mr. Carter.

Mr. Lydall, in Table II on page 755 (Vol. 51), gives the torque of a few motors, one of which is as much as 30,000 lb. at one foot radius. This is at the rated load and is not an exceptionally high figure. The turning moment of the couple discussed is about seven times this, and is therefore close on too tons at a foot radius. This figure, however, is an average, and these locomotives are practically all single-phase, so that the maximum value of the torque is twice the average; thus the maximum turning moment of this couple is of the order of 200 tons at one foot radius without any allowance for overloads, or for inertia effects, which may very materially increase the couple. A racking stress of this nature is very severe on the locomotive structure, so that even if no extra stresses are introduced by inaccuracy of workmanship, and these are very difficult to avoid where such close fitting is necessary, it will be seen to be no small problem to make the frame sufficiently rigid. No such stresses occur in the steam locomotive, for in the first place the driving force is applied in a reciprocating manner, and in the second place it is applied from two points not distant from the two points where it is used. It is the designer's business to arrange that the force exerted on each side of the locomotive is about equal to the force used on that side, so that there are no large forces applied on one side of the locomotive and used on the other. At a jack shaft the conditions are likely to be even worse than at the motor shaft, for here the connecting rod and coupling rod meet at an angle, and the effect on the locomotive frame is resolvable into a force the direction of which rotates round the jack shaft in the opposite direction to the crank, and a couple the axis of which rotates in a similar manner. If α is the angle between the connecting rod and the coupling rod, the value of the force is $T\sqrt{2}\sin\alpha$ and the moment of the couple is $Ta\sin\alpha/\sqrt{2}$. When the connecting rod and the coupling rod are at right angles (as in Mr. Lydall's Fig. 17) the values of the force and the moment of the couple are at their greatest, and are then equal to $T\sqrt{2}$ and $Ta/\sqrt{2}$ respectively. The turning moment of the couple is therefore, as before, of the order of seven times the torque of the motor. This is a more difficult condition to meet than that at the motor-shaft; for with the couple in one plane, rigidity has only to be provided in that plane, whilst with a couple whose axis is rotating, rigidity must be provided in all planes. It is therefore not surprising that locomotives of this type have given a great deal of trouble; for if these large stresses are able to produce any appreciable distortion, binding is almost inevitable somewhere, and the stresses become applied at points which cannot possibly be made strong enough to resist them.

Mr. Bowden.

Mr. J. BOWDEN: In this paper attention is first directed to the limitations of gauge, and electric locomotive engineers are confronted with the restrictions which, had Brunel's gauge policy triumphed, would not prevail on the roads of to-day with their heavy traffic. Apart from the question of electrical design, these limitations impose mechanical difficulties which may ultimately prove more serious than with steam locomotives. The heaviest maintenance expenses in electric traction may very easily be incurred on locomotives and rolling stock, and these are almost wholly governed by the mechanical design. Gears and bearings may seriously affect the maintenance cost, not by fracture and wear alone, but by

the expense incidental to failure in service, such as the loss of armature shafts and partial loss of tyres, owing to the necessity of clearing any obstruction to a closely timed train schedule with the least possible delay. With motors pressed to the duty imposed by the requirements of many suburban services, adequate mechanical design is difficult when gears are employed, and other ways of securing a reliable and economic transmission from motor to driving wheel have been sought. One alternative is illustrated in Mr. Lydall's paper by the 2,000-h.p. 600-volt continuous-current motors of which the mechanical arrangement has been designed by Mr. Gibb of the Pennsylvania Railroad. In this design a steam locomotive engineer of wide experience has adopted connecting and side rods of simple construction working from a jack shaft. Mr. Carter has indicated the weak points of such a design, which involves mechanical problems not met with in steam locomotive design. Another alternative used by the New York Central Railroad carries the armatures on the axles, eliminates gears, and obtains a simple yet substantial construction which has much to recommend it. Doubtless, difficulties arise in the electrical design, and the unsprung axle loads may not in some instances be permissible, but on the point of maintenance, experience of those who have operated this design is particularly favourable. Under the heading of control the paper deals at some length with the arrangement of resistances, having particular regard to shocks during starting. The largest electric locomotives in this country to-day were designed by Mr. C. Jones of the Metropolitan Railway Company. The gradations of resistance are there adjusted by trial and correction of error with satisfactory results. Automatic control is largely used by the Metropolitan Railway Company with excellent results on multiple-unit trains, but it has not yet been applied to electric locomotives.

The conditions of long-distance suburban trains making frequent stops near the central terminus and running as express trains when far out, call for special consideration. The combination of at first high acceleration and then high average speed over a longer distance will have to be more generally provided for as electrically-worked suburban services are developed. Some additional means of control is necessary, and perhaps the author will say whether field regulation has been successfully used in this direction.

Contactors reversers are mentioned in the paper. The drum reverser has not been very satisfactory, particularly where accelerated service has rendered necessary the frequent overloading of equipments. The objection to maintaining an increased number of contactors is not very serious if greater reliability and less burning of reversers can be secured. Low maintenance cost of contactors does not so much depend upon their number as upon confining the destructive opening of circuits to a few contactors. With regard to motor-generator control as outlined in the paper, perhaps the author will say whether this has yet been applied to electric locomotives, and if so with what success.

Mr. J. B. SPARKS: Mr. Stevens has asked me to show some slides which he prepared especially for this discussion and would have shown this evening had he been able to be present. They give the general design and the dimensions of the Baltimore and Ohio, New York Central,

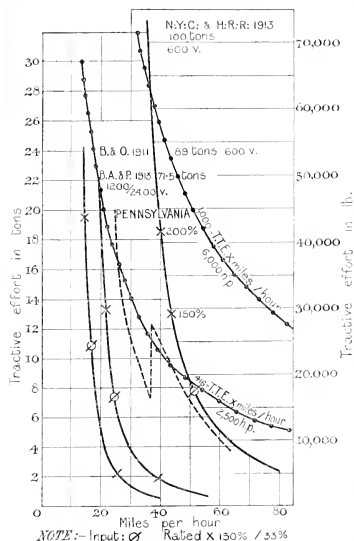

and Butte and Anaconda locomotives, and also some views of the last-mentioned locomotive.

With regard to Mr. Lydall's paper, I should like to call attention to his statement that, owing to the requirements of single-phase motor design, the voltage even at full speed is seldom more than about 300. At this pressure, assuming a power factor of 0.83, the single 1,800-h.p. motor of the 1-C-1 Siemens Schuckert locomotive takes a current of 6,000 amperes. Now a corresponding continuous-current motor with 1,200 volts across the commutator would take only one-fifth of that, viz. 1,200 amperes, so that, although in the continuous-current control it may be necessary to have a larger number of contactors, the fact that only one-fifth of the current has to be handled may make the continuous-current control gear both cheaper and less bulky. With a pressure of 2,400 volts across the commutator, which is quite practicable for a large motor situated in the cab of the locomotive, the current to be handled would be only one-tenth of the corresponding current for the single-phase motor. The effect of this heavy current on the design of the transformers, control gear, and motors, is probably one reason why single-phase locomotives are so much more expensive than continuous-current locomotives. Mr. Roger Smith in his paper mentioned £50 per ton as a figure to be aimed at. The cost of continuous-current locomotives is already only £60 or £70 per ton: for example, the average cost of the 47 locomotives of the New York Central Railroad works out at just over £7,000, which represents a little more than £60 per ton. Very few figures have been published for single-phase locomotives, but the cost is approximately double that of continuous-current locomotives. For example, the 800 h.p. 53-ton locomotives for the Mittelwald Railway, referred to by Mr. Lydall this evening, cost nearly £6,000 each, or £112 per ton. The price per horse-power appears to be £5 or £6 in the case of the continuous-current locomotives, and from £7 to £10 per horse-power for the single-phase locomotives. The figures vary, of course, within very wide limits, but the above are representative of the costs that I have been able to obtain.

Dr. S. P. SMITH: I agree with Mr. Carter's criticism of the paper, for I think the author deals far too favourably with many points; for example, the 1-C-1 locomotives for the Wiesenthal line, referred to by Mr. Carter. After the experimental locomotive gave "very good results" the remaining nine were "built to a slightly modified design," consisting of an entire redistribution of the load, with the result that they rattled. In consequence all nine locomotives have had to be altered again, but unfortunately the author is unable to tell us the nature of the alteration that has made them a success. However, at this late hour I only propose to discuss the comparison on page 386 between the motor for the continuous-current Pennsylvania locomotive and the single-phase motor for the 1-B + B-1 locomotive. In the first place, 2,000 h.p. is the short-period rating of the continuous-current motor, and not the one-hour rating at all—I believe it is really a 1,200-h.p. motor—whilst the so-called Löttschberg locomotive is, I think, running between Dessau and Bitterfeld. The comparison between these two motors is very unfair for the following reasons: Though the pressure on the continuous-current motor in this instance is only 600 volts, the standard pressure for such outputs would be 1,200 or 2,400 volts. When

we consider a high-tension continuous-current motor the problem is quite different, and a much heavier motor is obtained. As it is, the author tells us that the motor weighed 19 tons. It would weigh much more if it were a high-tension motor. The 800-h.p. single-phase motor weighs, I believe, 14 tons, and is of the repulsion type with phase compensation. I pointed out some time ago that this particular motor was about the most unfavourable type with respect to weight and speed that could be obtained for single-phase working. If the comparison had been with the compensated series motor, it would have been much more favourable. But even as it is I think we have an 800-h.p. alternating-current motor weighing 14 tons and a 1,200-h.p. continuous-current motor weighing 19 tons. Moreover, from the table given on page 397 I find that the continuous-current motor runs at 210 r.p.m. and the other motor at 168 r.p.m., a difference of about 25 per cent; though from an article in the *Electric Journal* of 1910 I think the speed of the continuous-current motor should be 280 r.p.m. Thus the comparison is very misleading. A fair comparison would show—that many designers have found out—that a large high-tension continuous-current motor weighs approximately about the same as the corresponding single-phase commutator motor.

Mr. T. STEVENS (communicated): I have obtained, by Mr. Stevens, the courtesy of the manufacturers, some data on a few

quite recent locomotives not included in the author's Table I.* He gave data for 23 locomotive designs, and to avoid confusion I have used as reference numbers, 24 to 28 inclusive. I note that in his Supplementary Paper† the author gives an outline of a New York Central locomotive (1914 type); columns 27 and 28 in the table herewith relate to the New York Central locomotives of the 1913 and 1914 types, and I leave this in the form in which I had prepared it before Mr. Lydall's Supplementary Paper was published. I also note that he gives the diameter of the Butte Anaconda driving wheels as 48 in. I have checked the dimension on the manufacturer's data sheet, which gives it as 46 in.; Mr. Lydall, however, may have later information. The Butte Anaconda locomotives are interesting as being the first to take their supply from contact wires at 2,400 volts. The slides, which were kindly shown by Mr. J. B. Sparks in my unavoidable absence, included a drawing showing the dimensions of the 17 locomotives on this line, photographs showing the side and top of the locomotive with the insulated busbar line for coupling two locomotives to take power from one collector, a photograph of a train in

service (this being a mineral service, as far as 15 locomotives are concerned, and passenger service operated by two locomotives which, as will be seen from column 25 of the table herewith, have a gear ratio of 3/2 and a speed of 24 miles per hour. In other respects the goods and passenger locomotives are alike). The photograph shows the nature of the country through which this line runs; and, as pointed out in my paper entitled "1,200-Volt Traction in the United States of America,"* there is no necessity in such a place for limiting the pressure-drop in the rails to such a small figure as is reasonable under Board of Trade Regulations, where previous interests have installed pipes that might be injuriously affected if the pressure-drop were high. The Board of Trade has under similar circumstances in this country been willing to extend the specified limit of voltage-drop in earthed returns in places where no pipes exist. A view was also given of the overhead construction on the Butte line, showing the wooden supports along the railway and the iron frames which carry the overhead wires across a bridge. The curves on page 402 show the tractive effort and speed of the Baltimore and Ohio 1911-type locomotive, and of the Butte Anaconda and New York Central 1913-type loco-

Stevens, motives in full lines, indicating the one-hour rating on the standard basis, but it should be remembered that these motors have forced ventilation. In this diagram the Pennsylvania locomotive curve and the 2,500-h.p. curve in Mr. Roger Smith's paper^{*} are reproduced, and in addition a 6,000-h.p. curve is shown, which crosses the New York Central curve at 28 tons' tractive effort.

The General Electric Company of New York supplied the locomotives referred to in columns Nos. 24-28 of the table, and my acknowledgments are due to them for the data from which the curves and table have been prepared.

Mr. E. O'BRIEN (*communicated*): Speaking from a railway point of view it is very desirable that the control of any locomotive should be entirely by contactors, and that the contactors should be placed in such a manner that any disturbances taking place in them cannot affect the driver. The cab should be kept entirely free from apparatus that is more than two or three feet above the floor level, so as to enable the driver to have a completely free look-out all round him. The geared-motor bogie type of

electric locomotive is undoubtedly the most suitable type for railway purposes and the one most likely to result in low maintenance costs. The sole objection to it appears to be the low centre of gravity of the bogies and their moment of inertia around their centres, both of which tend to have a destructive action on the track and affect the riding. In an electric bogie locomotive, therefore, there appears to be no reason why the centre of gravity of the motor should not be placed vertically above the centre of the axle, thus raising the centre of gravity to a reasonable extent. The paper as a whole will draw the attention of railway men to the extreme complexity and inflexibility of the electric locomotive, and will confirm them in their opinion that though it may render admirable service under special conditions, it is not suitable for general service. The attention of electric locomotive designers should be drawn to the extreme noisiness of all existing locomotives—steam or electric—as far as those riding in them are concerned, and endeavours should be made to damp out the vibrations which tend to make the cabs act like sounding boards.

Mr. LYDALL's reply to the discussion will be published in a later issue.

THE GULSTAD VIBRATING RELAY.

By W. JUDD, Member.

(Paper received 3rd March, 1914.)

In this description of the Gulstad Vibrating Relay the object is to bring to general notice this remarkably ingenious and efficient piece of telegraph apparatus.

Devised by Mr. K. Gulstad, sometime Engineer-in-Chief to the Great Northern Telegraph Company of Copenhagen, and given freely to the world by means of descriptions in the *Electrical Review* of June, 1898,^{*} and August, 1902,[†] it has been in use by that company for over 20 years, and in more recent years by other telegraph administrations to a small extent.

This relay, while being several times as sensitive as the ordinary polarized relay, is at the same time much more stable in the presence of disturbances from neighbouring lines, or from a defective duplex balance. These most important and valuable features consequently give a higher speed and more stable signals than any other polarized relay known to the writer.

It is only applicable to double-current Morse signalling, and is efficient on all land lines and on submarine cables having a KR of from 0.5 to 0.75 second. On a cable having a KR of 1 second it will give very fair results, but that is rather beyond the safe limit.

The somewhat remarkable combination of increased

sensitivity to signals and increased stability against disturbances, appears to be explained by a consideration of the vibratory circuits. Premising that no line current is present, it will be seen that when the tongue of the relay comes in contact with one or other stop, a condenser is charged through one relay auxiliary winding pressing the tongue momentarily on this stop. Then, the condenser being charged, the current rises in the opposite auxiliary winding, through an external resistance, and pulls the tongue off, when the discharge current from the condenser flowing through both auxiliary windings throws it vigorously over on to the other stop. The same cycle of operations is then repeated with opposite polarity of the battery. In this manner a continuous and regular vibration of the armature and tongue is set up, with contacts firmly made and cleanly broken.

The speed of these vibrations must be made equal (or nearly equal) to the pre-arranged speed of dot signals from the line to which the relay is applied, by suitable adjustment of the values of capacity and resistance in the local circuit, and the rate of rise of the local current also must be made to correspond with that of the cable current.

When these conditions are fulfilled, the only duty left for the cable current is to control the vibrations. This control is obtained by furnishing the electromagnets of the

* *Electrical Review*, vol. 42, pp. 751 and 702, 1898.

† *Ibid.*, vol. 51, pp. 294 and 332, 1902.

relay with a separate winding through which the signals received from the cable pass.

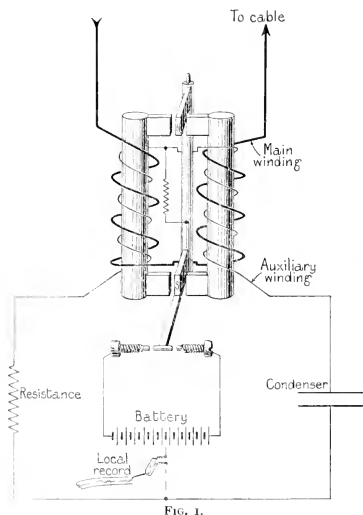

FIG. 1.

The heavier currents in this "main" winding, i.e. the cable "dash" or "space" signals, overpower the local vibrations, and hold the tongue on one or other stop

below that of the local current by an amount giving a preponderance to the latter. The armature is then surrendered to the local forces, is pulled off, and is driven vigorously over to the opposite contact by the discharge from the condenser.

When "dots" are received from the cable their current amplitude is so small that only a very slight control, and in some cases practically none at all, is exerted over the tongue.

If the cable to which the relay is applied is a short one, the dots may control the tongue's vibration to the extent of accelerating or retarding its natural rate, thereby tending to correct any difference of phase between the impulses of the cable dots and the relay vibrations. In working through a moderately long cable, however, the current amplitude of dots at the receiving end would not have any appreciable influence upon the vibrations, and only the heavier dash and space currents would control the relay, which, however, would still reproduce the dots perfectly, by reason of the continuation of the local vibrations during periods when no controlling force is present in the main winding to check them.

Briefly stated, the resultant effect of the controlling cable currents and the local currents in the relay is this: that where dots received from the cable are to be reproduced, the vibrations are allowed to continue, and where dashes or spaces occur, the vibrations are damped out; and the short and long contacts of the tongue thus obtained are registered on the local recording instrument with all the increased firmness and definition supplied by the local forces.

With the Gulstad relay the cable current is relieved of the work of moving the armature and of overcoming the magnetic inertia which falls upon it with an ordinary polarized relay; great sensitiveness is thus attained. The instrument is also very adaptable to signals of varying character or of distorted formation, by reason of the elasticity of the electrical combinations in the local circuit.

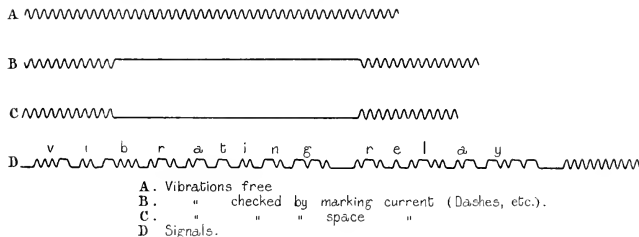

FIG. 2.—Signals registered on Local Record.

according to their polarity, until such time that the dash or space being completed at the distant end of the line the strength of the cable current at the receiving end falls

The accompanying diagrams, Figs. 1 and 2, illustrate the relation of the relay to its auxiliaries and show an example of the signals produced by it on the recording instrument.

THE "CASCADE" INDUCTION MOTOR.

By L. J. HUNT, Member.

(Paper received 15th January, 1914; read before the MANCHESTER LOCAL SECTION, 10th February, and before the YORKSHIRE LOCAL SECTION, 11th February, 1914.)

In 1907 the author read a paper on this subject before the Manchester Local Section of this Institution* when the motor was in its early stages of development. Since that time large numbers of these machines have been built and numerous new windings have been worked out and tried, with the result that the modern machines differ materially from those described in the paper to which reference has been made.

The works of Messrs. Sandycroft, Limited, where these machines have been developed, are largely devoted to the manufacture of mining machinery, and when the building of induction motors was commenced it was soon realized that the short-circuited-rotor type of machine without slip-rings and with a low-voltage rotor was the ideal construction for withstanding the rough handling and onerous conditions to which mining machinery is habitually subjected. The squirrel-cage motor met these conditions for all drives where constant speed was required and where a moderate starting torque sufficed; but its sphere of usefulness was distinctly limited, and any attempt to extend it led to trouble. What was required was a short-circuited-rotor type of machine with the same characteristics as those possessed by the slipping motor, and after several futile attempts at solving the problem the use of the "cascade" principle was investigated. It was not long before it was found that other investigators had followed the same line of thought, the earliest being Dr. Silvanus Thompson, who patented a single "cascade" motor in 1901.

In order to explain clearly the windings used in the cascade machine, this paper describes the step-by-step development of the motors, for it has been found that by treating the subject in this way a clearer understanding of them is obtained. A very large number of windings have been experimented with, and reference to a few of them, with the reason why they have not been used commercially, may be of interest.

GENERAL PRINCIPLES.

The application of the "cascade" idea is well known, as it has been used for many years in the control of three-phase locomotives, for obtaining several speeds in rolling-mill work, and for the driving of fans, etc. It is almost exactly analogous to the coupling of two or more motors in series on a continuous-current circuit. If two similar continuous-current motors be connected in series, with their shafts mechanically coupled, the speed of the combination will be half that of either motor directly connected to the line. Next consider one of the motors wound for a speed of 1,500 r.p.m. and the other for 750 r.p.m., with a pressure of say 300 volts across the terminals and the two machines in series. As the horse-power is proportional

to the back electromotive force and the current in the armature, the low-speed motor will develop two-thirds, and the high-speed motor one-third of the total horse-power developed by the combination. It will be obvious that for any given speed the back electromotive force generated by the low-speed motor will be equal to twice that generated by the high-speed motor, and therefore the back electromotive force of the two machines in series will be equal to three times that generated by the high-speed motor alone. The set will therefore run at one-third the speed of the 1,500-r.p.m. machine, or two-thirds of that of the 750-r.p.m. motor, i.e. 500 r.p.m.

In the case of two induction motors wound for speeds of 1,500 and 750 r.p.m. the speed of the two coupled in series or "cascade" will similarly be 500 r.p.m. In this case the secondary of the first machine is connected in series with the primary of the second machine, and therefore as the same currents circulate in both the frequency must be the same. As in the case of the continuous-current machines, the low-speed motor will develop two-thirds of the total torque. In an actual case the pressure-drop due to resistance in the first motor slightly affects this proportion. If the rotor of the first machine is connected to the stator of the second machine, the windings must produce a flux in both stators revolving in the direction of the mechanical rotation. At 500 r.p.m. the slip of the first motor will be 250 r.p.m. if the low-speed motor is connected to the mains. This motor will have 8 poles if wound for a 50-cycle circuit. The second motor will have 4 poles, and consequently the speed of its stator field will be equal to twice the speed of the slip of the first motor, or 500 r.p.m. It follows that the frequency of the currents in the second rotor will be zero—the condition for synchronous speed.

Let P_1 and P_2 be the two numbers of pairs of poles for which the motors are wound, R the mechanical speed of rotation of the rotor in revs. per second, and N the frequency of the supply circuit. The frequency of the rotor currents will be—

$$N \left(1 - \frac{P_1 R}{N} \right)$$

and the speed of the second stator field in revs. per second is

$$\frac{N(1 - P_1 R/N)}{P_2}$$

At synchronous speed there must be no relative difference in speed between this field and the mechanical speed of the second rotor, so that

$$N - \frac{P_1 R}{P_2} = R,$$

$$\therefore R = \frac{N}{P_1 + P_2}.$$

* *Journal I.E.E.*, vol. 39, p. 648, 1907.

In other words the speed of the combination is equal to that of a motor wound for the sum of the numbers of poles of the two machines.

If the second stator winding had been so connected that its field had rotated in the opposite direction the speed would equal

$$\frac{N}{P_1 - P_2}$$

This arrangement is not, however, of much commercial value.

At the synchronous speed of an induction motor no energy is transmitted to the rotor, and if we assume that the distribution of flux follows a sine law there will be no currents in the secondary windings. If, then, the mains are connected to the rotor of a machine the latter will revolve in a direction opposite to that of its magnetic field, so that at synchronous speed the field will be stationary in space and no electromotive force will be generated in the stator windings which now form the secondary of the motor. Instead of connecting the rotor windings of the first motor to the stator windings of the second machine, we may connect them to the second rotor windings, taking care to reverse two of the connections so that with currents circulating in both windings the magnetic fields produced will rotate in opposite directions. The stator winding of the second motor now becomes the secondary, and the rotor windings may be permanently connected without slip-rings. Control of the speed and starting torque is obtained by connecting resistances to the stator windings of the second machine. Here, then, we have a combination of two motors forming a single unit with their rotor windings permanently connected, and as no currents are brought out from the rotors the windings may consist of several parallel circuits, so that the voltages in them will be quite low even when the rotors are standing. This construction meets the requirements of a machine with a rotor winding approximating to that of a squirrel-cage machine, and with the same facilities for control of the starting torque and speed that can be obtained with a machine with wound rotor and slip-rings. We have, however, sacrificed much in obtaining these results. The necessity of using two machines leads to a greatly increased cost, and, further, the efficiency and power factor will be low, so that the construction is of little practical value. It was, however, the fundamental idea from which the motors described in this paper were developed, and will serve as a key to the explanation of their windings and properties.

There are examples of "cascade" coupling in nearly every power plant in the country. We install a step-up transformer in a power house and a step-down transformer in a sub-station; these are coupled in cascade and exactly represent a cascade motor at standstill. The energy current taken from the mains by the first transformer is dependent on the resistance (or load) connected to the secondary windings of the second transformer, and the first transformer takes from the line not only its own magnetizing current but also that required by the second transformer. In fact the calculations necessary for determining the currents in the windings, the power factor, etc., are identical in both cases.

To designers and engineers well versed in the design of induction motors all this will be very elementary, but as it

has often been said of previous descriptions of these motors that too much has been taken for granted, an endeavour has been made in the present instance to atone for these shortcomings.

The next step in the development of the motor was to make a single stator and rotor which would take the place of the two separate machines. The problem to be solved was so to arrange the two sets of windings that there should be no mutual interaction, electrically or magnetically, between them, except by the agency of the inter-connected rotor windings. It is interesting to glance at the various solutions of the problem arrived at by different inventors.

The stator of Dr. Silvanus Thompson's machine, to which reference has already been made, carried two sets of windings arranged in alternate segments of the circumference. If these segments be numbered 1, 2, 3, etc., the windings occupying all the odd-numbered segments were connected to form one winding and those occupying the even-numbered segments were similarly connected to form a second winding. One winding formed the primary and was connected to the mains; the other, which was unaffected by currents in the first winding, carried currents generated by a second rotor field and served as the secondary of the second element of the motor. The rotor carried a wave winding which was acted upon inductively by the primary stator field. The currents circulating in this winding also produced a second field, which in its turn acted inductively upon the secondary windings of the stator. Other inventors used the same type of stator windings with variations in the form of the rotor windings.

A German patent by Mr. G. Meller discloses another solution of the problem. In this motor there are two stators with windings carried in radial slots, and the rotor is in the form of a disc. One stator carries the primary windings and the other the secondary windings, the two being put in cascade by the windings carried on the single rotor.

Mr. F. Lydall's method of rendering the two sets of windings independent was to wind them for dissimilar numbers of poles, the numbers being so chosen that neither winding would act inductively upon the other. With this arrangement it was no longer necessary to confine each winding to certain parts of the stator, and all that was required was to provide two independent windings of ordinary construction placed one behind the other in the stator and rotor slots. This motor was patented in 1902.

Reference has been made to only a few typical examples of motors which have been developed, and these simply illustrate the methods suggested for obviating the necessity of two core bodies.

The first motor built at Sandycroft in 1905 was identical with Mr. Lydall's machine, the existence of which was unknown to the author until some time later. Tests made on this motor were satisfactory in so far as they showed that it was possible to construct a single cascade motor; but it was at once apparent that the electrical properties were inherently bad owing to the large losses in the two sets of windings and the necessity for the use of deep slots which caused the magnetic leakage to be very high. Electrically and magnetically the motor described later is identical with this machine, but new types of windings

are used in it which overcome the bad features of the original design.

POSSIBLE NUMBERS OF POLES.

The cascade motor is essentially a low-speed machine; and it is when designed for speeds which are abnormal for single-field motors that it shows to best advantage. The numbers of poles for which the machine can be constructed are determined by the following conditions:—

- (a) The numbers of poles in the two fields must be so chosen that their windings are mutually non-inductive.
- (b) The two fields when superimposed must not produce an unbalanced radial pull on the rotor.

The first condition is satisfied when the numbers of poles are such that at the points where the axes of the two field systems coincide at any given instant, half of the poles of one system are reversed relatively to those of

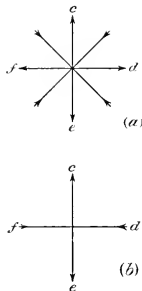

FIG. 1.

the other system. Fig. 1 (a) represents an 8-pole field, and Fig. 1 (b) a 4-pole field. The axes of the poles coincide at four points, *c*, *d*, *e*, *f*. The poles *c*, *e* are of the same polarity in each field, but the poles *f*, *d* are reversed; consequently the electromotive force generated in the 8-pole winding by the poles *c* and *e* of the 4-pole field is equal and opposite to that generated by the poles *f* and *d*. The 4-pole field acts in a similar manner upon the 8-pole winding. This method of illustrating the conditions is due to Mr. M. B. Field, and was suggested by him in the discussion of the previous Institution paper to which reference has already been made. The number of points at which the polar axes coincide is given by the "greatest common factor" of the two numbers of poles. In the example illustrated the numbers are 8 and 4, and the "greatest common factor" is 4. To obtain the necessary reversal of polarity it follows that at the points of coincidence all the poles of one field system must be similar, whilst consecutive poles of the other must be reversed. In other words the sector bounded by any two adjacent axes of coincidence must contain an even number of the poles

of one field system and an odd number of those of the other field. Therefore, condition (a) is satisfied when the two numbers of poles are such that when divided by their "greatest common factor" the quotient is in one case an even and in the other case an odd number.

To satisfy condition (b) the two superimposed fields must give a symmetrical resultant field. From what has been said above it follows that at one-half of the points of coincidence the gap density will be large owing to the similar polarity of the two fluxes, whilst at the other half of the points the gap density will be low, as the poles of the two systems are of opposite polarity. To satisfy condition (b) the "greatest common factor" must be a number greater than two. The most usual numbers of poles are in the ratio of 2 : 1; for example, 8 and 4, 12 and 6, 16 and 8, and so on.

STATOR WINDINGS.

The experimental motor with two sets of windings proved satisfactory in that it showed that a single motor could be wound to operate with concatenated windings. Beyond this the test results were not encouraging; for owing to the presence of two sets of windings the losses were high; and as deep slots were required to accommodate these windings both the power factor and overload capacity were low.

Leaving the motor for a moment the author would like to refer to the idea which seems to be prevalent, that the coupling of two motors in cascade must always result in a very bad power factor. This idea is apparently due to the fact that the magnetizing current of two similar machines so coupled is twice that of one machine alone. Naturally a larger magnetizing current is required as the speed of the set is only one-half of that of one motor alone. If a motor wound for, say, 12 poles is compared with two 6-pole motors of the same diameter connected in cascade it is found that the power factor of the cascade set will only be slightly lower, the reduction being due to the increased inductance of the end connections owing to their greater length and to the slightly increased magnetizing current called for by the greater length of the iron path. Against this reduction in power factor due to increased leakage we have to set an improvement resulting from the fact that the rotor copper losses tend to improve the power factor. In an ordinary machine the resistance losses in the rotor do not influence the primary power factor, so that if the stator and rotor copper losses are equal, only half the total I²R losses assist the power factor. In cascade-connected machines both stator and rotor carry magnetizing currents, so that if the losses are distributed in the same way, three-quarters of the total copper losses help to improve the power factor. Further reference to this matter is made in a later section of the paper.

Returning to the development of the motor, it was evident that to make the machine commercially successful a way had to be found to obviate the necessity for two separate sets of windings. What was required was a single winding suitable for two entirely independent currents, one at line frequency and the other at the frequency of slip. This was a stator problem; the treatment of the rotor windings, requiring a different solution, was left till a later date. The required winding had not only to be suitable for the circulation of these two independent sets of currents,

but had to be so connected that the induced or low-frequency currents could only circulate when paths outside the windings were provided for them. This was necessary in order that the starting torque and speed could be controlled by causing the induced currents to flow through

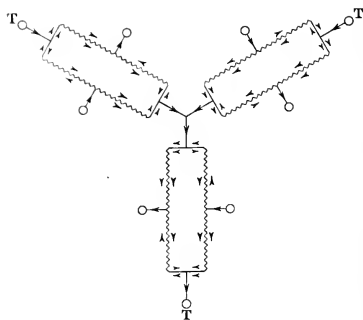

FIG. 2.

variable external starting or regulating resistances. Two sets of terminals were therefore required, one set for connecting to the mains and the other set to the resistances. The main currents must not be allowed to flow through the external secondary paths, and consequently it was essential that any one pair of secondary terminals should be connected to two points in the windings between which there existed no "main" potential difference. To meet these conditions a parallel-connected winding was necessary. Fig. 2 shows diagrammatically a form of winding which at once suggests itself. The main terminals are lettered "T," and the three pairs ofappings are those to which three separate sets of resistances would be connected for starting and speed-regulating purposes. When running at full speed each pair ofappings would be short-circuited. Arrow-heads shown inside the diagram indicate the direction of flow of the main currents at a given instant; those outside the diagram similarly show the direction of flow of the induced currents.

Having obtained this key diagram the next thing to be done was to find a winding which could be connected up in accordance with it. We shall now proceed to work out the winding again starting from this point. Fig. 3 shows the windings of one phase of an 8-pole stator. One slot per pole per phase is shown in order to simplify the diagram. Each radial pair of small circles represents the two coil sections occupying one slot, and the crosses and dots within the circles indicate the directions of flow of the main currents. Only the back connections of the coils are shown, as we have not yet found out how these coils are to be joined together. The main currents produce 8 poles, and we require to connect the coils so that induced currents generated by a 4-pole rotor field can circulate in them. This 4-pole field is shown in the figure, and we see that four of the slots containing coils are opposite the

centres of the poles and four are situated between the poles. The electromotive forces induced by the 4-pole field in the parts of the windings in the slots in the centres of the poles are consequently in quadrature with those induced in the slots midway between the poles. Therefore the key diagram should be modified so as to provide for two-phase currents in each of the three sections of the star winding.

We can now make a new diagram which will permit of this (Fig. 4); and it is a simple matter to connect up the winding shown in Fig. 3 so as to comply with this key. With the 4-pole field in the position shown, the induced voltages and currents will be in the directions indicated by the dots and crosses shown outside the coil circles. Alternate coils are marked A and B, and all the induced currents in the A coils are in phase with one another and in quadrature with the currents in the B coils. In Fig. 4 the secondaryappings of one phase are marked A, B, to correspond with Fig. 3.

Working from terminal T₁ and taking the left-hand path, we connect the top end of coil A₁ to the terminal and its bottom end to the secondary tapping A₂. To the same tapping we connect the top end of coil A₂ and its bottom end to the central bridge C. Also to this bridge is connected the bottom of B₁ with its top to the tapping B₂; and to the same tapping the bottom of B₂ and its top end to the neutral point N. Working up the right-hand path, A₄ top is coupled to T₁, and its bottom end together with A₃ top to the tapping A₅. To the bridge is connected A₃ bottom and B₃ bottom. B₄ top and B₃ bottom are connected to B₅, and B₅ top to the neutral point. Fig. 5 is the completed winding of one section of the stator, and the connections of the remaining two sections are carried out in exactly the same way. The arrow-heads in Fig. 5 refer to the induced currents only.

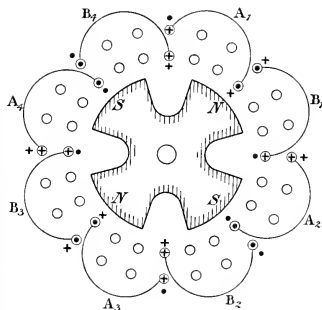

FIG. 3.

The application of this winding to machines having a larger number of poles introduces no difficulties. A winding for a machine with 24 and 12 poles would be connected in the same way, except that instead of there being only one coil in each section of the winding there would be three.

In Fig. 6, which is a winding for a motor having 8 main and 4 auxiliary poles, the currents induced by the 4-pole rotor field are indicated.

Values have been given in Fig. 6 to the induced cur-

each slot at the instant under consideration. The electromotive force or current in each coil is obtained by adding together the voltages induced in the two limbs of the coil. Outside the diagram a ring of figures shows the net values

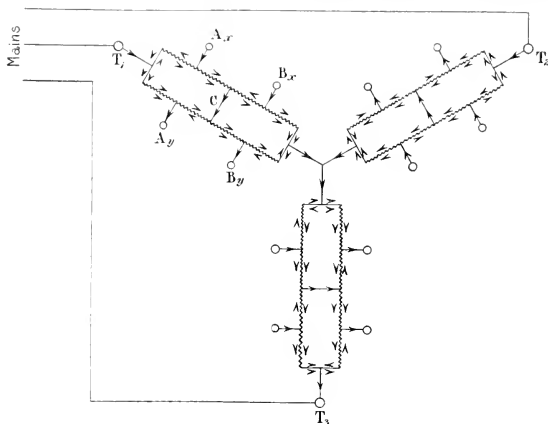

FIG. 4.

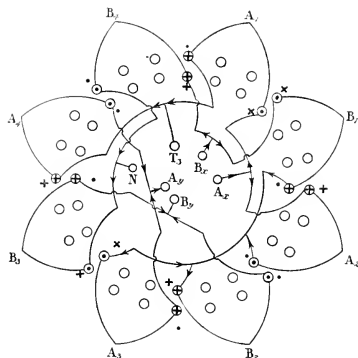

FIG. 5.

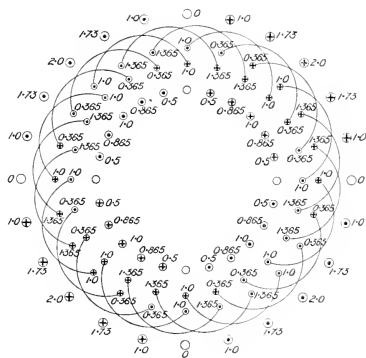

FIG. 6.

rents. These have been obtained by assuming that the 4-pole field would induce a maximum electromotive force of 1 volt in any bar. The flux and electromotive force are assumed to follow a sine law. The inner circle of figures shows the electromotive force induced in the conductors in

of the currents in each slot, from which it will be seen that of the total ampere-bars 70.7 per cent are effective. Of course this could have been deduced from the fact that each slot carries two currents in quadrature.

It may be well to mention that it is quite possible to

construct windings to fit the simpler key diagram of Fig. 2. A winding of the type that has just been considered could be used, but it would mean that in alternate slots the induced currents in the two coil sections would be equal and opposite and only one-half of the winding would be usefully employed by these currents. By using the winding shown in Fig. 6, the effective value of the ampere-bars is 70.7 per cent of the total ampere-bars; so that a very considerable reduction in the secondary losses can be obtained by increasing the number of secondary leads. In practice this increased number of leads has not proved objectionable.

In the windings illustrated, the slot pitch has been made normal for the larger number of poles. If this be increased, then with three-phase secondary currents the effectiveness of the winding will be increased. If the windings were given a 6-pole slot pitch (equal to the average pitch of the two numbers of poles) the slot pitch factor would be increased to 0.865 for three-phase secondary currents, but of course the effective value of the main ampere-bars would then be reduced in the ratio of 1 to 0.865. Windings with three-phase secondary windings and this average pitch have been used, but owing to the presence of additional leakage fluxes they are distinctly inferior to windings employing six-phase windings. Such windings have three groups of conductors per pole as x -pole windings, but only three groups per pair of poles as $2x$ -pole windings.

The winding shown in Fig. 6 may now be compared with the two separate windings of the original machine. This matter was dealt with fully in the earlier paper and it will only be necessary now to consider it briefly. In an average machine the number of the induced ampere-turns of the stator will equal about 46 per cent of the "main" ampere-turns. With two separate windings the total number will therefore be 1.46 if the main current produce 100. With a single winding the secondary ampere-turns will be 65, as the pitch factor is only 0.707. The heating effects of the two currents are proportional to the sum of their squares, so that a current equal to the geometrical sum of the two currents will have the same heating effect as the two separate currents. In this case this current will produce 119.5 ampere-turns instead of the 146 ampere-turns required with the double winding.

The whole of the copper being merged into one winding gives a greatly reduced effective value to the resistance, so that for a given weight of stator copper the I^2R loss is reduced to rather less than one-half.

ROTOR WINDINGS.

Having obtained the required stator winding, attention was next paid to the rotor. As both windings carry currents of the same frequency and no external connections are required, the treatment is quite different from that applied in the case of the stator. As with the stator winding, it will probably be clearer if we start from first principles and re-develop the windings. As there are only two axes of coincidence in a motor having 4 and 2 poles, such a machine is not practicable, as the shaft would be subjected to unbalanced radial forces. It will, however, save a lot of needless repetition if we work out the rotor windings for this number of poles. Such a

winding when obtained forms a unit that can be used in the building up of windings for any other numbers of poles. For instance, a motor with 8 and 4 poles would have a winding consisting of two such units, a 20- and 10-pole motor would have five units and so on.

The strength of the auxiliary field of the motor is proportional to the electromotive force across the windings producing it, and inversely proportional to the number of turns per pole in the auxiliary winding. The strength of the main field is proportional to the same electromotive force if we neglect the pressure-drop due to resistance, and is of course inversely proportional to the number of turns per pole in the stator winding. We are assuming that the number of turns in the stator and the rotor (main field winding) are the same. The strength of the main field is determined by the number of turns in the stator winding, and by varying the relative numbers of turns in the two rotor windings the strength of the auxiliary field may be changed.

If the main rotor winding has twice as many turns as the auxiliary rotor winding then each will have the same number of turns per pole; and as the area of an auxiliary pole is twice that of a main pole, the flux per pole of the second field will be twice that of the main field and the gap density of the two fields will be the same. The magnetizing current required for the auxiliary field will be equal to that required by the main field, and therefore the total magnetizing current of the machine will be twice that taken by the main field alone.

If both rotor windings are given the same number of turns, the rotor auxiliary flux will be halved and the gap density and the number of ampere-turns will also be halved. The number of turns being doubled, only one-quarter of the magnetizing current will be required to produce the auxiliary field, and the total magnetizing current of the machine will be 25 per cent greater than that required by the main field alone.

In practice the best results have been obtained with rotors having main and auxiliary windings in the ratio of 1.73 to 1.0. This ratio gives an auxiliary field with a flux per pole 73 per cent greater than the main flux. The gap density of the auxiliary field is 86.5 per cent of that of the main field, and the auxiliary magnetizing current is consequently equal to 75 per cent of the main magnetizing current, giving a total current 75 per cent greater than the main field current. With a given stator winding the magnetizing current of the auxiliary field varies inversely as the square of the number of turns in the auxiliary winding, and the reactance directly as the square of the number of turns. For windings in the ratio of 1.73 to 1.0 an average figure for the reactance of the auxiliary windings is 40 per cent of that of the main windings. It can be shown that for minimum leakage the winding ratio should be 1.414 to 1.0, which would give a total magnetizing current 50 per cent in excess of the main field current. Such a winding can be developed, but it requires deeper rotor slots to accommodate it and has to be wound for two phases. This winding together with a large number of others have been tried, but have all had a greater leakage than the 1.73 to 1 winding.

It has been assumed that the main stator and rotor windings have the same number of turns. It hardly needs to be pointed out that changing the number of

stator turns will not affect the relative values of the two fluxes. This relationship is dependent on the number of volts per turn; and any change in the stator equally affects the rotor.

Fig. 7 shows a developed diagram of a 4-pole winding. The slot pitch has been shortened to two-thirds the normal, so that bars carrying currents differing in phase by 60 degrees occupy the same slot. If the current per bar is 1 ampere, the effective number of ampere-bars per slot will be 1.73. The reason for choosing the shortened pitch is to reduce the ampere-bars per slot from 2.0 to 1.73. In the same slots is shown a two-pole winding of full pitch with 1 bar per slot. The two windings are interconnected

magnetomotive force. We therefore omit these bars. There are now left 6 slots each containing only one bar, as shown in the figure below, the original 4-pole and 2-pole windings. In each of the slots containing 3 bars, two of the bars carry currents of the same phase, and the current in the third bar differs in phase from the others by 60 degrees.

If a conductor carry two currents of the same amplitude differing in phase by 60 degrees, the crest value of the resultant current equals 1.73 times the crest value of either of the component currents, and the phase of the resultant current lies midway between the phases of these component currents. This phase relationship is found in an interconnected star and mesh winding.

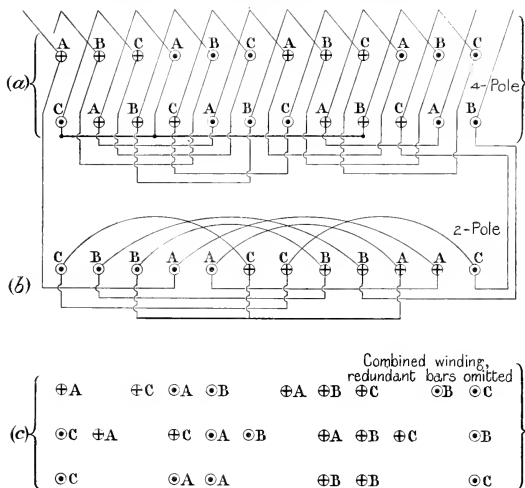

FIG. 7.

so that the same current circulates in each; consequently with 1 ampere per bar there are 1.73 ampere-bars in the 4-pole winding and 1.0 ampere-bar in the 2-pole winding in each slot.

In this diagram as well as in all the others in the paper instantaneous values of the currents are taken at the instant when the current in B is 1.0, and those in A and C 0.5 each.

From an examination of the winding it will be seen that in slots 2 and 3 there are two bars carrying currents of the B phase which are equal and opposite. In slots 6 and 7 the bars carry equal and opposite currents of the C phase, and the same conditions are found with currents of A phase in slots 10 and 11.

It is clear that two conductors carrying equal and opposite currents in the same slot can produce no useful

By connecting up the combination winding, Fig. 7, to form a star and mesh construction we can use two bars per slot instead of three, and thus simplify the winding. It is only necessary to merge two bars carrying currents

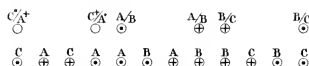

FIG. 8.

differing in phase by 60 degrees and call all such bars star bars. For example, in slot No. 1 the A bar and one of the C bars would be replaced by a single star bar. The slot conductors are now represented diagrammatically by Fig. 8,

and all that is required to complete the winding is to provide suitable end connections to give a star-mesh construction. This has been done in Fig. 9.

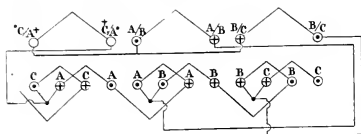

FIG. 9.

We can now compare the combination winding with the original construction in which two entirely separate windings were necessary. By combining certain of the bars we have not changed the magnetomotive forces produced by the component currents, although we have reduced the actual heating value of the currents from 20 to 173. The component currents still attain the same crest values which they had before we substituted single bars for two separate bars. As far as the magnetizing values of the currents are concerned, the skeleton winding in Fig. 7 is identical with the finished winding of Fig. 9, so that we may compare it

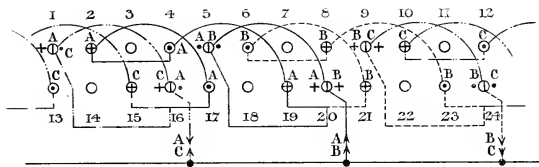

FIG. 10.

directly with the original 4-pole and 2-pole windings of Fig. 7. If the 4-pole winding (Fig. 7) is divided in two by a vertical line between slots 6 and 7 it will be seen that the skeleton winding (Fig. 7) consists of nothing more than a re-arrangement of the original 4-pole winding. The C bar in slot 7 has been taken out and placed in slot 1. The B bar in slot 2 has been removed to slot 8, and so on; so that the combination winding which takes the place of the original 4-pole and 2-pole windings is only a non-uniformly arranged 4-pole winding. In its symmetrical form the two conductors in each slot might be replaced by a single conductor carrying an effective current equal to 173 times the current in each bar, so that the total section of copper would be $12 \times 173 = 2076$ sq. mm., if for the sake of illustration we allow 1 sq. mm. per ampere and call the current in each single bar 1 ampere.

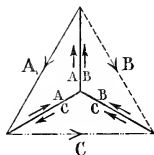

In the combination winding owing to its non-uniform nature there are only 6 bars carrying resultant currents of 173 amperes. The remaining 12 bars each carry 1 ampere. Allowing the same current density as before, the cross-section of the copper will be 2238 sq. mm., or the combination winding will require 7.8 per cent more copper than the original 4-pole winding.

VOL. 52.

Electrically the winding shown in Fig. 9 was very satisfactory, since the end connections being in two planes at right angles to one another had low inductance. Mechanically the construction was not so sound, for centrifugal forces acted directly on the joints of the end connections and it was not easy to support the windings sufficiently without seriously reducing the ventilation. Further, the use of two different winding pitches was objectionable.

To overcome these weaknesses the arrangement of the end connections was changed and a barrel type of winding of the usual type was used. This is shown diagrammatically in Fig. 10. The slot pitch of all the coils is the same and the end connections can be supported on rings in the usual manner and held in position by binding wire. In appearance it resembles an ordinary rotor except that one-quarter of the bars have been omitted.

It is now proposed to investigate the voltages in the several sections of the winding in order to prove that the back electromotive forces induced by the 2-pole field are equal and opposite to those induced in the winding by the 4-pole field. The 2-pole flux per pole is equal to 173 times the 4-pole flux per pole. Under load conditions the 2-pole flux would be slightly less, so as to leave sufficient voltage to drive the current through the resistance of the windings. In Fig. 10 the bars have been

numbered from 1 to 24, and in Fig. 11 the star-mesh key diagram is reproduced, the parts representing the different bars being numbered to correspond with Fig. 10. To find the voltages induced in individual bars we may make use of the original 4-pole and 2-pole diagram (Fig. 7) and treat it as a voltage diagram. The voltages producing the 4-pole currents are in phase with them, but the back electromotive forces induced by the 2-pole field will be opposite in direction to the currents. We can therefore take the directions of the voltages direct from the 4-pole diagram, but the directions must be reversed when reading the 2-pole diagram. In doing this we are taking the maximum electromotive force per bar induced by the 4-pole field as 173, so that as the flux per pole of the 2-pole field is equal to 173 times the 4-pole flux, we must take the maximum electromotive force per bar induced by the 2-pole field as 3°.

In Fig. 11 the double-barbed arrow-heads represent the 4-pole electromotive forces and the single arrow-heads the electromotive forces induced by the 2-pole field. A letter at the side of the arrow indicates the electromotive force and phase.

To make quite clear the method adopted, let us consider

the ray of the star consisting of bars 20 and 5. Starting from the neutral point we first find the electromotive force in bar 20 due to the 4-pole field. This bar is situated in slot 8; and from the 4-pole diagram (Fig. 7) we find that the voltage across this bar is $A B$ and from Fig. 10 we find that its direction is from the neutral. This we indicate on the star-mesh diagram by two double-barbed arrow-heads, marking them A and B . Referring now to the 2-pole diagram we find that the bar in slot 8 has a voltage $3 B$ induced in it; and remembering that this voltage will be opposite in direction to the current, we find that its direction is towards the neutral point. The next bar is in slot 5, and from the 4-pole diagram we see that the electromotive force is $A B$ and its direction is from the neutral. From the 2-pole diagram we find the voltage is $3 A$ and its direction is towards the neutral. The voltages across each bar are determined in this way and indicated on the diagram. The arrows show the instan-

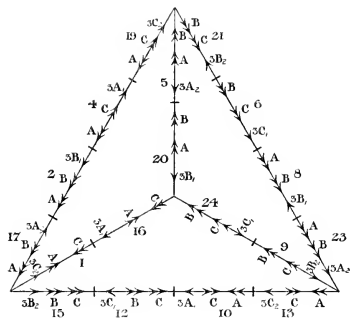

FIG. 11.

taneous directions of the currents, but we have to consider the amplitude of the electromotive force in balancing the voltages due to one field against those produced by the other.

The 2-pole diagram (Fig. 7) which we are using to find the back electromotive forces is made up of pairs of bars of the same phase in adjacent slots. The phase will of course only be the same when the bars are connected in series. In taking the electromotive forces from this diagram a distinction is made by denoting the phases as A_1 and A_2 ; B_1 and B_2 ; C_1 and C_2 . And as in each circuit there is an equal number of bars of each, the phase error is automatically corrected.

An inspection of the diagram shows that the voltages taken round the mesh are in balance. The 4-pole electromotive forces cancel out phase by phase, and the B phase electromotive forces of the 2-pole field are in opposition to those of the A and C phases. No currents can therefore circulate except by way of the star windings.

There are then only three circuits, and these are shown in Fig. 12. Taking the left-hand circuit we find the 4-pole

electromotive forces consist of $8 A$ and $4 B$ opposed to $4 C$. Now the B and C electromotive forces differ in phase by 120 degrees, so that their resultant is an electromotive force in phase with A . The total electromotive force is therefore $12 A$. Now taking the back electromotive force induced by the 2-pole field we find that the B and C electromotive forces cancel out and leave an electromotive force of $12 A$ opposed to the 4-pole electromotive force of the same value.

In the right-hand circuit the 4-pole electromotive force consists of $8 B$, $4 C$, and $4 A$ in the same direction. As before, the resultant of $4 C$ and $4 A$ is $4 B$, so that the total 4-pole electromotive force is $12 B$. The A and C electromotive forces produced by the 2-pole field cancel and leave a back electromotive force of $12 B$. In the third circuit we find a 4-pole electromotive force of $12 C$ balanced by a 2-pole electromotive force of the same value. In other words the back electromotive forces in

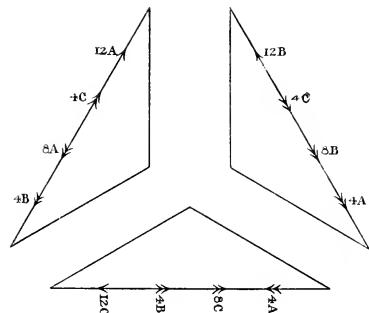

FIG. 12.

each circuit are equal and opposite to the electromotive forces induced by the main field.

This completes the description of the cascade machine in its simplest form. In another section of this paper motors with two or more efficient speeds are described, but in these the extra speeds are not obtained by cascade coupling. The windings already described are used in all the machines, and only certain additions are made to the rotor to enable it to operate at non-cascade speeds.

THE ONE-SPEED MOTOR.

The completed motor closely resembles a machine of ordinary construction. The stator windings are identical in appearance, and only differ in the cross-connections of the coils. Standard construction is also used for the rotor. The efficiency and power factor curves of a 330 h.p. 50-cycle 200 r.p.m. motor having 20 main and 10 auxiliary poles are shown in Fig. 13. The gap diameter of the motor is 56 in. The stator slots are of the completely open type, and those of the rotor are semi-closed.

The slots are chosen to suit the main poles; therefore

if a 30-pole motor is to be designed having 20 main and 10 auxiliary poles and 3 slots per pole per phase, 180 slots would be required. With the same number of slots per pole, a motor of the one-field type would have 270 slots. As a two-field motor requires only two-thirds of the number of slots, it is possible to build motors of this type for a very large number of poles with reasonably

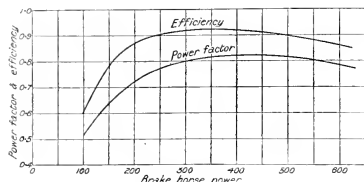

FIG. 13.

good power factors. As an example a motor which has been running in Scotland for some years may be cited. This machine has 28 main and 14 auxiliary poles and therefore operates at 42-pole speed, which is 140 r.p.m., as it is running on a 50-cycle circuit. The output of the machine is 100 b.h.p., and the gap diameter is 50 in. The power factor at full load is about 0.81.

The cascade machine has a very small slip because the resistance of the rotor does not directly affect it. In a one-field motor the no-load and stator copper watts are deducted from the watts input to the machine, and the slip is obtained by dividing the rotor copper loss by the net input to the rotor. In a two-field motor the slip is equal to the tapping copper loss divided by the net input to the machine. The net input is equal to the watts input of the motor less the no-load losses and the stator and rotor copper losses. As the whole of the stator copper forms the tapping circuits, the losses in these circuits are very low.

The efficiency of a cascade machine can be very easily calculated if the tapping current, stator resistance, and slip are measured. Knowing the tapping current, the losses in these circuits are known. The net input to the machine is found by dividing the tapping circuit loss by the slip; and the net input less the tapping loss is the output of the motor. The efficiency is of course found by dividing this figure by the gross input. By slip is meant the mechanical slip of the machine and not the slip of either field.

The core of a cascade machine has to carry both the main and auxiliary fluxes, but as the secondary flux is only rotating at the speed of slip the loss due to it is small and the flux density behind the teeth can be raised to a high figure. The density in the teeth must, however, be kept within reasonable limits otherwise the power factor may be considerably reduced. The actual iron loss in a motor of standard design is practically unaffected by the presence of the auxiliary field; with increasing density the second flux increases the losses considerably, but the normal working density is far below this part of the curve.

STARTING AND SPEED REGULATION.

The presence of the auxiliary field has a marked effect upon the behaviour of the motor when starting and "creeping." It gives the machine a more even turning moment; the motors will run quite steadily with resistances connected to the stator tappings at less than 1 per cent of their full speed, and at starting they develop a very steady pull. For these reasons the machines have been extensively used in the driving of all classes of hauling machinery, and they give satisfactory inching in the driving of printing presses and similar machines.

Owing to the very low-voltage windings used in the rotors and the absence of slip-rings, single-speed motors are found to be very successful in the driving of all classes of mining, cement, and quarry machinery, and they are now being introduced into rolling mills.

It is hardly necessary to say that machines of this type develop full-load starting torque with approximately full-load current, and that they can be designed to suit all conditions of starting. The standard design of motor starts against any load up to 2 to 2½ times the full-load torque, and of course regulation of the starting torque is obtained by varying the resistances connected across the stator tappings. At full speed these tappings are short-circuited in the same way that the rings are short-circuited in motors of the slip-ring type.

Unless the machines are required to run at reduced speeds for a considerable time it is unnecessary to provide resistances for all the stator tappings. Tests made some time ago showed that with resistances connected to two pairs of tappings in one leg of the winding the motor would start against a torque equal to a little more than full-load. With three resistances, one in each leg of the star, the three pairs of tappings being so chosen that the stator coils carrying induced currents are symmetrically arranged round the stator, the motor starts against a torque approximately equal to its maximum running torque. With resistances connected to four pairs of tappings, the maximum starting torque is approximately the same as with three resistances. In the usual way either three or four resistances are used at starting and for moderate speed regulation, and the remaining tappings are

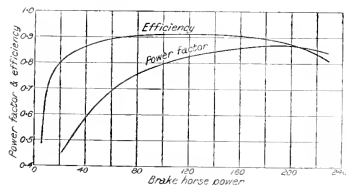

FIG. 14.

short-circuited when the machine has attained full speed. The short-circuiting of these extra tappings may be effected by contacts arranged on the starting switch, or by a short-circuiting switch mounted on the side of the stator.

The curves in Fig. 14 show the efficiencies and power factors of a motor recently built to an Admiralty specifica-

tion. The motor has an output of 150 h.p., at 250 r.p.m. and is wound for a 380-volt 50-cycle circuit. It has 16 main and 8 auxiliary poles.

For motors required to run up to speed against, say, full-load torque or a somewhat higher torque, the resistances may be permanently connected across the tappings and when the main switch is closed the machine starts, developing its maximum torque. After it has speeded up, a short-circuiting switch, mounted on the side of the stator, is closed. Such an arrangement is equivalent to a squirrel-cage motor with a very high-resistance rotor. The short-circuiting switch allows the resistances to be reduced to a low value at full speed.

TWO-SPEED MOTORS.

As the currents supplied to the main terminals of the stator winding (Figs. 4, 5, and 6) can only produce the

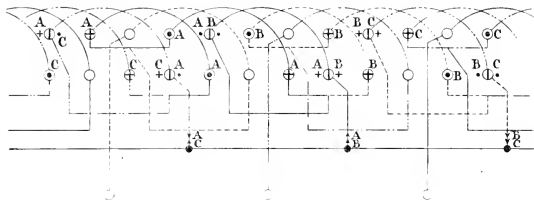

FIG. 15.

main field, and as there can be no difference of potential between any pair of tappings unless the windings are acted upon by a field having a number of poles differing from those of the main field, it follows that if an ordinary slip-ring rotor wound for the same number of poles as the stator be substituted for the cascade rotor the machine will run as an ordinary one-field motor. The machine will run 50 per cent faster than with its own rotor, and will possess the usual characteristics of a motor of standard design, except that as the iron density will be rather lower the core losses will be less. The copper losses will be slightly increased as the motor has been made a little longer than an ordinary machine in order that there may be the necessary iron to accommodate the extra flux when running at cascade speed.

In the first two-speed motors two windings were used on the rotors, one wound for the same number of poles as the main flux and connected in star, and the other wound for half the number of poles and connected in mesh. Both windings had the same number of conductors, but as one was connected in star and the other in mesh, the current in one was 73 per cent greater than that in the other, and the ampere-bars of the two were in the correct ratio. From the points of inter-connection of the two windings leads were taken to 3 slip-rings. When the motor was required to run at cascade speed the slip-rings were open-circuited and the machine was started by resistances connected to the tappings. When required to run at non-cascade speed, the tappings were open-circuited and the motor was started by means of resistances connected to the slip-rings in the usual manner. When run-

ning at top speed the short-circuited slip-rings prevented any appreciable current from flowing into the second rotor winding. This type of winding required very deep motor slots in order to keep the losses down, and this made it very difficult to get enough iron into the teeth to prevent over-saturation.

Referring to Fig. 10 we have already noted that the cascade rotor winding is non-uniformly distributed. If the winding can be made uniform when desired, the second field can be suppressed and non-cascade speed obtained. To do this it is necessary that all slots should carry the same number of bars. The question then arises as to how these additional bars are to be connected to the others so that all shall carry the same current. It was a long time before it was realized that the desired result could be obtained very easily. All that is necessary is to take the cascade winding, Fig. 10, insert the three coils

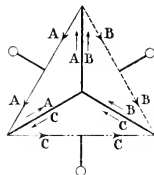

FIG. 16.

shown in Figs. 15 and 16. The three slip-rings are open circuited and the currents shown correspond with those in Fig. 11 for cascade working.

Let us now see what happens when the three slip-rings are short-circuited, as in Fig. 17. As before we are here considering the instant when the B current is 1.0 and the A and C currents each 0.5. We are also taking the electromotive force and current induced in each bar as simply A, or B, or C, because it is no longer necessary to consider this as made up of two component voltages. We see that at each point where three bars meet, the B current divides into A and C currents, so that each point is in reality a neutral point, and there are 8 such points in the winding.

The key diagram, Fig. 17, is drawn in the form of a

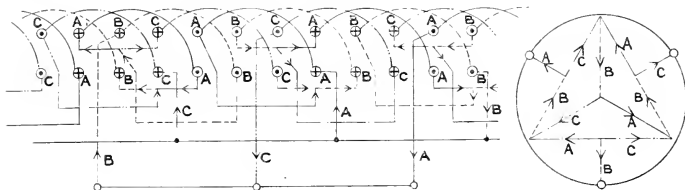

FIG. 17.

star and mesh so as to be exactly comparable with the cascade key, but it does not show correctly the phase relationship of the currents. Fig. 18 is the corrected diagram, and it can be divided into 4 parts as shown, namely, 4 interconnected star windings. The currents must necessarily all have the same amplitude and they will all be controlled by an ordinary three-branched resistance connected to the slip-rings.

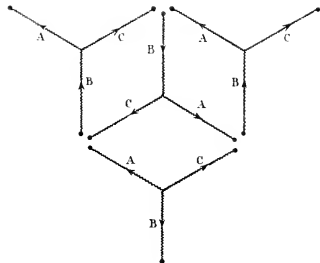

FIG. 18.

In extending the winding for use with a larger number of poles either parallel or series connections may be used. If the former plan is adopted, the key diagram would be a 12-sided figure for a machine wound for 8 main and 4 auxiliary poles, and to each slip-ring would be connected two leads from diametrically opposite points. For larger

numbers of poles the diagram is extended in the same way, the number of sides of the figure being equal to the total number of poles (main + auxiliary) of the motor, and the number of parallel connections to each slip-ring being equal to one-sixth of this number of poles.

If series connections are used, similar coils in each block of 4 poles of the winding are connected together; and for any number of poles there will be one connection to each slip-ring and the diagram will be a hexagon.

The weight of copper in this type of rotor winding is less than one-half of that in the original double windings; and as quite shallow slots will accommodate it the react-

ance is naturally very much less. The construction of the winding follows standard lines for barrel-type rotors, and any rotor with this type of winding can be made to give the extra cascade speed by changing its cross connections.

CHARACTERISTICS OF THE TWO-SPEED MOTOR.

A motor of this type is designed in exactly the same way as a machine of the ordinary type wound for the main number of poles. Of course the teeth and core are given appropriate areas to carry both fluxes when the motor is running with its second flux; and the depth of the slots is kept down so that the leakage will not be excessive when operating at cascade speed. Keeping these points in mind the windings are worked out for the main number of poles, as experience has shown that the maximum torque developed in cascade will be approximately the same as when the machine is working with only one field.

A word should be said with regard to the calculation of the cascade power factor. In ordinary designs the effect of the stator resistance on the power factor is generally but small. This is not so in a cascade-connected motor, especially if it is wound for low speeds, because unlike a one-field motor the rotor copper loss as well as the main current loss in the stator windings have the effect of increasing the power factor. Therefore as the tapping loss is only small, nearly all the copper loss helps in improving the power factor. The reason for this is the presence of magnetizing currents in the rotor windings. The rotor resistance has a much larger effect on the power factor than the stator resistance, because when the rotor is running at cascade speed the frequency of the currents in its windings is only approximately one-third of the line frequency. The author has found it convenient to calculate the currents in the various circuits with the rotor

standing; and when this method is used it is necessary to give the rotor resistance a fictitious value equal to 3 times the true resistance, in order that its relationship to the reactance may be the same as when running at cascade speed. Actually the figure should be slightly less than 3, owing to the slip. The exact figure is equal to $r_m/(r_m - r)$, where r_m is the synchronous speed of the main field and r the speed at which the rotor is running.

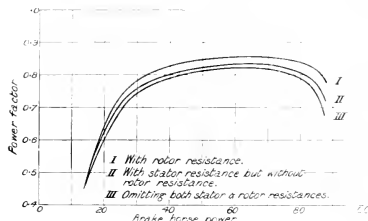

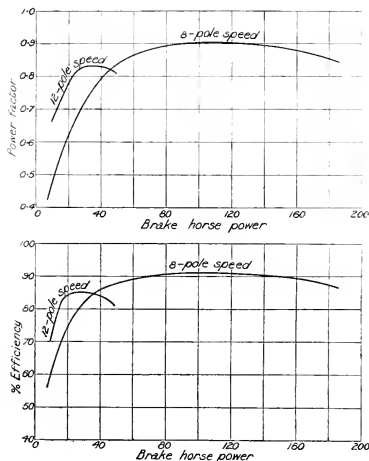

FIG. 19.

To show the effect of the resistance losses three curves have been drawn, Fig. 19, one showing the calculated power factor curve ignoring the resistances, the second including the stator resistance, and the third taking into account the effect of both stator (main circuit) and rotor resistances. The motor is of standard design giving 50 h.p. at 500 r.p.m. on a 50-cycle circuit, and consequently having 8 main and 4 auxiliary poles. Some crane motors which had quite average efficiencies and power factors and large overload capacities were found on test to take less current on quarter load than when running light. The iron was highly saturated, and owing to the resistance drop the magnetizing current fell off rapidly as soon as the machines were put on load.

These characteristics are of course common to machines having any number of speeds, one of which is obtained by concatenation, and would perhaps have been more in place in the section dealing with the one-speed cascade machine. It has already been mentioned that the pull-out torque of the two-speed motor is approximately the same at both the speeds, and in an earlier section of this paper it was shown that the no-load current at cascade speed exceeds that at non-cascade speed by 75 per cent. When a motor is required to drive a fan or any machine which requires less torque at its second speed than at full speed, a star-mesh switch is mounted on the motor so that the machine may be run with its stator windings connected in mesh at full speed and in star at cascade speed. This arrangement reduces the no-load current at cascade speed to one-third of its usual value, or 58 per cent of the full-speed current. The overload capacity is similarly reduced, but is ample for a fan driven at two-thirds its normal speed. The arrangement brings the cascade power factor well up on the curve and also permits of the use of a smaller motor, because the machine at cascade speed is operated with a main flux reduced to only 58 per cent of its value at full speed. The machine can therefore be designed for standard densities at full speed.

The curves in Fig. 20 are those of a two-speed motor driving a colliery fan. The machine gives 120 h.p. at 580 r.p.m. and 30 h.p. at 397 r.p.m. on a 40-cycle circuit, and is wound for 2,750 volts. It operates at 8-pole and 12-pole speeds, but as deeper slots than the standard were required to take the high-tension windings the power factor at the second speed is a good deal below the figure for low-voltage machines. Any speeds between the limits of 397 r.p.m. and 580 r.p.m. are obtained by resistances connected to the slip-rings, and speeds below 397 r.p.m. by resistances connected to the stator tapplings.

In the majority of cases speeds below cascade are not required and the control of the machine can then be considerably simplified. The curves in Fig. 21 show the power factor and efficiency of a high-tension motor which is used to drive a compressor at a colliery. This motor gives 550 h.p. at 243 r.p.m. and 370 h.p. at 164 r.p.m. on a 50-cycle circuit. An ordinary rotor starter is used, and on the side of the stator is mounted a 6-pole switch for short-circuiting the stator tapplings. When the maximum quantity of air is required from the compressor the machine is started and taken up to full speed by the rotor starter in exactly the same way as an ordinary motor. When a smaller quantity of air will suffice the motor is

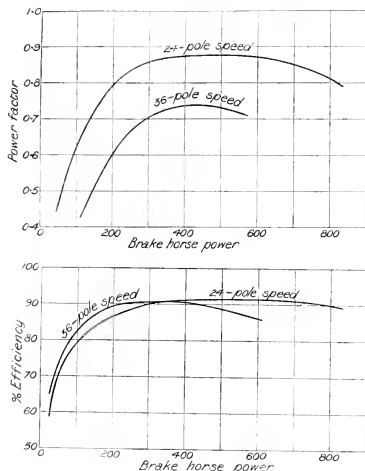

FIGS. 20A AND 20B.

started as before by means of the rotor resistance and is brought up to approximately cascade speed. The tapping short-circuiting switch is then closed and the rotor starter open-circuited. It is not necessary to bring the speed exactly to its cascade value before closing the switch, but

the nearer it approaches it the smaller will be the jump in current.

Quite a large number of machines are running which are started from rest by simply closing the stator tapping switch when cascade speed is required. This is quite satisfactory if the momentary rush of current is not an objection and the starting torque required does not exceed the full-load torque. Motors of 50 h.p. have been started in this way, and owing to the cascade coupling the momentary current on first closing the switch is 30 per cent less than would be the non-cascade current under similar conditions.

FIGS. 21A AND 21B.

Reference has already been made to two-speed crane motors, and a few particulars relating to their sphere of usefulness and method of control may be of interest. For operating foundry cranes the single-speed machine is generally used on account of its inching qualities; but two-speed motors are used for the longitudinal motion of travelling cranes in long shops. When travelling with a load the machine runs at the second speed, and the high speed is only used when the crane is travelling light. The controller, which is generally of the tramway type, is provided with three extra contacts with an extra high-speed notch. When the motor is required to run at top speed the controller handle is brought over to the extra notch, in which position the stator tapplings are opened and the slip-rings are short-circuited. This arrangement is very simple and has proved entirely satisfactory.

In the applications mentioned an attempt has been

made to give a few typical examples of the uses to which these motors have been put, and this list, very incomplete as it is, will serve to illustrate the characteristics of these motors.

Their application to the driving of winding engines and rolling mills is a development of recent date. Two winders have been put into commission in South Africa during the last few months, and figures will shortly be available by means of which it will be possible to compare their characteristics with those of other winders of similar capacity of the Ilgner, Ward-Leonard, and the plain induction motor type.

Fig. 22A is a diagram of a complete wind when an ordinary induction motor is used; and the companion diagram, Fig. 22B, gives the same particulars for a two-speed motor drive. Comparing these diagrams we see that the R.M.S. output of the ordinary induction motor is 530 h.b.p., whilst that of the cascade motor is 490 h.b.p. There is a reduction of 2.8 units per wind in favour of the two-speed machine, omitting the energy returned to the line during retardation. The maximum input required by the ordinary motor during a wind is 1,225 h.b.p. and the corresponding input of the cascade machine is 1,035 h.b.p., showing a reduction in the peak of nearly 16 per cent. The depth of the inclined shaft is 5,000 ft., the incline being 65 degrees. The maximum winding speed is 2,500 ft. per minute, and the motor is wound for 500 and 333 r.p.m. on a 50-cycle circuit. The duty is 10,000 lb. of ore per wind.

For a given torque the output of a motor is proportional to its speed, and the input in a one-speed machine is the same at all speeds, the surplus input being absorbed in resistances. The cascade machine has two definite speeds at which there are no external rheostatic losses, and the input at the second speed is consequently only two-thirds of that at the top speed for the same torque. The actual input will be 1.2 per cent more than this, as the efficiency at the second speed will be reduced by this amount. Neglecting the internal losses of the motor, and considering only the acceleration torque, Fig. 23 is the starting diagram for a one-speed motor, and Fig. 24 a similar diagram for a two-speed motor. The shaded areas represent the losses in external resistances during the acceleration period, and the unshaded rectangle in the second diagram shows the saving in resistance losses effected by the use of a two-speed machine.

The second diagram shows the conditions which obtain when the torque is kept constant during the whole of the accelerating period. Up to cascade speed the input is reduced by 33 per cent, as has been explained above, and one-half of the input, measured as horse-power-seconds, during this period is lost in resistances. Above cascade speed the input has to be increased by 50 per cent, but as the motor has now attained two-thirds of its full speed the resistance losses during the second stage of the acceleration period are only one-half of one-third of the input measured in horse-power-seconds.

For two speeds in any ratio, let

$$K = (\text{second speed})/(\text{full speed}).$$

Then the input during the first stage of the wind = $K'Wt$ watt-seconds, where W is the input and t is total time of acceleration.

The 10^{-5} during this period of the wind will be $0.5 K^2 W I$.

The input during the second acceleration stage $= (1 - K) W I$ watt-seconds; and the corresponding resist-
ance loss is $0.5(1 - K)^2 W I$.

unity and multiply by 100, we obtain an expression which gives the percentage reduction in these losses. This simplifies to $200 K(1 - K)$.

For the smallest possible loss $K = 0.5$, or the second speed is half the top speed, and the reduction in the rheo

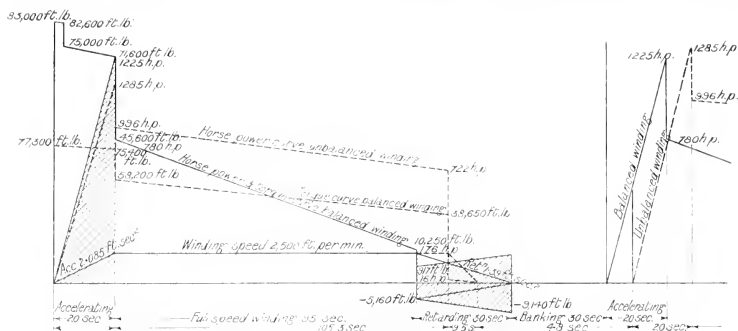

FIG. 22A.—Power Diagram of Slipping Winder Motor.

R.M.S. output (balanced): 530 h.p.
Units per wind = 17.

R.M.S. output (unbalanced): 820 h.p.
Units per wind = 27.

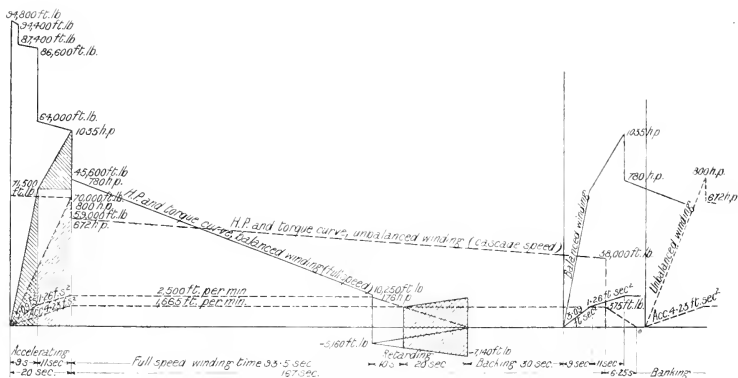

FIG. 22B.—Power Diagram of Two-speed Cascade Winder Motor.

R.M.S. output (balanced): 440 h.p.
Units per wind = 14.2.

R.M.S. output (unbalanced): 534 h.p.
Units per wind = 25.4.

The total loss during acceleration is

$$0.5 W I [K^2 + (1 - K)^2].$$

As $0.5 W I$ is the acceleration loss of a one-speed motor, the expression in brackets represents the two-speed losses as a fraction of such loss. If we deduct this fraction from

static losses is 50 per cent. In the case of the winders under discussion $K = 0.66$, and the percentage reduction in the losses is $200 \times 0.66(1 - 0.66) = 44$ per cent.

These figures show that with a two-speed motor having speeds in the ratio of 3 : 2, the efficiency during acceleration is 64 per cent, and with a one-speed machine 50 per cent.

So far we have only considered a motor developing the same torque during both stages of the acceleration period, with an input during the second stage 50 per cent greater than during the first stage. This is not the correct way to control a winder, as the first essential is to reduce the peak load as much as possible. In order to attain this result the input should be the same during the whole period of acceleration; this gives up to two-thirds full speed, an acceleration 50 per cent greater than that during the

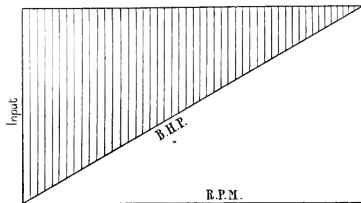

FIG. 23.

remaining part of the period. The diagram for these conditions is shown in Fig. 25.

Let us now compare this diagram with that for constant torque (Fig. 24). However we may change the relation of the torques during the two acceleration stages, the kilowatt-seconds input for each stage will be the same if the acceleration efficiencies are not affected. A glance at the diagrams shows that during the first stage the efficiency must always be 50 per cent. In the second stage the input usefully employed is

$$\frac{2}{3} W_2 t_2, \quad \frac{1}{2} \cdot \frac{1}{2} W_2 t_2 = \frac{1}{4} W_2 t_2,$$

which is also constant and gives an efficiency of 83.3 per

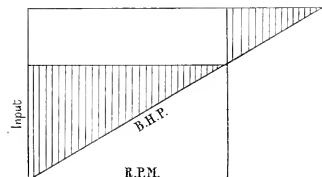

FIG. 24.

cent. Therefore we can study the question from the point of view alone of reducing the peak load, knowing that however we may vary the control we cannot lose the 44 per cent reduction in the external resistance losses.

The shaded areas in Figs. 22a and 22b represent the losses. These are dissipated in resistances during acceleration and in brake friction during retardation. Whilst slowing down to cascade speed the motor is driven as a generator by the load and returns energy to the line. Below this speed the brakes are applied.

With regard to the controlling gear, this is arranged so that resistance is automatically cut out of the stator tapings until the machine has attained two-thirds speed. The next step connects resistances to the rotor, and opens the stator circuits, and the rotor resistances are reduced until they are finally short-circuited with the motors running at its full-speed. The cascade system offers the advantage of gradual change from cascade to full-speed coupling with the motor connected during the whole time to the line. The stator is never disconnected from the mains until the brakes have been applied and the motor has been brought to rest.

For the reasons already stated there is no fierceness in the control at creeping speed and when starting; consequently decking is under complete control.

A modification of the stator windings, described later, enables us to reverse the main and auxiliary fields so that instead of there being $2x$ main poles and x auxiliary poles, the former has x poles and the latter $2x$ poles.

It is immaterial to the rotor windings whether the main or auxiliary fields have the greater number of poles when operating in cascade; the currents distribute themselves

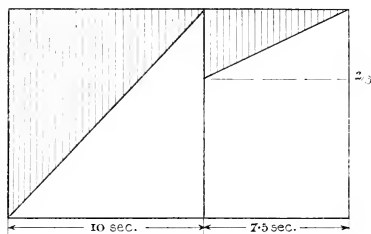

FIG. 25.

in the windings in exactly the same way under either condition.

With the slip-rings short-circuited the current distribution is changed, as is explained in the section dealing with three-speed motors; but beyond requiring slightly more copper no alteration in the windings is necessary. With this arrangement of windings the motor has two efficient speeds in the ratio of 3:1, and electric braking can consequently be obtained down to one-third of full speed.

Fig. 26 is the acceleration diagram of a motor with this speed ratio. From the general formula which has already been worked out we find that the rheostatic losses with speeds in the ratio of 3:1 are the same as for a speed ratio of 3:2. That this is so can be seen from the diagram, for with constant input the torque will be three times as great at cascade speed as when running on the slip-ring, so that the machine will run up to one-third speed in one-seventh of the time that it takes to reach full speed. If Wt be the total input in kilowatt-seconds, $Wt/14$ will be the loss in resistance during the first stage of acceleration. At the commencement of the second stage the motor will have attained one-third speed, and the resistance loss

whilst accelerating to full speed will be $\frac{1}{2}(\frac{3}{4}W)(\frac{1}{2}t) = \frac{3}{8}Wt$. The total losses are $15/42 Wt$, and the amount usefully employed is $27/42 Wt$. The efficiency is $27/42 Wt \div Wt = 64/3$ per cent, which is the same as for a speed ratio of 3:2. It is therefore possible to obtain the same reduction in acceleration losses and peak load with this type of motor as with the one previously considered; but with constant input the torque attains a

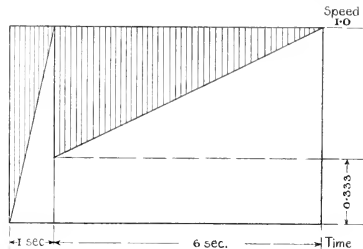

FIG. 20.

very high value during the first acceleration stage. Fortunately a motor with this speed ratio is capable of developing a considerably larger maximum torque at cascade speed than at top speed, so that the conditions for minimum peak are not impossible of attainment.

WINDINGS FOR SPEED RATIOS OF 3:1.

Instead of describing the finished winding the author proposes to adopt the same procedure as before and develop it from first principles. As the currents in all windings are to be confined to definite paths, we have not the help of a squirrel-cage construction to damp out harmonics, and we must therefore decide to work with three groups of slots per pole for both main and auxiliary fields.

Let us work out a stator winding suitable for a motor having 4 main and 8 auxiliary poles. The main field calls for 12 groups of slots, and the auxiliary field for 24 groups. Consequently each group carrying line currents of one phase must be so arranged that it can be divided to carry induced currents of two phases. Assuming that we are going to use a star winding, each leg will have to be arranged to permit of the circulation of two induced currents of different phases. The key diagram will therefore be the same as that used before (Fig. 4).

The next question to be settled is the slot pitch. Obviously this cannot be made equal to the normal pitch of a 4-pole machine, because if this were done all the coils would exactly embrace two poles of the auxiliary field, which could induce no electromotive forces in them. On the other hand we cannot use a normal 8-pole pitch, for with such a short pitch a satisfactory 4-pole winding would be impossible. An average of the two must be chosen, and this will give us a pitch coefficient of 0.865 for both numbers of poles.

We can now draw a diagram (Fig. 27) showing one main phase of this winding and fill in the phases of the line currents A, B, and C. Outside the circles the induced currents X, Y, and Z, are shown. The same convention has been adopted as before, namely, the instantaneous values of the currents in phases B and Y is 1.0, and those in A and X and C and Z 0.5 each. The cross-connections are now drawn, the method followed being exactly the same as before, except that each ray of the star is now made up of two groups of coils situated in adjacent slots instead of a whole pole-pitch apart. The secondary currents are three-phase, although there are still six secondary circuits.

Each slot carries two sets of wires, the currents in which differ in phase by 60 degrees, so that the number of effective ampere-wires per slot is equal to the number of ampere-wires per set of conductors multiplied by 1.73.

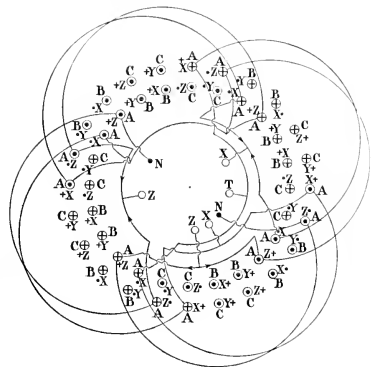

FIG. 27.

This applies to both the main and induced currents, and is due to the contraction of the 4-pole slot pitch by 60 electrical degrees and the extension of the 8-pole pitch by the same angle. The slot-pitch coefficient is necessarily the same for both fields, and is of course equal to the cosine of half the angle of contraction or extension, that is to say it is 0.865.

The arrangements for the control of a two-speed motor with this winding do not differ from those previously described.

The machine is used where a large difference between the two efficient speeds is required, or where regeneration down to low speeds is desired. Reference has already been made to this in connection with electric winders. For electric lift work it is also useful, since besides allowing for electric braking and regeneration it makes it much easier for the lift attendant to bring the cage to rest when exactly level with the landings. The "creeping" properties of the motor are also available as the machine is operating in cascade.

The rotor winding for a $(4+8)$ -pole motor is given an 8-pole pitch and is identical with the winding for an $(8+4)$ -pole machine. The distribution of the currents when the slip-rings are short-circuited and the motor is running at 4-pole speed is quite different from the state of affairs that exists when the winding is working with an 8-pole field, because the slot pitch is contracted to one-half the normal. This is explained in the next section of the paper.

THREE-SPEED MOTORS.

The two-speed motor can be operated at a third speed if the stator windings be so arranged that they can produce two different numbers of main poles. For example, a two-speed motor wound for 8 main and 4 auxiliary poles, and running at 750 and 500 r.p.m. on a 50-cycle circuit, can be made to run at a third speed of 1,500 r.p.m. by changing the stator winding in such a way that the line currents will produce a 4-pole field.

The $(4+8)$ -pole stator winding (Fig. 27) can be used for this purpose if the two groups of coils of each phase are divided and the neutral point is opened as shown in

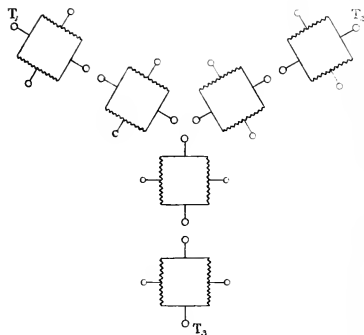

FIG. 28.

Fig. 28. To connect this winding for 8 main poles, we place in series two groups of coils in adjacent sections and then by means of a suitable switch connect the whole winding to form a star, Fig. 29.

Fig. 30 shows the winding re-connected to give 4 poles. The diagram is self-explanatory. This winding requires a large number of terminals, but as the switch for changing the number of poles is mounted on the side of the stator frame this is of no great moment. Unless speed control is required below cascade speed (and this is seldom necessary) the switch for short-circuiting the tappings is also fixed on the stator frame, and then the only external connections are the three line wires and three leads to the slip-rings.

As stated before, the type of rotor winding used for a three-speed motor is identical with that shown in Figs. 15, 16, and 17, and as a motor wound to run at non-cascade speeds corresponding to 8 and 4 poles and a cascade speed corresponding to $(8+4)$ poles, would have a winding with a full 8-pole slot pitch, the rotor winding of Fig. 16 would be suitable for it.

The $(4+2)$ -pole two-speed winding, Figs. 15 and 17, is reproduced in Fig. 31, and the phase of the electromotive force induced in each conductor by a 2-pole field is indicated by the letters A, B, and C in the key diagram, Fig. 33. Again, the instantaneous value of the B-phase voltage is 1.0, and the A and C phase voltages 0.5 each.

An examination of the relative phases of the electromotive forces in each coil will show that those between the mesh and the slip-rings and between the mesh and the neutral point differ in phase by 60 electrical degrees, and the resultant maximum electromotive force is therefore equal to 1.73. In each coil in the mesh part of the winding the two electromotive forces differ in phase by 120 electrical degrees, and their resultant maximum electromotive force is therefore equal to 1.0. Where the electromotive forces in one of these coils belong to phases A and C, the resultant electromotive force is B; where B and C, the resultant is A; and where C and A, the resultant is B. Fig. 34 is the key diagram with these resultant electromotive forces substituted for the two component electromotive forces.

We see from Fig. 34 that the winding has now taken another form, which may be described as a double star-mesh. At each point where three coils meet, the electromotive forces in any two of them give a resultant equal, as regards both amplitude and phase, to the electromotive force in the third conductor. There will therefore be no distortion of the electromotive forces, and these will therefore produce currents in phase with them.

We can now indicate these electromotive forces as currents in the rotor winding diagram and study the distribution of them (Fig. 31). In each slot one of the components of the current in a star bar differs in phase by 120 electrical degrees from the current in the mesh bar, and consequently the resultant of these two currents has the same amplitude as, and is in phase with, the second component of the star current. That is to say, currents in both bars in each slot are equivalent to a single current of twice the amplitude, and of the same phase, as one of the components of the star current. As we have assumed that the amplitude of a single current is 1.0, the heating value of the ampere-bars per slot is $1.73 + 1.0 = 2.73$, and the actual magnetizing value of the ampere-bars is 2.0.

To illustrate this further, let us consider the currents in slot 1. The star bar carries a current made up of two components of phases B and C, and the mesh bar carries a current of phase A, its direction being opposite to that of the component currents in the star bar. As the B component and the A current differ in phase by 120 electrical degrees, the effects produced by them are the same as those which would be produced by a single current of the same amplitude as either of them, and consequently equal to, and of the same phase as, the component current C. As far as the magnetizing effects of the currents are concerned we may then represent them by substituting equi-

valent currents for the actual currents. This has been done in Fig. 33.

FIGS. 35A AND 35B.

Particulars of two three-speed machines may be of interest; the first was built to the specification of Mr. G. H. T. Hooghwinkel, and drives an air compressor

at a colliery in South Wales. It gives 400, 200, and 133 h.p. at speeds of 300, 150, and 100 r.p.m. on a 25-cycle, 440-volt circuit. It is wound for 10, 20, and (20 + 10) poles.

The second machine gives an output of 300, 150, and 100 h.p. at speeds of 300, 150, and 100 r.p.m., on a 25-cycle, 440-volt circuit. The efficiency and power factor curves of this motor are shown in Figs. 35A and 35B. This machine also drives an air compressor used for refrigerating purposes.

This concludes the description of the machine as it stands at the present time. It would be futile to say that its development is complete, for cascade operation is full of possibilities, and we have only recently seen an entirely new development in the speed regulation of induction motors by various methods employing a commutator machine coupled in cascade with the main driving motor. Experiments are now being made with a view to developing a self-starting synchronous motor from the machine described in this paper, by substituting continuous current for the induced stator currents, and starting the machine as an induction motor by resistances connected to the slip-rings. Again, a combination giving a large number of speeds is possible by coupling a change-pole type of squirrel-cage motor in cascade with a two- or three-speed machine, and it is hoped that in the near future something may be done in this way.

In conclusion, the author takes the opportunity of expressing his thanks to those who have so greatly assisted him in the preparation of this paper. To Messrs. T. M. Dutton and H. C. Carter for the various diagrams, and to Messrs. Kilburne and Munzell for the curves reproduced in the paper.

MANCHESTER LOCAL SECTION, 10TH FEBRUARY, 1914.

Dr. E. ROSENBERG: This paper describes the results of at least eight years' hard work on the part of the author in developing one of the most fascinating problems of electrical machine design, namely, the superposition of currents in the same winding. The motor itself is only a little more complicated than the ordinary induction motor, but there seems to be some difficulty in using liquid controllers for these motors, and also in winding the stators for such pressures as 3,000 to 6,000 volts, for which ordinary induction motors are easily wound.

Mr. W. CRAMP: It is well known that alternating-current problems may frequently be simplified by substituting for

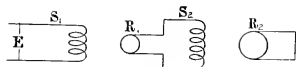

FIG. A.

the actual conditions an equivalent circuit made up of resistances and reactances, with variables to represent the variable factors in the original circuit. Such a plan may be pursued in the case of the cascade motor, and in my opinion it results not only in presenting the problem in a simpler manner, but also in showing how the vector

equation may be written down correctly. Thus in a Mr. Cramp, cascade motor or concatenated pair of induction motors, let S_1 (Fig. A) be the stator of the first motor, having across its terminals the potential difference E , and let R_1 be the rotor of the first motor. Let S_2 and R_2 represent corresponding parts of the second motor. Then the equivalent electrical circuit is represented by Fig. B, wherein the suffixes 1 and 2 refer to the respective motors. The small letters denote complex quantities, and have the following usual meanings: y = stator admittance; z = stator impedance (including reactance due to leakage flux only); r = rotor resistance; x = rotor leakage reactance. If the frequency of the supply be denoted by N , the revolutions of either motor by n , and the number of pole pairs for which either motor is wound by p_1 and p_2 respectively, then the frequency in the first stator is N , and in the first rotor and second stator it is $N - p_1 n$, while the frequency in the second rotor is $N - (p_1 + p_2) n$. Thus in order to represent the circuit conditions exactly, r_1 and r_2 must be assumed to vary with the speed. They then become—

$$N - p_1 n \quad r_1 \quad \text{and} \quad N - (p_1 + p_2) n \quad r_2 \quad \text{respectively,}$$

while x_1 and x_2 remain constant. The magnetizing current of the first motor flows through the admittance y_1 at constant frequency N , while that for the second motor flows

through v_2 with varying frequency ($N - p_1 n$). From this simple diagram, without writing down any equation, we may at once draw the following conclusions and contrast them with the statements made by Mr. Hunt:—

1. The first speed at which the torque becomes zero is when $(p_1 + p_2)n = N$, and the torque of the combination then changes sign. But if the combination be then driven faster, the torque may reverse again before $N = n$, and this will assist the combination to run up to its higher speed when used as a two-speed motor. Resistance in the second rotor reduces this tendency; but with a normal short-circuited rotor it should be very noticeable, although the author does not mention it.

2. It is clear that the behaviour of the motor up to a speed $N/(p_1 + p_2)$ may be approximately expressed by a circle diagram. This diagram becomes simple if the product $e_1 y_1 z_1$ be neglected, so that $e_1 y_1$ is constant; and more simple still if the current $e_2 y_2$ be supposed to be added to

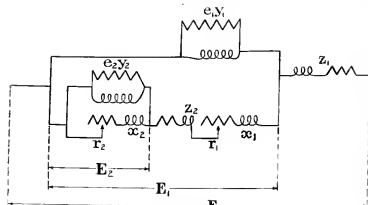

FIG. B.

$e_1 y_1$, and z_1 be added to z_2 . On account of the varying frequency in the reactance z_2 , such a diagram can be used with tolerable accuracy near the point of synchronous

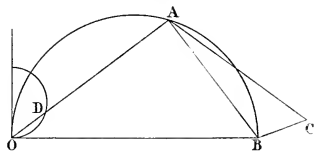

FIG. C.

Current Scale:—

speed of the second motor, if the reactance component of z_2 be calculated for this speed. Fig. C is this diagram on the assumption of a ratio of transformation of unity for the windings; and the various corrections for greater accuracy are easily deduced from Fig. B.* The influence of the

* For similar approximate diagrams and corrections, see W. CRAMP and C. F. SMITH, "Vectors and Vector Diagrams," especially Figs. 83, 84, 95, 109, 110, and 111.

rotor and stator resistance is easily seen and may be compared with the author's remarks on pages 408 and 415. A fact which he neglects is the variation of the magnetizing current of the second motor; this is evidently much smaller and more variable than the magnetizing current of the first motor. This fact contradicts the statements made by the author on page 411 concerning the relationship between the main and auxiliary flux and the main and auxiliary windings, and helps to explain the practical advantage that ensues from different values of the main and auxiliary ampere-turns.

3. In order that the cascade motor may compare with the ordinary induction motor it is clear that the resistances, reactances, and admittances of the cascade pair must not exceed the corresponding values for the ordinary machine. It is in this direction that the author has been so successful, and the combined windings which he has developed have in this their chief importance.

4. The statement made by the author, to the effect that cascade connection of motors is the same as cascade connection of transformers, is seen to be untrue. For the frequency throughout both the transformers is identical, but in the second motor it is lower than in the first. Further, the fact that the first motor develops part of the mechanical power is another cause of difference in the analogy.

It is interesting to see what results one gets in practice from these motors. Some five years ago I put certain machines into operation and the following figures show the results obtained on test as compared with the ordinary slip-ring motors supplied by other firms:—

	Slip-ring Type	Slip-ring Type	Cascade Type
6-h.p. Motor			
Speed ... (r.p.m.)	480	1,420	500
Air-gap ... (in.)	0.026	0.0107	0.0235
Efficiency ...	80 %	82 %	83 %
Power factor ...	0.69	0.85	0.78
12-h.p. Motor			
Speed ... (r.p.m.)	570	570	500
Air-gap ... (in.)	0.026	0.0107	0.0235
Efficiency ...	82 %	85 %	83 %
Power factor ...	0.76	0.82	0.83
15-h.p. Motor			
Speed ... (r.p.m.)	750		500
Efficiency ...	86 %		85 %
Power factor ...	0.80		0.83
30-h.p. Motor			
Speed ... (r.p.m.)	750		500
Efficiency ...	87 %		86 %
Power factor ...	0.87		0.85

In all the above cases the prices were practically equal when switchgear was included; so that the superiority

of the cascade motor for low speeds is very obvious. On page 411 the author states that there is no objection to the increased number of leads. As long as the starting switch can be fixed on the motor this is all right, but if it has to be mounted away from the motor then the cost of the cables is a distinct objection. On page 419 the author refers to the use of the cascade motor for crane work. He says that the machine can be used for cranes. But I think it does not get over the main trouble with induction motors for such work. With series motors and proper resistances very slow movement of the motor with light loads may be obtained, but what happens with the induction motor and the cascade motor is that when there is with a large resistance in the rotor, so as to get "inching," heavy loads, the motor runs away if the load decreases. I think I ought to say, however, that the operation will be better with the cascade motor than with the ordinary induction motor.

At the commencement of the paper the author says that the behaviour of the cascade motor is similar to that of two motors in series on continuous-current circuits. In view of the control question he should say, similar to that of two shunt motors. Is it not true that on his principle the La Cour converter could be made with its two windings on the rotor together, so that its two machines would be merged into one? The stator would then become like the stator of the ordinary series-wound alternating-current commutator motor. Perhaps the author will say in his reply whether he has considered this problem.

Mr. F. C. ALDOUT: The author refers to the improvement in the power factor of the cascade motor due to the resistance of the rotor, and refers to a 50-h.p. motor. This improvement is obtained at the expense of efficiency, and would be smaller for machines of greater output. The same effect is observed due to the resistance of the stator in the case of a normal induction motor where the measured power factor on load is found to be appreciably higher than that calculated from the no-load and short-circuit currents by the Heyland diagram or by the Steinmetz method. This difference may amount to from 4 per cent to 6 per cent on motors up to 50 h.p., but is reduced to 1 or 2 per cent on large machines. The reference to the motor which took less current at quarter load than at full load is interesting. A highly saturated cascade motor will actually take under certain conditions practically constant current at all loads up to full load. The author is to be congratulated on having made it possible to manufacture the cascade motor commercially, because along with the many advantages which that motor possesses there are inherent disadvantages as compared with the slip-ring motor. The periphery of a motor may be divided into what may be described as the "winding space" and the "flux space," the units of which are respectively a slot and a tooth. Whereas in the ordinary slip-ring motor the whole of the flux in a tooth and the whole of the ampere-wires in a slot act upon one another, in the cascade motor two fluxes exist in the tooth and, in effect, two sets of ampere-wires in the windings, and each flux acts upon one set of currents only. In this feature the cascade motor is analogous to a two-speed induction motor with two separate windings. In the last-mentioned case one complete winding is always idle, but the whole of the tooth is utilized with the active winding; in other words,

no "flux space" is ever wasted. As a result of the super-imposed fluxes the value of $\frac{d\Phi}{dt}$ for a cascade motor must be greater than that for a normal induction motor of the same output built under similar conditions. In addition to this, when limited by the saturation of the iron the cascade motor requires a considerably greater depth of stator core in order to carry the two fluxes, thereby increasing the cost of the machine and to a greater extent the overall dimensions. It will be found that for machines designed under similar conditions on the same frame and with the same air-gap, from 15 to 20 per cent less output is obtained with the cascade motor than with the normal slip-ring motor. The power factor of the two machines is about the same and the efficiency of the cascade motor is slightly less. The performance figures given by Mr. Cramp may be correct, but they are of little value for comparative purposes, since no figures are given for the relative overload capacities of the different machines.

The author states on page 415 that the cascade motor can be built either with a smaller diameter or with a higher power factor than the one-field motor. Many low-speed one-field motors with two and three slots per pole per phase in the stator and rotor respectively are built with power factors of 0.8. A cascade motor could be built with a smaller diameter only by using two slots per pole per phase for the primary number of poles; this would give a very low power factor. A further disadvantage is the small choice of speeds, the possible speeds with a 50 \sim supply being 500, 333, and 250 r.p.m., whereas with the normal motor the speeds over the same range would be 500, 428, 375, 333, 300, 273, and 250 r.p.m. From the point of view of the manufacturer this small range of speeds might be an advantage if the machine to be driven could always be adapted to one of the available speeds. The author has referred to the even turning moment of the cascade motor at low speeds. A well-designed slip-ring motor gives a very even turning moment at low speeds, and it is doubtful if anything better is needed. Mr. Cramp evidently misunderstood this remark of the author, who referred to the even torque developed from point to point, and not to the speed variation with varying torque. In the case of a delicate operation such as lifting a pattern from a mould, a great deal depends on the crane driver. Even squirrel-cage motors with high-resistance rotors have been found to give excellent results with sufficiently skilful drivers. The application of the two-speed cascade motor for the driving of winding engines is of great interest, and if feasible should result in a considerable saving of power. The author's remark on page 419, that "This means a reduction of 2.8 units per wind," is rather misleading. The number of units per wind is in no way dependent upon the R.M.S. value of the output of the driving motor. In fact, in certain cases the number of units per wind might be lower for a greater R.M.S. value. The saving could never be quite as great as that shown, since the cascade connection could never take the motor quite up to cascade speed owing to the slip and to the fact that resistances are always in circuit. A disadvantage is that the tapping voltages are high, especially on a 3,000-volt motor, where the electromotive force between the tappings would on reversal be of the order of 2,000 volts and might cause flashing over in the controller. I believe the case referred to by the author is for 2,000 volts; the electromotive force between tappings

on reversal would then be of the order of 1,400 volts. The control gear would also be complicated, and it is doubtful if many mining engineers would be prepared to sacrifice the simplicity of the slip-ring motor for a slight reduction in the energy consumption.

Mr. W. BOLTON SHAW: When the author read his previous paper I doubt was expressed by some of those who took part in the discussion as to whether there was any real advantage in being able to run a three-phase motor at two speeds. I think it is now generally accepted that there are many advantages. The author mentioned a number of applications of the cascade motor. One application to which I should like to refer and which has not been mentioned in the paper is their use for driving large dock pumps. Some years ago I was interested in a scheme where three-phase electrically-driven pumps of over 1,000 h.p. were put forward in competition with engine-driven pumps. The heads against which the pumps had to lift varied from a few feet to over 40 ft., and with the cascade motor arranged for three and even two speeds the scheme put forward was very favourable. The advantage of getting rid of slip-rings in mining work, and particularly on high-speed motors, is obvious, and there is one direction in which it appears to me that the cascade motor would have considerable value if it could be applied, i.e. the driving of high-speed pumps. I understand that up to the present time the problem is one which has not been solved, and that the cascade motor is only designed to run at speeds up to 500 r.p.m.

Professor E. W. MARCHANT (communicated): The author gives in his paper many facts which should be of great value to designers of cascade motors, such as the most desirable ratio to use for the two rotor windings in order to obtain the greatest winding efficiency for the motors. Data such as these are the result of long and arduous experiment, and they cannot fail to be of value to electrical engineers generally; the paper indeed is one which I am sure will, in the future, be a standard for reference on these motors. During the last few months we have had the opportunity of testing a 10 h.p. motor which has been presented to the Electrical Engineering Department of Liverpool University by Messrs. Sandycroft, and I think the results which we have obtained may be of some value. With this motor the power factor when the motor was running at full speed and maximum load was 0.88. When running at cascade speed the current was 30 amperes and the power factor 0.76. The slip at full-load speed was 5 per cent, and on cascade it was 8.8 per cent with the rated current of 21.5 amperes. One of the best and most useful features of this motor is the ease with which a powerful starting torque can be obtained with the cascade connection. In order to obtain this result with ordinary induction motors, large and expensive starting resistances have to be employed; in this case, with the very simple form of liquid starter fitted, with drums containing less than a quart of soda solution, regulation to give full-load starting torque was easily made, and the motor was, if not easier, at least as easy to start and regulate as a continuous-current motor. A motor of this type, in which a powerful starting torque is obtained so easily, should prove of the greatest value for such purposes as lifts or cranes, or for railway operation.

* Journal I.E.E., vol. 39, p. 648, 1907.

Speaking generally, the drawback to cascade motors is that there are two sets of windings, one for each of the cascade motors, even when the windings are combined, as they are in this motor, on one armature. The natural consequence of this is that the motor becomes relatively inefficient, since there are two sets of copper losses when the motors are running in cascade. One of the many improvements made by the author on the original cascade motor is in having so designed his windings that these losses are minimized by the balance of the currents in the two windings, whenever this is possible. The cascade principle, as the author points out, is capable of further development, but even the development up to the present time has enabled a motor to be produced which possesses qualities that the engineer of a few years ago would have regarded as almost impossible for an induction motor; perhaps the greatest of these is that the motor can run continuously at two or even three speeds without regulating resistances of any kind, and that its efficiency at the lower speed is almost as high as it is when the speed is the greatest possible.

Mr. L. J. HUNT (in reply): Dr. Rosenberg referred to the possibility of using liquid controllers with cascade motors. Controllers of this type have proved entirely satisfactory and have been largely used for all voltages up to 2,200. It must be remembered that the pressure across a pair of tappings is only about 30 per cent of the line voltage, so that even with 2,200-volt motors the pressure across each liquid starter at the moment of starting is less than 700 volts. Motors for pressures up to 3,300 volts are in regular operation, and no insulation troubles have been experienced. Of course the controllers must be insulated for the full line voltage to earth, and by making liberal use of porcelain there is no difficulty in doing this. In the case of two-speed motors where no speed regulation is required below cascade speed, the starting switch is connected to the rotor and only a short-circuiting switch, mounted on the stator itself, is required.

Such an arrangement is not possible in the case of winding engines; and for high-voltage machines, in order to simplify the gear as much as possible, it will be well to return to a double winding for the stator—one winding for the line currents and the other for those induced by the second field. The saving that is effected by the use of a single winding is not nearly so great in the case of motors used for driving winding engines, because they are nearly always wound for high voltages. If two distinct windings are used, the one wound for high tension may be wound for one coil per pair of poles, so that there will be only one coil section to be insulated in each slot instead of two. This results in a considerable reduction in the space occupied by insulation. The secondary winding will be wound for, say, 500 volts, and will have only three terminals, so that a controller of standard construction may be used. The use of two stator windings will necessitate an increased length of core, and in a 3,000-volt machine of, say, 600 h.p., a drop in the efficiency of something less than one per cent. It will entail an increase in the cost of the motor of $\frac{7}{10}$ to 10 per cent, but this will be more than counterbalanced by the saving in the controller.

It is always valuable to have a case presented from a different point of view, and by introducing the circle diagram, Mr. Cramp has made the theory of the machine

Mr. Hunt.

clearer. He referred to the possibility of a cascade or two concatenated motors running at speeds other than cascade. The top speed of a two-speed motor is reached when $p_1 n = N$, and if the stator tapping switch is closed and the slip-rings are open-circuited, the motor will continue to run at full speed although connected in cascade. If the tapping switch is opened and the motor be allowed to slow down to a speed slightly higher than the mean of the full and cascade speeds, and then the tapping switch be closed again, the machine will accelerate to its top speed. If, on the other hand, the speed be allowed to fall slightly below the mean speed, the machine will develop negative torque and the speed will fall to its cascade value. When running at full speed and connected in cascade the second field is very small, for the frequency of the induced stator currents is approximately $p_2 N/p_1$ and a very small field will induce the necessary voltage to overcome the impedance of the stator winding. If a cascade motor be connected to the supply mains with its stator tappings closed, and if it be run up to speed by starting and running up the generator driving it, it will run through cascade speed to full speed. This will only happen if it is running absolutely light; but as the torque developed is extremely small, it will not run above cascade speed if belted to a loose pulley. When started with resistances connected to the tappings, it is absolutely impossible for it to pass cascade speed.

Mr. Cramp referred to the variation of the magnetizing current of the second field. In pointing out the effect of the rotor resistance on the power factor, I omitted to mention specifically the causes of this. In a motor of ordinary construction the effect of stator resistance is twofold. It improves the power factor by causing the magnetizing current to decrease with increasing load, and it also shields the rotor windings from a part of the stator self-induction, and thus reduces the demagnetizing component of the rotor current. In a cascade motor this effect is increased by the presence of magnetizing currents in the rotor winding, so that both the stator and the rotor resistances reduce the demagnetizing components of the currents in the tapping circuits, and decrease the magnetizing current of the second field.

Mr. Cramp has misunderstood the statement on page 411 with reference to the relative values of the magnetizing currents. The statement refers to the values of the currents at no load, and the knowledge of their respective values enables us to determine the coefficients of mutual inductance.

He also finds fault with the comparison of the cascade coupling with two transformers connected in series; here again the disagreement is more apparent than real. It is stated on pages 417 and 418 that it has been found convenient to calculate the characteristics of a cascade motor when the frequency is the same in all the windings, that is to say when the machine is at rest; and it is when so treated that the circuits of the motor are identical with those of two transformers connected in series.

I do not think there would be any difficulty in merging the two separate machines forming the La Cour converter into one machine in the way suggested by Mr. Cramp; in fact a patent covering such a machine has been in existence since 1906, but lack of time has prevented experiments from being carried out on these lines.

Mr. Aldous also referred to the effect of the resistance of the rotor windings on the power factor, and mentioned that any improvement that can be obtained is at the cost of the efficiency. This is only true within certain limits, and to illustrate my meaning let us consider a motor of ordinary construction. Here the stator resistance can improve the power factor, but the rotor resistance can have no effect upon it. Let us suppose that means are at hand to ensure effective cooling of the stator windings; then we may cut down the cross-section of the stator copper and correspondingly increase the area of the rotor copper so that the total copper losses remain the same as in the original machine. In this way we can greatly improve the power factor without reducing the efficiency. In the cascade motor the greater part of the copper loss directly affects the power factor, and it is for this reason that these losses have a greater effect upon the power factor of cascade motors than do those of ordinary machines. The improvement in power factor by stator resistance (the only resistance effect in ordinary motors) is shown in Fig. 19 (curve II).

With regard to the question of relative dimensions, Mr. Aldous is comparing ordinary motors having semi-closed stator slots with cascade motors having open stator slots, and since he had the opportunity of making such comparisons numerous modifications in the designs have been found possible. Recent experiments have shown that it is possible to increase the density in the iron at the back of the slots; and in the latest designs of these motors the iron has been so much reduced that in many cases its depth is determined by mechanical requirements only. It is true that in the stator there are two distinct currents, but as they both flow in the same windings the heating value is only equal to their geometrical sum. There is considerably less copper in a cascade motor than in a one-field machine, and after allowing for the absence of slip-rings, short-circuiting gear, and brush-lifting devices, the works cost of such machines is lower than that of slip-ring machines of the same rating. In comparing cascade motors with slip-ring machines made by one of the largest manufacturers, it has been found that, for a given rating, the diameters are approximately the same, and the lengths 10 per cent greater. Mr. Aldous mentions that one-field motors are built with two and three slots per pole per phase in the stator and rotor respectively, when wound for low speeds; but the same equally applies to cascade machines, so that the latter still only require two-thirds the number of slots of the ordinary machine.

I quite agree with Mr. Aldous that a well-designed slip-ring motor will develop a fairly even turning moment at low speeds, but it is a question of degree, and the fact remains that the cascade machine is so superior in this respect that it is constantly being specified to drive machines where creeping is required, because manufacturers of ordinary machines are unable to give the necessary guarantees.

Professor Marchant mentions 8.8 per cent as the slip of a small motor which he has been testing. There must have been some resistance in the circuit to account for this excessive slip. When tested at the works the figure obtained was $\frac{2}{3}$ per cent.

Mr. Hunt.

YORKSHIRE LOCAL SECTION, 11TH FEBRUARY, 1914.

Pohl.

Dr. R. POHL: The author has undoubtedly succeeded in turning an almost purely theoretical idea into a practical machine, and the electrical industry owes him a debt of gratitude. This, however, need not prevent us from criticizing his paper. Very frequently when a new machine or appliance has been perfected for practical use it is applied not only within but beyond the borders of its legitimate field, where its use does not represent either an improvement or an economy. This, in my opinion, applies to the cascade motor when it is employed as a constant-speed machine. Its legitimate field lies within the wide range of variable-speed work, and I think it requires more than common enthusiasm to adopt it in place of an ordinary induction motor for constant speed. Let us analyse its advantages and disadvantages. Comparing it with a squirrel-cage motor it has only serious disadvantages, and where the starting torque required permits of the use of a squirrel-cage motor the cascade motor is obviously inapplicable. Coming to the slip-ring machine, the cascade motor for constant speed has the advantage of not possessing slip-rings. Superficial observation might lead one to think its rotor is equivalent to a squirrel-cage rotor. This, of course, is far from being the case. A squirrel-cage rotor, besides having no slip-rings, does not rely for its performance on any insulation; and in modern examples it has no soldered joints. It is therefore free from the four chief causes of trouble possible in a slip-ring rotor, namely, short-circuits, earths, bad joints, and slip-ring trouble. The cascade rotor only avoids the last, and so far from being free from possible trouble due to short-circuits or earths, it seems to me that there is a danger of such faults being more detrimental here than in the ordinary slip-ring machine. I should like to ask the author whether there is not under certain conditions the possibility of a cascade motor running up to a speed above the normal if short-circuits or earths occur in the rotor. For example, since a two-speed cascade motor for 500 and 750 r.p.m. is made to run at the higher speed by short-circuiting certain points in the rotor winding, cannot unintentional short-circuits cause a motor, designed for a speed of 500 r.p.m. only, to race until its speed reaches 750 r.p.m. The absence of slip-rings is undoubtedly a very valuable feature, but it must be considered that only the constant-speed cascade motor, and not the two-speed or three-speed motor, is without slip-rings, that this constant-speed motor is essentially a low-speed machine, and that the slip-rings which it is proposed to displace would naturally be fitted with brush-lifting and short-circuiting gear, and would run at a low speed. Whilst I admit that high-speed slip-rings for large and continuous duty are probably the most vulnerable part of a machine fitted with them, I suggest that the kind we are here considering, if properly designed and made, is a highly reliable and straightforward piece of mechanism requiring practically no attention. The absence of such slip-rings in the cascade motor has been obtained at what I consider to be far too great an expense, namely, not only a complication in the rotor windings themselves, but a more serious one in the stator windings. These must always consist of two parallel circuits, necessitating twice as many conductors in the stator as in any ordinary

Dr. Pohl.

machine—a serious disadvantage in all machines, but particularly so in high-tension machines. Then there is the addition outside the symmetrical coils of a large number of joints and connections (which form the weakest part in windings and should always be kept down to a minimum), an extraordinary number of leads and terminals, a starting resistance consisting of 3 or 4 individual resistances connected by a large number of cables to the windings, and a type of winding very difficult to follow and almost impossible for any ordinary works or colliery electrician to repair. In addition to these disadvantages, the power factor of the machine is rather worse due to the long end connections, and the magnetic field consists of two superimposed fields creating a very high peak at one point equal to the arithmetical sum of the two maxima, thus necessitating low average densities in order not to reach saturation at this point.

On coming to variable-speed work, we reach the legitimate field of the cascade motor. I was particularly pleased with the application shown for colliery windings, plants, and other cases where frequent starting and stopping are needed. I believe that here is a wide field which presents many opportunities for useful application of the author's motor. I do not consider it is applicable, however, to colliery fan-driving except in rare instances. The author has given an example of a fan drive on page 418, where a fan has to run at between 400 and 600 r.p.m. on a 40- \sim circuit, requiring 30 h.p. at the bottom speed and 120 h.p. at the top speed. I suggest that a better solution of this engineering problem would have consisted in the use of a 120-h.p. slip-ring motor, designed with no other view than the best possible operation at its full power at 600 r.p.m., and of a 30-h.p. squirrel-cage motor direct coupled on to the shaft of the 120-h.p. motor, and designed for a speed of 400 r.p.m. I take it that the fan in question would generally be run at the top speed during the week and at the bottom speed at weekends. The small squirrel-cage motor might be simply connected to the mains without any starting gear, and the installation would be simple, highly reliable, and economical in first cost and running cost. It should be pointed out, however, that in the vast majority of cases the speed variation required for a colliery fan is less than 33 per cent, and as the cascade motor unfortunately does not give a smaller speed-step than in the ratio of 3 to 2, it is generally impracticable to take advantage of it for colliery fan-driving.

I was particularly interested in the author's remarks on inching. The question whether a motor is suitable for inching work or not depends of course on the uniformity of the starting torque, irrespective of the relative position of the rotor slots to the stator slots. Some years ago I carried out a series of experiments to determine the variations in the starting torque of 3-phase motors as a function of the position of the rotor. As a result, I am able to state that if the number of slots in the rotor and stator is carefully chosen so as to get as nearly as possible uniform magnetic reluctance, it is possible to obtain almost exactly constant starting torque. To obtain this, it is also desirable to skew the rotor slots by one slot pitch. Motors made in

Dr. Pohl. this manner present no difficulties when used for inching work.

In conclusion, I would venture to express a somewhat bold opinion on the general principle of cascade control, and I am not thinking of the author's ingenious motor only, but also of the many other applications of this principle for obtaining varying speeds in 3-phase plants. I believe that it is a kind of "blind alley" development. It certainly has brought us nearer to the goal, *i.e.* a 3-phase motor variable within wide limits without speed steps and comparable with a continuous-current interpole motor, but it can only lead a certain distance towards this goal, and we shall ultimately have to retrace our steps and reach our destination by another route. It looks at the present time as if this different route would involve the use of commutators; but even this may not be the ultimate outcome of the work on which many keen investigators are engaged at present. I hope that Mr. Hunt, who has shown such admirable skill, ingenuity, and patience in the development of the cascade motor, will also apply these qualities to the development of a machine which lies in a more direct line of progress than, in my opinion, the cascade motor seems to do.

Mr. Wright. Mr. H. H. WRIGHT: In spite of what Dr. Pohl has said in criticism of the Hunt cascade motor I think it has a distinct, though limited, field of usefulness, which cannot be filled by either the slip-ring or squirrel-cage induction motor. For winding engines, haulage, and printing machinery, it is distinctly an advance on account of its smooth starting and large torque with a moderate current at very low speeds. It would be interesting to hear whether the author has applied this motor to the propulsion of ships, and if so with what result. I think it might there be applied with success, particularly if the frequency of the current supplied by the alternator could be varied so as to increase the range of speed. On page 414 the author mentions in connection with the one-speed motor that the stator slots are of the completely open type. This being so, are the slots bridged over with a narrow strip of iron after winding is completed, and are the stator coils former-wound?

Mr. W. E. BURNARD: Where a heavy starting torque is unnecessary I believe that a plain squirrel-cage rotor with a pole-changing arrangement on the stator, similar to that described last year by Messrs. Nicholson and Haigh,* would be equally efficient and somewhat more simple than the cascade arrangement; but of course, owing to the combination of the starting torque with efficient speed variations obtained in Mr. Hunt's machine, I think there is a certain field for this which is filled more efficiently by the cascade arrangement than by any other machine at present available. One of the first things that impressed me in connection with the paper was the widely varying application of similar principles with which we keep coming into contact: for instance, the recent developments in extra-high-frequency alternators for use in wireless telegraphy involve substantially the same principles as the Hunt cascade motor, whilst Fig. 2 shows the same principle that is utilized in the phantom circuit of ordinary telegraphy, whereby two circuits are made to act as three without interference.

I wish to make two very minor criticisms of the paper,

* J. S. NICHOLSON and E. P. HAIGH. "A Single-phase Motor with Pole-changing Windings." *Journal I.E.E.*, vol. 50, p. 268, 1913.

the first being that I do not think the analogy given in the opening paragraph under "General Principles," a good one. The two continuous-current machines mentioned by the author would only run at the speeds mentioned if they were shunt-wound with the fields in parallel and the armatures in series; also the speed ratios are dependent on the relative voltages of the two machines and have nothing to do with the poles; whereas the cascade principle in alternating-current machines is a matter of poles and not of voltage ratios. The continuous-current analogy also does not involve the double transformation of power for the second motor. The second point is on page 408, where it is stated that "in an ordinary induction motor the resistance losses in the rotor do not influence the primary power factor." This statement is often made when describing the circle diagram for the induction motor. Whilst this is undoubtedly correct for a given input to the motor, also, for a given torque, it is not correct for a given output which is really the purpose for which the motor is used. As is well known, to increase the resistance of the rotor increases the slip in practically the same proportion as the resistance without affecting either the ampere input or the power factor for the same torque; but to obtain the same power in watts or horse-power, obviously the torque must increase in the same proportion as the speed decreases. Considering the circle diagram, therefore, to get this increased torque the point of input has to move forward in exactly the same manner that it would move for a larger load; this in turn has exactly the same effect as regards the primary power factor as an increase of the load, and it may either increase or decrease this power factor according to whether the machine is already lightly or approximately fully loaded. If lightly loaded, the effect would obviously be to increase the power factor, but of course that is one of the worst methods of doing so. I think the complication of the cascade motor is more apparent than real, and is due to our being less familiar with this machine than with, say, ordinary continuous-current machines. I am not, however, a great believer in simplicity as the measure of fitness of a machine; what we require in a machine is that it shall be more fit than its predecessors for the end desired.

Mr. J. C. B. INGLEBY: In view of there being such a multitude of closed and paralleled circuits all round the stators and rotors of these motors, would not a difference in the length of the air-gap—say, caused by wear of the bearings—have a tendency to create excessive heating or serious out-of-balance currents locally on the stators or rotors? It would be interesting to know whether the relative magnetic flux density in the stator and rotor teeth, in respect to the density in the air-gap, is of great importance in choking down such out-of-balance currents.

Mr. L. J. HUNT (*in reply*): Dr. Pohl objects to the use of cascade windings for a constant-speed motor, and his criticism in the main consists of a comparison of the cascade with the squirrel-cage motor, much to the advantage of the latter type of machine. In writing this paper I have endeavoured to point out the various classes of drives for which in actual practice the cascade motor has proved its superiority. It has never been suggested that this motor meets every case, and where the conditions permit of the use of squirrel-cage motors it would be folly to consider any other type. But much has been done to

Mr. Burnard

Mr. Ingleby

Mr. Hunt

discredit this extremely useful machine by the reckless way in which it has been installed, often to meet conditions for which it is entirely unsuitable. We can all probably recall instances where squirrel-cage motors have been installed to drive machines the starting conditions of which have been very severe, resulting in difficulties and serious trouble. I can recall an instance of this where large squirrel-cage machines were installed for driving air compressors. The machines were quite incapable of accelerating under load, and the compressors had to be started by admitting air to the cylinders. Needless to say, all the rotors had to be removed and new ones with slip-rings installed instead.

Winding diagrams necessarily look complicated, and those of the cascade machine are no exception to the rule, but there is a considerable difference between the finished windings and the paper representation of them. The actual machines are extremely simple and there is not on record a single case of any of these one-speed rotor windings breaking down from electrical causes. It may surprise Dr. Pohl to hear that as the result of practical experience these machines are being exclusively used in a large number of installations where high-speed machines could have been used at a considerable saving in initial outlay.

It must be borne in mind that, owing to the large number of parallel paths in the rotor windings, the maximum possible voltage is very small, and a further advantage is obtained by the self-balancing effect of this construction. In order to investigate this property, tests were made some years ago, first with a series coupling of the rotor windings and afterwards with parallel connections, and it was found that owing to the automatic balancing obtained with the latter, the magnetizing current and the no-load watts were quite appreciably reduced. The suggestion made by Dr. Pohl, that a single-speed motor might run at 50 per cent above its proper speed if a short-circuit occurred in the rotor, is very interesting, and at first sight there might appear to be something in it, but he has overlooked the fact that the omission of certain of the rotor bars renders it absolutely impossible for the current distribution to become uniform, the condition necessary for super-cascade speed. As a matter of fact it is extremely difficult to detect a short-circuit in the rotor windings unless a motor be allowed to stand for quite a considerable time with full voltage on the stator. On one occasion a motor went through all its tests perfectly satisfactorily, and it was not until a final trial was made, with the rotor standing for some time, that it was found that a short-circuit caused by the presence of solder had existed whilst all the tests were being made.

Dr. Pohl criticizes the parallel-connected stator windings, and is under the impression that they must require twice as many wires as a series winding for an ordinary motor wound for the same speed. He has, however, overlooked the fact that a 12-pole cascade motor is wound for only 8 poles. With regard to the question of power factor, the cascade machine has a distinct advantage over the one-field machine, especially when wound for very low speeds. It should be pointed out that all the machines described in the paper have completely open slots. If they had semi-closed slots very much higher figures could be obtained. Cascade motors with semi-closed stator slots are being built by Continental makers of these machines.

I much value Dr. Pohl's opinion as regards the suitability of these machines for driving winding engines. Results already obtained are very encouraging, and in a few weeks test figures will be available on some large winders that have recently been started up.

I am surprised that Dr. Pohl does not consider these machines suitable for driving colliery fans, because in this connection and in the driving of air compressors the multi-speed motor has met with considerable success. The horsepower required to drive a fan falls rapidly with the speed, and that is the reason for operating the motor in mesh for full speed and in star for cascade speed. This change in connections gives a much reduced magnetic flux in cascade, so that a standard slip-ring machine may be employed without fear of over-saturation of the iron at cascade speed. The difference between a two-speed fan motor and a standard slip-ring machine is only a change in the end connections. The arrangement suggested by Dr. Pohl would be much more expensive, occupy more space, and be more complicated.

I now come to the question of inching, and I have no doubt that Dr. Pohl can obtain by very careful design excellent properties with a one-field motor. I am constantly hearing that manufacturers will not guarantee very low-speed running with slip-ring machines; and to illustrate this it is only necessary to mention that at the present time cascade motors are being installed in a steel works in Sheffield for the operation of steel converter plant, where it was originally intended to use slip-ring machines running at 750 r.p.m. After seeing cascade machines running at creeping speeds the engineer decided to change his gearing and install machines of this type wound for 500 r.p.m.

Mr. Wright referred to the application of these machines to marine propulsion. A good deal of consideration has been given to this subject, but time has not permitted of any experimental work. It is not at all difficult to design alternators for two numbers of poles in the ratio of 2:1; and with such a machine and a two-speed motor, propeller speeds can be obtained in the ratio of 6:4:3:2 and all the starting can be done by means of slip-ring resistances.

The stator slots of all the motors described are of the completely open type without any form of magnetic bridge, and the rotor slots are of the semi-closed type. The stator coils are former wound.

In reply to Mr. Creedy, patents have existed for some years for the application of the single-core cascade principle to machines having commutators, but the development of the induction type of machine has occupied all the available time.

Mr. Burnand referred to the application of pole-changing arrangements to squirrel-cage motors for starting purposes. A motor of this type was developed in 1903 and 1904 and has a high-resistance squirrel-cage winding to which is connected, at certain points, a low-resistance ring. This machine is fully described in the 1910 edition of Mr. Hobart's book entitled "Electric Motors." Machines of this type proved quite successful and will start a load with considerably less current than ordinary squirrel-cage machines.

Mr. Ingleby raised the question of out-of-balance currents due to the parallel connections of the windings. As has been explained in replying to Dr. Pohl, these parallel con-

nections enable the motor to operate satisfactorily even when the rotor is very badly out of centre. In each phase of the stator winding the two parallel paths are interconnected at three points; this feature gives the winding great flexibility. Mr. Ingleby also asked a question as to the comparative weights of a cascade machine and two

separate machines connected in cascade. In the case of fan driving, the weight of the two-speed motor would be the same as that of the first machine of the separately connected cascade set, so that the weight of the latter would be that of the two-speed motor plus that of the second machine.

DISCUSSION ON

"BRITISH PRACTICE IN THE CONSTRUCTION OF HIGH-TENSION OVERHEAD TRANSMISSION LINES." *

SCOTTISH LOCAL SECTION, 3RD FEBRUARY, 1914.

Mr. D. M. MACLEOD: The author has done well to call attention again to the unsatisfactory position of the law pertaining to the erection of overhead lines by electric supply authorities. As matters now stand, the delay in getting an overhead line approved is a most serious handicap to power development. Wayleaves have to be arranged with the ground superiors and permission obtained from the agricultural tenants, and plans and specifications have to be issued to the Postmaster-General, the Board of Trade, and the local authority; five parties have thus to be satisfied before the work becomes an accomplished fact. In my opinion the requirements of the Board of Trade and the Postmaster-General could quite well be met by the issue of suitable regulations, specifying the requirements of the two departments and framed on similar lines to those recently issued by the Home Office. In addition to this, detailed constructional plans that have been approved and certified might be held as evidence of the consent of the above departments, and as such could be submitted to the local authority; such plans could be approved for a period of five years unless revoked earlier. It seems unnecessary that the same formality should have to be gone through for every new line. It is particularly gratifying to note Mr. Trotter's remarks with regard to carrying overhead lines by the side of public highways. These remarks augur well for the relaxation of the stringency of the Board of Trade Regulations dealing with the angle at which a public highway may be crossed. In some cases it is necessary to use underground cable for road crossings on account of it being impracticable to meet the conditions for an overhead crossing. I wish also to endorse the author's remarks as to the importance of carefully surveying and setting out a line. In my opinion the success of an overhead line depends almost as much upon its position as upon its construction. Due allowance must be made for the fact that in the United Kingdom the prevailing wind in stormy weather is south-westerly in direction. If through ignorance or neglect of this fact an engineer builds a line immediately to the north of a tree or plantation, the first gale will cause small branches to be detached from the swaying trees and carried sometimes 15 or 20 yards until they fall across two or more of the conductors. This factor is so important, not only from a

supply point of view but also from a public safety standpoint, that it ought to be laid down as a standing regulation that no high-tension line should be carried past the north side of a tree or plantation at a less distance from it than 40 yards.

Reference is made in the paper to the split-conductor system. It seems to me that this system as applied to overhead construction has very little to commend it, for the very simple reason that for a given total sectional area of line twice as many insulators have to be used as if only one circuit were employed. I think it will be conceded that the insulator is the weakest part of overhead construction; if that is granted, then doubling the number of insulators doubles the risk of failure. If I correctly understand the Merz-Hunter system, the failure of one line causes both circuits to be automatically made "dead." For three-phase overhead construction I am of opinion that a single set of conductors with Merz-Price balanced protective gear employing bare pilot wires requires a lot of beating. With reference to the author's suggestion to use insulators of different colours for each circuit, I am not sure that there is much need for such discrimination, as it seems to me to be inherently bad practice to attempt to carry more than one circuit on any given pole line on account of the great risk of fatal accidents. The colour which is found to attract least notice from wayfarers is dark brown. It is only necessary to look at the condition of some of the Postmaster-General's white porcelain insulators to be convinced that white is a colour to be avoided for high-tension transmission-line insulators. I understand that celluloid envelopes for attachment to the top of insulators are largely used all over the Continent. In actual practice it is a matter of great difficulty without some such device to locate punctured insulators, as testing appears to show that the line is in good condition. In wet weather particularly, even a sound line seldom shows more than a few hundred-thousand ohms insulation resistance. With the provision of a celluloid cap fitting tightly round the neck of the insulator, as soon as an insulator fails the celluloid cap is burnt. For a while the Clyde Valley Electrical Power Company were very much troubled with punctured insulators; it was found by careful observation that the cause was due to unequal expansion in the insulator itself. After a spell of warm weather, when the long

* Paper by Mr. B. Welbourn (see pp. 177, 217, and 302).

channel arms were exposed to the sunshine of a hot day, it was found that the heat was conducted from the arms by the steel pins to the inside of the porcelain, which was thus maintained at a high temperature. When a cool breeze arrived, internal stresses were apparently set up, and it was only a question of time before fissures began to develop in the insulators, eventually leading to a failure. We have had as many as six punctured insulators over a length of one mile. It would naturally be expected that warm weather would be particularly favourable to overhead transmission, but this is only so when suitable provision is made for dissipating the heat from the sun-baked ironwork. Experience goes to show the wisdom of making the cross-arm construction as light as possible, consistent with mechanical strength; and the use of reinforced wooden insulator-pins are found very effective in arresting the conduction of heat to the inside of the porcelain. I am rather surprised to observe that no reference is made to trouble arising from birds settling on overhead lines. The terminal pole arrangement shown in Fig. 12 is one which seems liable to disturbance from birds settling on or about the choke coils. On the lines for which I am responsible the bird trouble has been effectually overcome by the use of treble insulation on all terminal and turning poles.

Mr. E. SEDDON: The reason for our lack of knowledge on this subject is probably due to our natural and abundant coal resources, together with the densely populated towns which have contributed largely to our placing stations just where the supply of electricity was required, and consequently there has been practically no alternative but to develop the underground cable system. Engineers abroad had to face a different position, as most of their power resources were in another form and far away from the area of supply. Consequently, the overhead system appeared to be the only practical method of transmission, so that all our early information on the subject was imported. But now we are collecting data of our own from British experience, and if we are to realize in practical form such a scheme as that outlined by Mr. McWhirter for utilizing the series of lochs between Fort William and Fort Augustus, we shall then no doubt have a transmission system that will rival those on the Continent. In comparing the relative costs of the two systems, the author has probably been a little conservative with his figures for cables. When a new cable route is commenced there is the temptation to lay down many more ways than would be required in the immediate future: also, large street boxes are built to accommodate all the future cables. This extra expense is idle capital for many years, although of course it may prove a good investment later as the business expands. I see that no reference is made in the paper to reinforced concrete poles. Are these unsuitable because of the electrolytic corrosion that is likely to occur and cause cracking? I should like to ask the author what objections there are, if any, to earthing one phase of the line. It seems to me this would considerably cheapen the construction, as only two insulated wires would be required and the earthed line wire might then take the place of the ordinary earth-wire. Perhaps there are Board of Trade objections to this procedure. With regard to arresters, I have had experience with the aluminium type and I consider it a very reliable piece of apparatus. In positions

where persons are more or less in constant attendance, the daily charging of the arrester is not a very troublesome operation. There is the advantage that the horns are cleaned of dust at the time of charging. For station use it is desirable to have some device fitted to give an alarm each time that the arrester operates, so that the time of each discharge can be recorded—this time might be found to coincide with some fault on the system.

Mr. J. A. ROBERTSON: I should like to ask the author whether the estimate on page 178 is for underground cables laid solid or drawn into conduits. I made an estimate recently for a similar size of cable at 10,000 volts, and the price for underground work varied from £1,150 per mile for laying direct in the ground to £1,850 per mile for drawing in fibre conduits. We adopted the latter system as immediate economy was not of primary importance. The cost of an overhead line for the same duty amounted to £620 per mile exclusive of wayleaves, which I understand the author has capitalized in his estimate. I am pleased to note that he has not joined in the criticism (much of it ill-informed) which has been levelled at the Board of Trade in recent years. I agree with Mr. Trotter that the Board of Trade Regulations are really a record of the best practice, and I think it is general experience that the Board is always ready to consider new circumstances as these arise. No doubt it would be convenient to have a standard system of overhead construction as pointed out by Mr. Macleod, but it is extremely difficult to say how such a system could be devised in view of the rapid development in appliances and methods of construction. I should also like to ask the author whether he can explain the curious fact brought forward in the London discussion: that snow does not accumulate on overhead aluminium conductors while current is passing through them. I have heard it suggested that oxide of aluminium is a non-conductor and that the effect is due to electrostatic causes.

Mr. B. WELBOURN (*in reply*): In reply to Mr. Robertson, the figures on page 178 are necessarily representative of the general case. They were taken from actual contracts which in my opinion represent average conditions. The cables are armoured and laid direct. The cost of the overhead line does not include the capitalized value of wayleaves, and it is perhaps higher than in the case cited by Mr. Robertson, because a lead-covered telephone cable is included. With regard to the behaviour of aluminium in a snowstorm, there is an extraordinary divergence of opinion. Some Canadian engineers are emphatic that aluminium does not gather snow; but I know that on an aluminium line in this country sleet and snow did collect. I think that experiments on this subject should be made with both old and new copper and aluminium wires, and there is reason to think that the matter will soon be cleared up by independent investigators. I was pleased to hear the remarks in support of the factors of safety prescribed in the Board of Trade Regulations.

In connection with Mr. Macleod's suggestion of obtaining rules from the Board of Trade to cover all lines to be constructed during a period of five years, I think it might be rather unwise, in view of the number of changes that take place, to tie one's hands for five years. In five years we have got away from the complicated cradle-guards required by the Board of Trade, and in another five years we may have done away with guard wires altogether. As

Mr. Seddon.

Mr. Robertson.

Mr. Welbourn.

regards the split-conductor system, it is quite true that the parallel circuits are both shut down in the event of a fault, but actually they should be considered as one circuit. I have seen and heard about the celluloid caps for insulators, but I do not know of a case in this country where they have been used. It is probable that Mr. Macleod's trouble with burst insulators would disappear if he would adopt heavy twine packing when fixing the pins. This would allow for the expansion of the pins and insulators. With reference to reinforced concrete poles, so far as I know these have not been used on high-tension lines in this country, but I know of two low-tension lines where they are used. One of these is in a chemical works where neither wood nor steel would stand, and the results have been good.

WESTERN LOCAL SECTION, 16TH FEBRUARY, 1914

Mr. C. T. T. ALLAN: The author has referred to binding where the lines are on level ground, but makes no mention of binding on steep slopes. There are some cases in South Wales where the gradient is 1 in 3. With ordinary side binding the conductor will rest on the top shed, owing to the slope of the hill. For level country we use the ordinary Post Office side binding with chafers wire; and for slopes we rest the conductor in the top groove of the insulator and bind it in with strands of the line wire, which are secured at each side by Crosby clips costing about 1d. each. We have had no trouble whatsoever with these two binders. I should very much like to have the author's views on the position of the earth-wire. American engineers place it above the conductors, while we for other reasons put it below. Which is the better position in relation to atmospheric disturbances? We know that where it is over the conductor it should in general be of the same metal as the conductor. For some three or four years past we have been experimenting with iron choke coils. I think they have some value. On several occasions when the consumer's protective and other apparatus has been destroyed in a thunderstorm, the power company's apparatus has not been affected, with the exception of the current transformers on the meters. From this it would seem that a cheap choke coil is a current transformer. I noticed that in the earlier discussions of this paper it was stated that to prevent damage to transformers it is well to insulate the last turns extra heavily. We have found that even with this arrangement transformers have broken down, and the whole transformer has had to be sent away to the makers for repair. Would it not be cheaper to provide the extra heavily insulated turns in a separate tank outside the transformer and so avoid the necessity for sending away the whole transformer when a breakdown occurs? We have tried the permanent leak type of arrester, the horn type, the usual multiple-gap, and the electrolytic type, and we have experienced more trouble with than without them. For a wooden pole line it is usually specified that all cutting for cross-arms, etc., shall be done before creosoting; but after erection climbing irons form innumerable rain pockets which surely will tend to rot the pole. We avoid this by fixing round section iron pole steps, costing 1d. each, when erecting the pole line. The first step is above the

The question raised by Mr. Seddon of earthing one phase of a three-phase line has been discussed, but I do not think the system has been adopted. I see no reason why one phase should not be earthed so far as overhead construction is concerned, but in order to avoid disturbances of G.P.O. and other circuits the earth-wire would have to be insulated at all points except at the alternator or transformer. In ordinary circumstances the insulation of the earth-wire need not amount to much, but such a wire may be called upon to carry a high voltage in an emergency. On the other hand the insulation of the other parts of the circuit, such as cables, transformers, etc., would have to be designed to withstand the pressure between the phases instead of between one phase and earth. This is probably the reason why the method has not been adopted.

barbed wire coils. To reach it the patrol man carries a very light 10 ft. to 15 lb. ladder. Instead of riveting the earth-wire to the earth-plate, we usually unstrand the earth-wire, spread it, and run the cast iron forming the earth-plate round it. It is well I think to procure the best insulators that one can and to pay a good price for them. It is cheaper in the end. As regards the speed at which a repair can be effected, pole lines have the advantage as against a cable. On a Sunday, 12 miles from the base, a bird caused a pole-line insulator to break down. Within 3½ hours the line was repaired and alive again. Pole-line troubles as a rule are very few. After our first pole line was made alive the daily average of birds killed was rather high, but after the first month the average was reduced to one or two per month. The birds seem to have become educated, because on pole lines subsequently made alive there have been scarcely any bird casualties at all. Our chief trouble is malicious damage. A police court prosecution, however, usually cures this. Both malicious damage and wayleave troubles are to a great extent remedied by high poles and long spans. A rifle is needed to break the insulator on a high pole, and with long spans where the line crosses arable land the poles can generally be fixed at the hedges. This method is of further benefit in reducing the number of insulating points. It is especially adapted for the South Wales hilly districts, particularly in crossing narrow and rocky valleys. Our longest span in a case such as this is about 1,500 feet. I quite agree with the author that telephones should not be run on the same poles as power wires. I am of opinion that they, as well as duplicate pole lines, should be on separate poles, and if possible by separate routes. In Stockholm there was considerable trouble where telephone lines were run on the same poles as the live conductors of the single-phase railway. Our telephones are always run by a separate route, and we usually have the use of them when most wanted, namely, during breakdowns. I should like to mention that the well-remembered local tornado a few months ago caused no damage to our high-tension pole lines, one of which was at right angles to its path, although houses two hundred yards away had the roofs and windows wrecked.

Mr. H. M. BAMFORD: From my experience of pole lines I consider the use of steel poles and long spans is almost

always preferable. The cost of maintenance is somewhat higher than that of wood poles, due largely to inefficient painting, but this is partly counterbalanced by fewer breakages of insulators. Too much care cannot be taken with the paint and its application; for if applied over rust or dirt, as I have seen it, satisfactory results cannot be expected. Even in a wood pole line it is generally necessary or advisable to use iron fittings, which are greater in number and also affect maintenance. With regard to the author's remarks on creosote, I have frequently noticed when lifting poles, in clayey ground, a quantity of creosote at the butt, generally two to three pints.

Mr. C. F. PROCTOR: On the question of wind pressure, 25 lb. seems to be abnormal. I have heard of cases of 18 lb. to the square foot with a very high structure, and in one exceptional case it was 22 lb., but only for one foot, and on erecting a big shield 25 ft. square the mean wind pressure was reduced to about 18 lb. per square foot. I think the real trouble is the question of snow. It seems to me that we should not fix a certain distance and a certain wind pressure, but consider each neighbourhood on its merits; for instance, what is correct in Wales cannot be so on the North Coast where we get heavy snowstorms and clinging snow. With regard to the author's remark that on live aluminium wires the snow has been found not to stick, is it owing to heating of the wire? I think this has been found to be the case on several overhead lines. We have seen snow sticking to telegraph wires, and not so much on transmission wires. I have found aluminium very liable to crystallization after a time. I do not know whether this is purely a question of the purity of aluminium; motor-car builders, however, do not trust aluminium unless it is abnormally thick. I should like to ask the author whether old wires turn crystalline and lose ductility.

Mr. H. LEWIS: Whilst I agree with Mr. Allan that the landlord is sometimes justified in objecting to the ugly creosoted H-poles, which damage the grass and kill his cattle, and for which he only gets a nominal remuneration, yet this does not apply to the Urban, Rural, or District Councils. From my point of view, they are the worst offenders: they constantly refuse even to consider the question of overhead lines being erected in their districts, although the ratepayers will materially benefit by being able to obtain electrical energy; and if they do consider the matter they impose such obligations as to make the line almost as expensive as laying the cables underground. I think the Board of Trade should, in the interests of the statutory undertakers and the ratepayers, consider on its merits each application for the erection of overhead wires and have the right to dispense with the consent of the local authority, if it think fit. I quite agree that the Board of Trade is right in adhering to the regulations concerning the factors of safety, but I am of the opinion that there are cases in some of the side streets of a town where these regulations might be slightly relaxed.

Professor F. BACON: On page 178 the author gives a table of costs. I gather from his remarks that he concludes from that table that the cost of underground cables compared with that of overhead lines is proportionately greater the higher the pressure, and also proportionately greater the larger the number of kilowatts conveyed. I do not

quite see how the table brings out this second fact, viz. that overhead lines become cheaper in comparison with underground cables the larger the power transmitted, the pressure of transmission being the same in each case. Next as to the wind pressure, previous speakers have commented on the high values mentioned; but the method of calculating the effective area exposed to the wind pressure seems to me quite as important as the actual value assigned to the wind pressure itself. I notice that 0.6 times the diameter is taken as the effective breadth. I should like to know how the coefficient 0.6 came to be adopted. The problems presented by aeroplane construction have led to so much research on the wind resistance of wires that more precise information ought to be available than formerly, and I think we might expect to find that instead of employing 0.6 in all cases it would be more correct to vary the coefficient according to the diameter, possibly also according to whether the line was a stranded cable or a single solid wire of the same overall diameter, though I must admit this is rather splitting hairs when there may be snow on the wires increasing their diameters by many hundreds per cent.

I was very interested to hear what the author said about the mechanical testing of materials. I entirely agree with him that the stress allowed in a wire should be based upon the elastic limit, meaning thereby the limit of proportionality of stress to strain. I am afraid, however, that the fixing of the limit of proportionality is apt to be much influenced by the sensitiveness of the extensometer employed; though perhaps this difficulty is not so strongly felt in the case of hard-drawn wire which can be tested in long lengths. In the case of wrought copper it is exceedingly difficult to decide at what point on the stress-strain curve the proportionality ceases. In fact, in the case of soft annealed copper and certain other alloys which behave in the same way, I think there is absolutely no limit below which it is safe to say a strict proportionality exists. With regard to the use of aluminium in place of copper, I should like to ask for information as to the possibility of using certain rich aluminium alloys that are stronger than pure aluminium. I have tested mechanically a number of these alloys—duralumin in particular—and have been impressed with the apparently excellent results that can be obtained. Is it that the small amounts of magnesium, iron, zinc, etc., which are added to aluminium to increase its mechanical strength spoil the electric conductivity to an extent which makes the metal commercially unsuitable for transmission lines, and is there no prospect that an alloy of aluminium will be found stronger than aluminium itself, but not materially higher in specific resistance? I should also like to ask the author whether he thinks it necessary to test his finished cable after it is stranded as well as the individual wires. I know it is a difficult job to obtain a really satisfactory tensile test of a stranded cable, and if it has once been conclusively shown that no useful purpose is achieved by making such a test, perhaps it is better omitted.

Mr. T. SCHONHEIL: I quite agree with what the author has said about wayleaves. In regard to his remarks as to the evident heating of stranded aluminium conductors, it seems to me that this may possibly be due to a cause which I think is well known, i.e. that in drawing aluminium a skin forms on each wire, such skin being a partial dielectric. The author mentioned that interest

has been taken in poles creosoted by the Rüping process. I believe this is the process by which the poles are creosoted and then de-creosoted as far as possible. It seems to me that by this process the advantages of the creosoting are taken away, especially that advantage to which the author referred—that in the ordinary way the surplus creosote runs down to the earth line and protects the pole. The greatest deterioration of poles undoubtedly takes place at the earth line, and I should like to suggest an additional means of protection. This consists in covering poles with a collar of concrete extending about 18 in. to 2 ft. below the earth line and about 4 in. above. This has been tried with excellent results. With regard to the continuous earth-wire, the author did not state whether the earth-wire that he refers to is of steel or copper. As far as I know, copper is far preferable. Perhaps he would give his opinion on that point. Reverting back to the question of poles, one drawback to the use of steel poles is that corrosion takes place inside more than outside. If a steel pole is properly coated—when it is as free from rust as possible—with a good quality paint and repainted at proper intervals, I do not think much deterioration will take place outside, but certainly it takes place inside, and it is practically impossible to get at that corrosion. I understand that in America steel tramway poles have been filled with reinforced concrete with very good effect, and no doubt something like that will have to be done here. Some of our tramway poles, such as those on the first electric lines in Dublin, Bristol, etc., have been in use for 10 to 15 years, and no doubt a very large amount of corrosion has taken place inside the poles, or rather on the inside surface of the poles. The author suggested that a better plan than that of erecting H-poles to carry duplicate overhead lines would be to construct ring mains; that method, however, would lead to additional wayleave difficulties. I think perhaps the better plan is to put the poles alongside, not close together, but a sufficient distance apart, so that if a pole carrying one line happens to be blown down, it will not foul the other line. I think this plan has been adopted in some cases. The author seems to advocate rigid binding, but I think he has overlooked one great disadvantage of this method. If a conductor should break, the strain has to be taken up by the adjacent insulator pins, which in all probability would not bear the strain; whereas if an ordinary more or less loose method of binding is used, the conductor in a case of breakage simply slips through and does no damage to the adjacent insulators or insulator pins. With regard to the reinforced system of crossings, I understand that the Board of Trade does not require a guard netting underneath, but is quite satisfied, as are also most railway companies, with merely the reinforced system.

Mr. B. WELBOURN (*in reply*): The point which Mr. Allan raised in regard to the binding in of insulators on slopes is not a difficulty that many engineers have to contend with. I have never had to deal with a line such as he mentioned. He also referred to the position of the earth-wire. I think that is a matter everybody must decide for himself. It seems to me that lightning is not sufficiently frequent in England to justify the placing of the earth-wire above the power line. There have been cases where the continuous earth-wire has broken, fouled the power lines, and interrupted the supply. Not only so, but

if an earth-wire which has been properly earthed does fall Mr. and the protective gear does not operate sufficiently quickly, the power wires probably get burnt, so that these have also to be renewed in at least one span. I have discussed this matter extensively with Canadian engineers and I have found that considerable difference of opinion exists. One engineer told me that he had tried his earth-wire in both positions, but that he certainly favoured the position below the power wires. The chief use of the earth-wire in this country is not to protect lines against lightning, but to connect all metal-work on the poles and afford a sure method by which it can be earthed. Another advantage of having the continuous earth-wire below the power lines is that if it is desired to carry on the line a lead-covered cable, it is there ready for the work. I think one speaker misunderstood me with regard to the material to be used for the earth-wire. I stated quite clearly on page 188 of the paper that the earth-wire should undoubtedly be of the same material as the power line, or of bronze; it certainly ought not to be of galvanized steel, which would have a shorter life.

I was very interested in Mr. Allan's experience regarding the insulated turns of transformers. The arrangement referred to in the paper is of course cheap. No noticeable increase in the cost of these transformers over that of the old arrangement is seen from tenders recently received; and this is the main thing. I believe that I am correct in stating that not one of these specially insulated transformers has ever been known to break down in this country on account of lightning. I know of one or two lines where insulated coils are placed outside the transformer, but this arrangement entails difficulties in sub-stations in finding room and connecting up.

I was pleased to hear Mr. Allan's confirmation of the difficulties that have been experienced with nearly all types of arresters. I have definitely come to the conclusion that there is not an arrester at present obtainable which is entirely satisfactory for all conditions, although the Moscicki condenser deals satisfactorily with high-frequency disturbances and reduces the potential gradient of a surge.

The difficulty of tearing the poles on account of linemen going up and down with climbing irons, is one which is being much discussed, and in some districts ladders only are used. I know many engineers who will not permit linemen to use climbing irons, but the expense of carrying ladders is very serious. Mr. Allan's combination of pole steps with a light ladder is excellent.

With regard to insulators, I agree with Mr. Allan that the best should be used. It is only a question of a few pounds' extra cost; and the gain when the best are secured is very great. I have said in the paper that attention should be paid to detail. This is one of those details which I had in mind. There is no doubt that money spent on good insulators is well spent.

I have been surprised to notice that in all the discussions only one speaker has mentioned the colour of insulators. Possibly the way in which insulators are shot at may be due to their colour. On some lines where white ones are used, they are a target for every mischievous person in the district.

The matter of wayleaves has formed a striking feature in these discussions, and I hope it will be dealt with by the Institution.

Mr. Allan also referred to the question, of factors of safety. There has been no request in any of the discussions for any further reduction in the factors of safety. The attitude of the Board of Trade in regard to wind pressure is not quite clearly understood. Mr. Trotter has a collection of wind-pressure records which he would place at the disposal of any members who would like to consult them in London. There are many localities where a pressure of 25 lb. per sq. ft. is never reached, 17 lb. usually being the limit. In all cases where the former pressure has never been recorded, Mr. Trotter is quite willing to allow the lines to be designed so as to meet the highest recorded wind pressure.

With regard to Mr. Proctor's point about wind pressures, not only is there much information gathered by the Meteorological Department available, but the National Physical Laboratory has carried out extensive tests, which I hope will shortly be published. There is much evidence to show that if the wires are arranged in a horizontal plane, the resultant total wind pressure on the structure is less than if they are arranged in a vertical plane.

In regard to calculating the effective wind pressure, $\sigma/6$ of the diameter is the figure given in the Regulations of the Board of Trade, and $\sigma/60$ in those of the Post Office. The question of which may be correct is not very material on account of snow loading. The moment that any wire begins to collect snow it becomes a snow rope, which continues to load indefinitely. I know of a case where telegraph wires were loaded to a diameter of 2 in. No overhead line can be expected to withstand such conditions if erected on a commercial basis.

Mr. Bamford's point about painting has been referred to in what Mr. Wigham said in his communication to the London discussion. He says that on the steel lines which he has erected in Cornwall the question is highly important because of the salt-laden atmosphere, and that he has found Dixon's graphite to be superior to all the so-called bitumen paints.

The question of the crystallization of aluminium is, I think, one of purity of the metal and its proper annealing. I have never encountered a bona-fide case of crystallization when aluminium of at least 99.30 per cent purity was used. I have certainly met with cases of failure of so-called aluminium castings, but in every case there was considerable admixture of alloys.

Mr. Lewis went far in confirming my introductory remarks, viz. that much low-tension work must be considered very carefully in regard to the question of cost (*i.e.* in deciding whether overhead or underground cables should be used), especially where wayleave difficulties and the requirements of local authorities have to be borne in mind.

Professor Bacon referred to the cost table on page 178, from which it is certainly apparent that for practically the same capital cost in overhead lines three times the number of kilowatts can be transmitted at 20,000 volts that can be transmitted at 6,000 volts, and that compared with underground cables the savings are, at 6,000 volts, approximately in the ratio of 1 to 1.5, and with 20,000 volts of 1 to 2.2, neglecting the capitalized value of wayleaves.

Professor Bacon also dealt with a very interesting point, viz. the limit of proportionality, and the difference between stranded and single wires. I have examined this question during the last three weeks, and although the experiments have not gone very far, they tend to show that a stranded conductor of aluminium has a limit of proportionality about 3 per cent higher than that of a single conductor. Measurements are about to be made by the National Physical Laboratory so that the results should be generally acceptable.

The question of aluminium alloys on overhead-line work is not only one of specific resistance, but mainly one of corrosion. I am satisfied that no aluminium alloy can be obtained, which if not protected from air and moisture will not fail due to local electrolytic action. Experiments have been carried out in this connection and the results are so conclusive that I would never recommend the use of aluminium alloys for an overhead line.

Mr. Schontheil referred to creosoting by the Rüping process. One of the valuable points raised in this discussion was the statement by Mr. Stubbs that poles so dealt with can be painted. He said that experiments are now being made between Messrs. Richard Wade, Sons & Co. and the Post Office Engineering Department to find the best mixture to use for this purpose.

Mr. Schontheil also dealt with the question of protecting the poles from the action of wind and water at the ground line. On page 184 of the paper particulars are given of a mixture with which I have had some experience, and perhaps if Mr. Schontheil has a case in mind he would like to try it.

I am familiar with the method of filling tubular steel poles with ferro-concrete as used in America. It promises to give satisfactory results.

Referring to the question of binders, I think that flexible binders such as I have shown here to-night will not allow the conductor to slip through if a line wire breaks. It is rather more likely that the binder will slip round the insulator and so relieve the strain. I think the Board of Trade will now permit suspension guards to be used without cradling below, and it is only sentiment which causes the flat guard below the wires to be retained.

FURTHER CONTRIBUTIONS TO THE DISCUSSION.

Mr. A. W. ISENTHAL (*communicated*): With regard to the use of the Moscicki condenser as a separate system of protection, I have carefully read the remarks of speakers at the various Local Section meetings, and have gained the impression that one of the most essential reasons for the adoption of such condensers has been entirely overlooked: I refer to the effect of the condenser on the potential gradient of the surge wave. For instance, in the

discussion before the Newcastle Local Section? Mr. Hunter agrees that in so far as the Moscicki condenser does away with the spark-gap it must be an improvement on other types. This goes of course to the very root of the matter; but he discounts this very great advantage of this type of arrester by expressing the opinion that the apparatus would become very large and expensive if it had

to dissipate the surge energy. This does not go quite as far as the objection raised by some early opponents of the system, who maintained that the condenser could not dissipate any energy at all; but the fact is—as Professor Petersen, among others, has shown—there is no need whatsoever to dissipate the energy of the surge in the condenser. Its legitimate function in the case of protection is partly to reflect the incoming surges upon the line, where their energy will be rapidly dissipated, and also (and this is the more important part) considerably to lessen the steepness of the incoming wave fronts, or, in other words, to reduce the potential gradient of these surges. By far the larger number of defects that can be traced to surges of this character are due to the abnormal potential distribution in the windings of generators and transformers brought about by the steepness of these surge waves, and are not the consequence of the absolute voltage excess produced by such surges. Now, it has been shown that a comparatively very small capacity is capable of bringing about a flattening of these potential fronts quite sufficient for all practical purposes, and beyond a certain minimum size (which is dictated by other considerations) the protective condenser battery is quite independent of the amount of energy that is transmitted over the line.

Many speakers have recorded their conviction that spark-gaps should be avoided; but this is a generalization that is likely to be misleading. The destructive effect of surges may be due to two causes, according to the nature of the surges. There are the surges which are either of a high-frequency nature, or which travel along with very steep wave fronts, and in both cases a spark-gap would certainly be not only a possible source of new surges, but also entirely useless, because the amplitude of the surge voltage may conceivably be such that no spark-gap (which is set at a voltage higher than the working voltage of the line) would be bridged, and only the abnormal potential distribution introduces danger to the plant. There are other surges which are characterized by an actual, and sometimes very considerable, rise of pressure at a more or less normal potential distribution. This class of surges can only be dealt with by providing suitable gaps between the line and earth, but—and this is important—it is difficult to construct a gap which does justice to two very conflicting conditions, i.e. that it should permit a sufficient amount of energy to pass off in the shortest possible time, and yet that its total resistance should be sufficiently high to preclude the generation of oscillatory discharges when operating. The majority of gaps in actual use are either apt to produce new surges of an oscillatory and therefore highly dangerous nature, or the resistance which has to be placed in series with them is so high as to make the efficiency of this "by-pass" very questionable. Dr. Garrard, in the course of his remarks at the Birmingham meeting,² mentioned this matter, and referred to the Giles valve, which has been shown in practice to be a satisfactory solution of the conditions governing the design of a spark-gap. It then comes to this; that from the very nature of the matter we must have several types of arresters, because it is impossible to expect, for instance, a water jet or an iron-core inductance, which can deal very effectively with static charges, to be of any use in the case of high-frequency surges or switching surges.

² See p. 257.

Mr. A. E. McCOLL (*communicated*): On page 178 the author has given a table of comparative costs per mile of overhead transmission at pressures of from 6,000 to 20,000 volts to show the small increase in the initial cost due to increasing the voltage. This holds good for what can be classed nowadays as low or moderate-pressure systems, where the length of span, sag, windage, method of suspension, and arrangement of the conductors, are a larger factor in determining the spacing than the electrical characteristics of the air itself. When we come to very high voltages, the strength of the air as a dielectric is the factor that determines the spacing of the conductors—other conditions remaining the same—owing to larger and broader towers and greater wayleave expenses being necessary, and in the case of three-phase transmission at still higher pressures possibly greater separation of the phases on individual towers or poles. The conductor separation is affected by several things, among which are: factor of safety, size of conductor, barometric pressure, and in a lesser degree the temperature. Weather conditions, such as fog, sleet, rain, and snow, all lower the critical disruptive voltage of the system, and increase the loss of power. In a three-phase transmission system where the separation of the line wires is from one-half to one-third of the distance to the ground, the stress at the conductor surface may be with sufficient accuracy stated as—

$$e = \frac{V/\sqrt{3}}{r \log_e D/r}$$

where V is the voltage between the lines,

D is the distance between the conductors in inches, and R is the radius of the conductor in inches.

The disruptive gradient of air (R.M.S. value with sine wave) is 53,600 volts per inch with round, smooth, polished wires. A condition depending on the state of the conductor surface lowers the permissible stress that can be reached without power loss taking place in the form of corona discharge. This condition for weathered or roughened wires we may take as 0.95. The above permissible stress holds good for the barometer at 29.92 inches and a temperature of 77° F. The separation of the conductors, D , may be readily found for varying values of the barometer and temperature readings, and factor of safety. Where e is the stress at the conductor surface—

$$e = 53,600 \times 0.95 \times \frac{17.91 \times 29.92}{459 + 77} \times \frac{1}{\text{factor of safety}}$$

Low factors of safety are taken on high voltage lines; the distance between the phases then becomes

$$\log_{10} D = \frac{0.4343 V/\sqrt{3}}{e \times r} + \log_{10} r.$$

Let us take an example. Suppose the spacing D has to be found for the following conditions: $V = 150$ kilovolts, $e = 53.6$ kilovolts, $r = 0.3$ in., factor of safety = 1.1, temperature = 41° F., barometer = 27.5 in.

$$\text{Then } e = 53.6 \times 0.95 \times \frac{17.91 \times 27.5}{459 + 41} \times \frac{1}{1.1} = 45.6 \text{ kilovolts,}$$

$$\text{and } \log_{10} D = \frac{0.4343 \times 150/\sqrt{3}}{45.6 \times 0.3} + \log_{10} 0.3 = 2.2264.$$

$$\therefore D = 108.5 \text{ ft} = 14.04 \text{ ft.}$$

Coll. This distance should represent a possible out-of-phase swing of the conductors. The length of span and amount of sag will increase the above spacing.

On such a system, with the conditions given, the kilowatt loss would be small, although the number of kilovolt-amperes required to charge the line at no load would be large. There would be no loss due to corona, since the disruptive critical voltage (E_c) to the neutral is greater than the operating voltage, these being 9526 and 866 kilovolts respectively, E_c being given by $45.6 \times r \log D/r$.

It is interesting to consider the loss which would take place if the line pressure were raised to 200 kilovolts, the transmission length being taken as 200 miles, and the frequency as 25 \sim .

Capacity of line per leg = $\frac{0.0388}{\log_{10} 168.5/0.3} \times 200 = 2.822$ mfd.

Charging current per phase

$$= \frac{2\pi \times 25 \times 2.822 \times 200/\sqrt{3}}{10^3} = 51.2 \text{ amperes.}$$

Number of kilovolt-amperes required to charge the line

$$= 51.2 \times \sqrt{3} \times 200 = 17,700.$$

Applying Mr. Peek's formula,⁶ the power loss due to corona per mile of single conductor would be found to be 2.411 kw. The total loss would therefore be $2.411 \times 3 \times 200 = 1,446$ kw. No account has been taken here of the progressive rise which would take place along the line if open-ended at the receiving station. Such rise would, especially at the higher frequencies of 50 to 60 \sim , add considerably to the above values of the kilovolt-ampere and kilowatt losses.

The author has stated that the cable makers are prepared to keep pace with the rise in operating pressures in this country. Although it may not be necessary to go to the excessive pressures that are used on some systems abroad, still I think we shall probably be using in the not distant future in connection with railway electrifications alternating pressures of from 50 to 100 kilovolts. Cables for such pressures, and especially for the higher pressure mentioned, will be auxiliary to, and will not supplant, overhead lines. For a large scheme operating, say, a 250-mile transmission at 100 kilovolts, the charging current would be so excessive as to make underground transmission altogether out of the question, especially at the higher frequencies of 50-60. As the mercury converter seems likely to become a serious competitor of rotary converting plant the tendency will be to go above 25 cycles and toward the higher frequencies.

Let us compare the charging currents of an overhead and an underground transmission.

Three-phase overhead lines.

Voltage between conductors 100 kilovolts, i.e. 57.8 kilovolts to the neutral.

Spacing of conductors = 10 ft.

Diameter of conductors = 0.4 in.

Length = 250 miles.

Frequency = 50 \sim .

Capacity = 3.5 mfd.

Charging current per phase = 63.5 amperes.

Capacity of plant required to charge line at no load = 11,000 k.v.a.

Mr. McColl.

Three-phase underground cable.

Each phase to comprise a separate single-phase conductor operating above ground at 57.8 kilovolts.

Diameter of conductors = 0.4 in.

Dielectric strength of insulation = 360 kilovolts per inch.

Specific inductive capacity = 3.

Factor of safety = 2.5.

From the formule given above, $D = 1.488$ in., and the thickness of the insulation = $1.488 - 0.2 = 1.288$ in.

The capacity per leg is—

$$\frac{0.0388}{\log_{10} 1.488/0.2} \times 3 \times 250 = 33.4 \text{ mfd.}$$

and the charging current

$$= \frac{2\pi \times 50 \times 33.4 \times 57.8}{10^3} = 606 \text{ amperes.}$$

The capacity of the plant required to charge the line

$$= 606 \times 100 \times \sqrt{3} = 105,000 \text{ k.v.a.}$$

Rather extreme conditions have been assumed, for the purpose of giving more forcible results. More favourable conditions could have been taken for the cable, but they would have rendered its size beyond practicable dimensions. If graded cables had been used, having insulation of varying specific inductive capacity, the results would have been still more unfavourable to the underground system. Of course it is not put forward seriously that a cable system would receive consideration for the foregoing conditions. The comparison is merely intended to show that what is practicable under certain conditions with overhead transmission is impossible with an underground one, as it is not generally realized what exceedingly large plant capacities are required to charge such lines.

Mr. T. S. WALLIS (communicated): It may be of interest Mr. Wallis, to members to hear how things are done in Sweden. The supply from the Trollhättan water-power station is at 50,000 volts by overhead lines, and the distance to Gothenburg is approximately 50 miles. From there the energy is distributed at a pressure of 10,000 volts, also by overhead lines where practicable. Our supply at Surte has to return 10 miles from Gothenburg, although the 50,000-volt line passes only about half a mile from these works. I understand that the explanation is that there was already a consumer half-way to Gothenburg before our supply was thought of. The 50,000-volt line runs for the most part on the top range of hills along the coast and is very exposed to the stormy weather that is experienced here. Steel lattice-work poles are used, the majority taking the form of an inverted "V," while every fourth support is of a stronger nature, consisting of two inverted Vs leaning against each other. The poles are square in form and mounted on concrete blocks. The spacing appears to be about 4 ft. 6 in. between wires, and the average height of the supports is 30 ft. I am

* F. W. PEEK, JR. "Law of Corona." *Transactions of the American Institute of Electrical Engineers*, vol. 30, p. 1894, 1911.

Mr. Wallis. unable to give any details of the span, but it is fairly large. The most remarkable construction, however, is that of the 10,000-volt line. This is mounted on ordinary telegraph poles, and the insulators are fixed on iron supports screwed into the pole, a wire connecting the earth-wire with each of the iron screws. The line looks exactly like a telegraph line with extra large insulators, and it passes for a distance of 10 miles over houses, roads, and fields. The conductors are spaced about 2 ft. apart.

Mr. B. WELBOURN (*in reply*): Mr. Isenthal's explanation of the function of the Moscicki condenser is opportune and goes, I think, to confirm the views that I expressed in connection with the protection of lines. I have had no experience with the Giles valve on an overhead line; but

I know of a large distribution network of cables on which Mr. much trouble was experienced through pressure rises and where since Giles valves were installed two years ago the breakdowns have ceased. Mr. Isenthal's summary shows how difficult the question of protection may be. The inference is clear; there is great need for the invention of a combination arrester which will take care of all the different conditions that may be experienced.

Mr. McColl's contribution refers in the main to work at voltages which have not been employed in the United Kingdom. As stated in the paper, however, a raising of working pressures cannot long be delayed in this country, and then Mr. McColl's comparisons will prove very useful.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 26TH FEBRUARY, 1914.

Proceedings of the 563rd Ordinary Meeting of the Institution of Electrical Engineers, held on Thursday, 26th February, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on Thursday, 12th February, 1914, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Messrs. J. H. Johnson and O. L. Record were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Associate Members.

Browne, George Henry.
Harvey, George Miller.
Hogg, Patrick Mackintosh.

Graduates.

Church, Alfred David.
Day, Isaac.
Finlason, Walton Scott.
Levett, John Victor.
Mills, Percy Maurice.
Morris, Harold Arthur.
Parr, Walter Thomas.
Ravenscroft, John Dewhurst.

Students.

Bainford, Edgar.
Bhatt, Motiram Harikrishna.
Bolton, Charles Richard.
Boxall, Charles William.
Coombs, Charles Alfred.
de Holland, Raphael.
Easter, Charles Edward.
Gates, Reuben.
Ghose, Klagendra Nath.
Gillman, Ernest Percival.
Grose, Stewart Jewell.
Hall, Thomas Haffenden.
Hardie, Herbert John.
Haws, Norman.

Hopkins, Alfred Stephen.
Hornycold, Henry.
Jardine, Cecil William.
Knight, Cyril Sherwin.
McKenzie, Hector James.
Morton, Charles Albert.
Painon, Edgar Theodore.
Palmer, William Samuel H.
Richardson, Walter.
Tindall, Frederick Joseph, B.Eng.
Tolley, Henry John.
Wells, Reginald Iredale.
Woodside, Hugh.
Young, Clifford Neil.

TRANSFERS.

Associate Member to Member.

Batters, John Henry.
Sykes, James Arthur.

Maytham, Albert Archibald.

Student to Associate Member.

Brown, Ivan Crisp.
Brown, William.
Dixon, Victor Cyril.
Harley, Thomas Edgar.

Student to Graduate.

Ayengar, T. K. Ramasami.
Blander, James.
Cheal, Arthur Ernest Edward.
Christian, David Adam.
Curling, Harold William.

Graduate to Associate Member.

Golden, William Thomas.

Donations to the *Building Fund* were announced as having been received from The Association of Municipal Electrical Engineers of Greater London, R. A. Dawbarn, Professor A. Hay, D.Sc., J. S. Highfield, H. Hirst, Vice-Admiral Sir H. B. Jackson, K.C.B., F.R.S., Professor J. T. Morris, D.Sc., H. M. Sayers, A. Stroh, Sir Joseph Swan, D.Sc., F.R.S., A. Wright, and L. T. Young; and to the *Benevolent Fund* from H. Alabaster, G. F. Allom, A. B. Anderson, I. Braby, R. A. Chattock, V. K. Cornish, B. Davies, A. Denny, J. Devonshire, H. C. Donovan, B. M. Drake, W. Duddell, F.R.S., K. Edgcumbe, F. Gill, Dr. R. T. Glazebrook, C.B., F.R.S., B. B. Granger, F. E. Gripper, C. C. Hawkins, K. Hedges, D. Henriques, S. Hill, H. W. Kolbe, A. E. Levin, J. R. P. Lunn, L. B. Miller, W. M. Mordey, E. Parry, The Hon. Sir C. A. Parsons, K.C.B., F.R.S., W. H. Patchell, A. H. Preece, W. L. Preece, W. R. Rawlings, T. Rich, R. Robertson, S. R. Roget, A. Siemens, A. Stroh, A. J. Stubbs, A. P. Trotter, T. C. T. Walrond, and C. H. Wordingham, to whom the thanks of the meeting were duly accorded.

A paper by Mr. F. Lydall, Member, entitled "Motor and Control Equipments for Electric Locomotives" (see page 384), was read and discussed, and the meeting adjourned at 10 p.m.

No. 231.

THE DESIGN OF ROLLING STOCK FOR ELECTRIC RAILWAYS.

By H. E. O'BRIEN, Associate Member.

(Paper first received 2nd February, and in final form 21st February, 1914; read before THE INSTITUTION 12th March, 1914.)

It is now a well-known fact that the possibility of the application of electric traction proving remunerative depends on the density of the traffic plus the possibilities of development; in other words, the larger the number of stations per mile the greater is the probability that electric working will result in a reasonable return being obtained on the capital expended. It must also be remembered that on railway systems embracing several large towns the suburban and interurban passenger mileage is a very large percentage of the total passenger-train mileage. In the more densely populated parts of England the train mileage on lines of railway companies which have sufficiently heavy suburban traffic to make electrification worth considering is probably not less than 20 per cent of the total passenger-train mileage. Railways engaging in electrification of large suburban areas therefore find that the cost of operation of the electrical services is an important proportion of their total expenditure; and bearing in mind the large addition to their original capital expenditure involved by electrification, every means of reducing both the capital cost and the cost of operation becomes a matter of serious importance and worth the minutest investigation. The whole cost of electrification and of subsequent operation will depend on three factors:—

- (1) the number of stops per mile;
- (2) the schedule speed of the trains;
- (3) the weight of the trains.

Factor (1) is fixed by the nature of the district.

Factor (2) is a matter for determination by the management: the needs of the population of one district can only be served by a very fast service, while in another district a slower schedule with more frequent trains will attract just as much traffic. The main object of electrification is of course increased traffic, and this is obtained by enabling people to live at a distance from their work and yet reach it without spending an unreasonable amount of time in travelling; and also to induce their dependents to travel as far and as often as possible. The office hours, and the meal-times customary in this country fix within narrow bounds

the limits of an electric system. The maximum length of time that a business man will consent to spend in a train at each end of the day is 45 minutes, and this is also the maximum period that will allow other persons an hour's shopping between one meal and the next. This time limit represents a radius of 22 miles at a schedule speed of 30 miles per hour. With stops one mile apart such a schedule is practically the highest attainable with any type of train or motor.

If the train equipments had to be designed for lines with stations placed at uniform distances apart, and on a level track, the problem of securing the most economical motor and control would be comparatively simple. But it will often happen that a profitable electrification will involve runs with very short distances between the stops in the vicinity of a large town, and also runs with much longer distances between the stops as the trains get farther from the urban area; and very possibly at the extremity of the electrification a secondary urban area is approached necessitating a number of stops in close proximity to each other.

The most remunerative traffic will be that between the extremities of the electrification, between the primary and secondary urban areas; consequently the equipments will have to be designed so as to make a journey of this length a reasonable one. The gradients also vary, and a long run, say two miles, may be on a continuous up-grade of 2 per cent, or even less, while the short runs may be on comparatively level ground. Expresses as well as stopping trains will be required (as has been found on the London Underground Railways), and as in most cases the setting aside of special stock for express services would involve extra capital expenditure, a compromise has to be accepted both in the motor characteristic and in the gear ratio. The equipments would normally be of such a character as to permit of a fairly large percentage of coasting on the longer runs for maximum economy, but the commercial management will soon realize that time can be saved by maintaining full speed nearly as far as the stopping-points in these cases; also as the district develops extra stations will be introduced, which will make the original gear ratios in-

correct. In consequence the equipments will normally run in such a way as to require a high energy consumption. This energy consumption is the sum of that wasted in the resistances and motors, of that wasted in the brakes, and of that utilized in overcoming train resistance. The first two of these losses are directly proportional to the weight, and the third—the train resistance—is so nearly proportional to the train weight that it may be taken as being so for practical purposes. Fig. 1 shows the resistance of the Lancashire & Yorkshire Railway Company's trains as actually obtained by the coasting method.

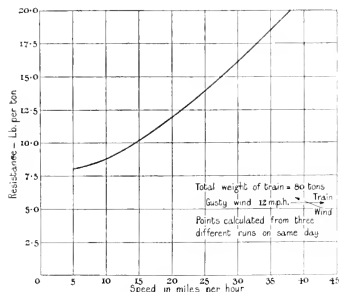

FIG. 1.—Resistance of 2-Car Train.

Fig. 2 shows the approximate division of the total energy between its various components.

The curve in Fig. 3 shows the percentage of the whole used for acceleration for runs of half a mile and upwards. The schedule speed is maintained constant by prolonging the coasting period for the longer runs. This curve emphasizes the enormous importance of light rolling

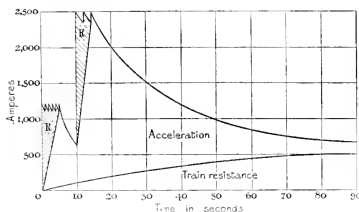

FIG. 2.—Typical Curves showing Energy Losses.

stock, as far as the influence on the energy consumption of the trains on high-schedule short-distance suburban services is concerned. It will be seen that the energy consumed varies almost directly as the weight of the trains, although for runs between stations less than one mile apart the importance of the acceleration component increases as the distance decreases.

High energy consumptions per ton are likely to accom-

pany commercially successful electrifications, and the sole variable factor that can be attacked, and which enormously influences the whole problem, is the weight of the rolling stock. It is therefore very important to consider in detail how rolling stock may be built so as to give a maximum value to the ratio—number of seats provided per ton weight of train.

The fact that the coaches must be comfortable must not be lost sight of; but there is no need to assume that light coaches are uncomfortable to ride in. Excellence in riding is obtained by the use of bogies of the maximum wheel base permissible, and by careful design of the seating and springing systems; also by concentration of the motor masses as near the bogie centre and as high as possible. The necessary protection against the possible effects of collision and fire must be provided, but such protection is not necessarily obtained by extra weight.

The lighter the colliding bodies the less the force of the collision, and in the case of collisions with bodies of infinitely large mass, such as with a dead end, the lighter the train the less severe are the effects. The bodies of an electric train form a homogeneous whole; there is practically no sandwiching of heavy and light bodies such as

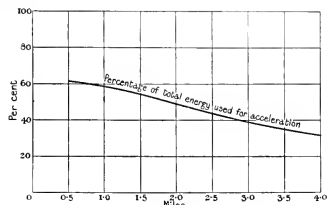

FIG. 3.—Curve showing Percentage of Energy Input used for Acceleration for Runs of $\frac{1}{2}$ mile and upwards.

must occasionally occur in steam trains: the weight of the heavier coaches is mainly in the bogies.

The disastrous effects of collisions are mainly due to the frame of one coach over-riding the frame of another and the bogies being packed together under the coaches.

It is not a difficult matter so to design the ends of the underframe as to prevent over-riding of one underframe upon another, and in the United States it is proposed that the bogies should be anchored more securely to the bodies in order to throw more of the energy lost by the collision into the bogies and to use them as stops to prevent over-riding. It is much more rational to proceed on these lines than in increasing the strength of the underframe, pillars, and roof.

Non-inflammability has hitherto been secured by the extensive use of steel instead of wood, but there is no reason why a lighter metal should not be used.

Lightness of construction may be obtained either by using reduced scantlings, which is undesirable as involving a reduction in the factor of safety, or by using lighter materials, or by using materials of greater intrinsic strength, thus enabling the scantlings to be reduced without sacrificing the strength of the whole structure. Unfortunately it is necessary to buy more costly materials in order to

combine strength with lightness; some of the lightest and strongest materials are still very costly, one proprietary article exceedingly suitable for rolling stock construction costing over £300 per ton. It is necessary at this point to consider to what extent increased capital expenditure is justified by the saving effected in running expenses.

Assuming 100 watt-hours per ton-mile at the ends of the high-tension feeders as a typical energy consumption in the near future, and 60,000 miles per annum as a probable mileage per car per annum, then every ton of motor car involves a consumption of 6,000 kilowatt-hours per annum. This is equivalent to an annual expenditure of £12·5 per annum per ton for energy if a total cost of 0·5d per unit is assumed. It is recognized that with centralized power distribution a lower selling cost than this is attainable, but except on the North-East Coast it is hardly probable that electricity could either be bought from companies or corporations or produced by railway companies themselves at a cheaper rate. Unfortunately the evening railway peak coincides with the winter tramway and lighting peak in large towns, thus militating against a

£14·5 per trailer in labour and material in order to save a ton in weight on the particular service chosen for this illustration, or, in other words, every pound of weight saved produces an economy of about 2d. per annum, or is equivalent to securing one additional passenger per annum in perpetuity.

But further considerations of capital expenditure are involved. Every ton of coach involves a consumption of 6,000 kilowatt-hours per annum, and plant has to be provided to produce this energy. It will be observed in Fig. 4 that the maximum demand for energy acceleration is exactly proportional to the weight of the train. The capital expenditure in small or medium systems does not decrease directly as the weight of the train, but is affected by the ratio of the maximum load to the mean load. After a certain point the capital expenditure per ton of train will decrease owing to the reduced cost per kilowatt of the power house and sub-stations, but not sufficiently to affect in any marked way the arguments advanced in this paper.

In a plant supplying an infinite number of trains the maximum and mean loads would be the same, and in a plant supplying only one train the ratio would be approximately three to one. An average plant carries about 50 per cent overload momentarily, and consequently the cost of the turbines, generators, rotary converters, and transformers will be more than increased proportionately to the weight in any system carrying less than about 14 trains, as shown in Fig. 4. Hence the smaller the system and the severer the schedule the more important is the weight of the train.

In designing cars to give a maximum seating capacity for a minimum weight a careful investigation of the maximum possible width is the first essential, because extra seats can be given by extra width with a smaller increase in weight rather than by extra length: in many cases extensive slewing of tracks will be justifiable if practicable where structural alterations to the platform are not too expensive, or where tunnels do not prohibit this. In settling the dimensions of the cars the ultimate range of the rolling stock must be considered, but it does not appear necessary or desirable to make suburban stock of such dimensions that it will conform to the minimum loading gauge for the whole of the system. If bows are required on the roof to collect current from an overhead wire, an elaborate survey of the whole system that may ultimately be served by overhead conductors will be essential, as places occur on English railways where it is absolutely impossible to run an overhead conductor.

If 60-ft. coaches are used an extra 12 in. in width will give 15 more seats on a basis of 4 sq. ft. per passenger; the width of the gangway must be 2 ft., and consequently if the cars can be made 10 ft. wide, instead of 9 ft., five seats can be given crosswise instead of four. If the average coach seats 100, ten more seats per car will result in a 10 per cent decreased capital expenditure on rolling stock. The increase in weight will be limited to that for the increased width of the floor, roof, and seats, and is about 2½ cwt. per 10 ft., or 15 cwt. per 60-ft. car; or in other words, the additional seats gained by the extra width represent 1 cwt. per seat. If this extra seating is provided by extra coaches an extra weight of about 5 cwt. per seat is involved.

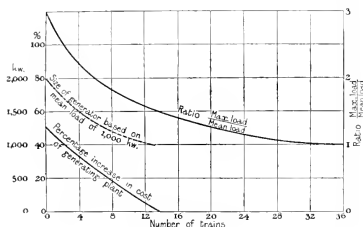

FIG. 4.—Influence of Number of Trains upon Capital Cost.

reasonably cheap supply. Production by a railway company has the advantage that no selling or advertising charges, or charges involved in laying mains in streets, have to be borne. Further, the operation of a generating station and sub-stations falls naturally within the province of the Chief Mechanical Engineer's Department, and not only is the highest efficiency obtained but also management charges are reduced to a minimum, and the changes of policy that occur with municipal stations are avoided.

The cost of repairs to each ton of rolling stock will amount to about £5 per annum for a high-speed service; and its passage over the rails will probably involve repairs to the track equivalent to another £1 per annum, or a total cost per ton of motor car of £18·5 per annum. On similar lines the cost per ton of trailer car will be about £14·5 per annum, the energy charge remaining constant and the other charges being smaller. The capital cost per ton of motor car will be approximately £70, and per ton of trailer £45. Hence every ton of weight saved represents (taking interest and depreciation on capital at 10 per cent) a total saving per annum of £25·5 per ton of motor car and £19 per trailer car per ton per annum. It becomes therefore a commercial proposition to spend as much as £185 per motor and

The length of the coach must next be considered; this will be determined by the throw of the coach, the versed sine of the worst curves on which trains will pass each

along a train in search of a seat or of friends is much appreciated. The absence of doors decreases the cost of maintenance, and appreciably increases the strength of the

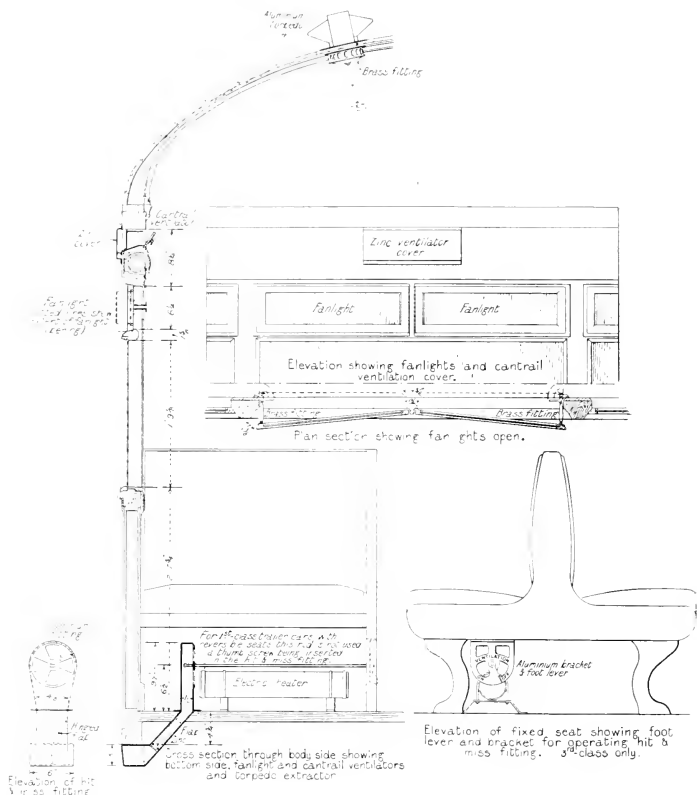

FIG. 5.—Arrangement of Ventilation on New Electric Trailer Cars on Lancashire & Yorkshire Railway.

other, and the minimum width between the tracks at that point. With corridor coaches, or side-door coaches with doors opening inwards, or sliding doors, a very small clearance can be adopted with safety.

The comfort of the corridor coaches is greater than that of the side-door coach, and the possibility of moving

body, while ventilation and heating can be carried out more uniformly and efficiently.

The ventilation of the cars has considerable influence on the energy consumption of the coaches, because the heating load becomes very appreciable in cold weather. On urban railways in the English climate it may be estimated

that there will be at least an increase of 9 per cent in the load in the winter months due to heating only. It is most important to secure a minimum weight for the heating equipment, and it would pay so to arrange it that it could be entirely removed when not required.

The latest arrangement of ventilators and heaters as used on the Lancashire & Yorkshire Railway is shown in Fig. 5. It will be noticed that cold air is collected along the sides of the coach at the floor level and is passed over the electric heaters as it enters the coach, a supply of warm fresh air being thus secured, which is eventually extracted by either the ventilating fan or the ordinary torpedoes. It is essential that the heaters should be raised well above the floor level so that the floor can be washed thoroughly from end to end without danger of damaging the electrical apparatus. Drain holes should be provided in the floor for the water used for washing to run out, and all corners should be provided with a curved moulding of either wood or sheet aluminium so that the corners can be thoroughly brushed.

Ventilation can be equally well effected on the elliptical type of roof by means of fans communicating with shallow ducts running the full length of the roof. The weight of a fan-extracting equipment is practically the same as that of a set of torpedo extractors, so that the net increase due to the use of fans will be the weight of the shallow troughing which runs the length of the car.

The fanlight and cantrail ventilators are more for summer than for winter use. The result of adopting the corridor coach with such a system of ventilation and heating is a uniformly warm and comfortable coach—a result which cannot possibly be obtained with side doors.

The absence of doors which may fly open and foul trains on an adjacent track enables the maximum width of coach to be used, with a consequent increase of earning capacity, and also does away with the possible danger of trains leaving a platform with the doors adjacent to the seats in an open position.

As previously stated, the limit of suburban services is about 22 miles, and coaches that have to traverse such a distance in the open country must be of the corridor type in order to give the great comfort which is necessary to develop the traffic to its greatest extent.

Having decided on the maximum length and width permissible for the body, it is important to consider further the directions in which weight can be saved in this part of the coach, as this has a very direct influence on the total weight. A light body with weights distributed to the best advantage permits the use of a lighter underframe, and this in its turn reduces the rated horse-power of the motors for a given schedule.

The reduction in the rated horse-power of the motors permits of lighter bogie scantlings, and also in many cases of a lighter design of control apparatus. The influence of the weight of the body is therefore progressive throughout the whole car, and for every ton of weight saved in the body it is probable that another ton can be saved in the bogies and motors.

The roof of the body may be either of the clerestory or elliptical type. The clerestory type of roof is very little used in this country on modern rolling stock, but is still extensively used abroad, mainly on account of its supposed superiority for ventilation purposes. The elliptical roof

is lighter than the clerestory type, and also enables a coach to be more uniformly lighted, owing to the superior reflecting qualities of the smooth surface of the elliptical roof. In order to obtain the best illuminating effect the finish of the roof should be a matt-white and the lamps shaded so that the filaments do not come into the line of sight. The design of the clerestory roof is inherently weak, and is specially unsuitable where bows have to be supported on the roof. It is to be noted that the presence of bows which will weigh 10 cwt. necessitates a considerably stronger roof, not only to carry the weight of the bow, but also because it will be frequently necessary to walk on the roof, when attending to inspection and repairs.

Very little difference is made in the weight by the use of any material other than wood for the roof sticks and pillars. It would appear that there is little object in using steel for the pillars, as some of the Australian hard woods are practically as non-inflammable as metal, when the scantlings used are not too small.

For the actual outside roof, wood, steel, or aluminium can be used. There is practically no difference between the weight of the roofing in a wood or aluminium roof, but approximately half a ton in weight can be saved on a 60-ft. car by the use of an aluminium roof instead of a steel roof.

At this point it may be as well to point out that aluminium, in addition to its extremely light weight, has the advantage of being non-corrodible, and therefore requires very much less painting than either steel or wood. A considerable saving should also be effected when repainting is required, as a single coat of paint and one of varnish ought to meet all requirements.

The main difficulty that has been encountered by the use of aluminium is the erosion of the holes where screws or nails are put through the plates to secure them. If the coach, however, is properly constructed and the movement of the structure is not too great, this is not of much consequence, as shown by the sample aluminium panel exhibited.

By the use of aluminium for the outside panels a saving of nearly half a ton can again be effected as compared with steel.

The comparative weights and cost of various panelling materials are as follows:—

	£	s.	d.
426 sq. ft. steel panelling 18 W.G. at 195 lb. per sq. ft.	830	7	3
426 sq. ft. baywood panelling 3/8 in. thick at 1 lb. per sq. ft.	426	10	6
426 sq. ft. aluminium panelling 16 W.G. at 0.88 lb. per sq. ft.	375	18	4
426 sq. ft. 4-ply panelling 5/16 in. thick at 1.06 lb. per sq. ft.	452	16	17

The weight of the glass in a modern coach is a very considerable item, amounting to 7 cwt., or 1.4 per cent of the weight of the whole coach. Though it is a comparatively small matter, some slight weight is saved by having a perfectly plain finish to the interior of the car. Not only does this produce the most artistic effect, but it also facilitates inside cleaning and avoids the use of expensive woods, carved work, and meaningless pieces of scroll work and pillars.

It is also possible to effect economies in the seats. If throw-over seats are used it is essential to use iron castings, as aluminium is not strong enough to stand the constant turning-over of the seats. By the use of fixed seats, instead of turn-over seats, the same material being used in each case, approximately 1 lb. per seat can be saved. By the use of aluminium or other light alloy castings for the fixed seats, the weight would probably be reduced to half that of reversible seats, and, as the seats per car weight approximately 1·5 tons, nearly 0·75 ton saving in weight can be effected in this direction.

If traffic considerations permit, fixed seats may be used, with a consequent increase in the seating capacity of approximately 10 per cent per car, which is, of course, equivalent to an eventual reduction of 10 per cent in the total weight of the rolling stock to be moved.

It is becoming generally recognized that on the comparatively short journeys made by suburban rolling stock the public do not mind which way they sit; consequently fixed seats should always be used. Weight can be economized by not providing seats, or by leaving a large amount of standing space. This is not advisable, and as far as possible seats should be provided for every passenger.

Fig. 6 shows in diagrammatic form how fixed seats provide the increased seating accommodation. It is advisable to provide a certain amount of open space in the vicinity of the gangways, as this forms a sort of a reservoir for passengers to stand in when they are getting in and out simultaneously, or when a large number of people are getting out at the same time.

Wood has very commonly been used in the construction of the floor. The relative weights of floors of various materials are as follows:—

	Ton	cwt.	qr.	lb.
Weight of floor, yellow pine 1 1/2 in. thick	0	16	0	19
Weight of steel plate (5 lb. per sq. ft.) with yellow pine covering 3/4 in. thick	1	13	1	1
Weight of corrugated iron, No. 18 gauge with expanded metal 3/4 in. mesh and 1 in. thick composition at 7 lb. per sq. ft.	2	10	0	4
Weight of composition 1/2 in. thick and yellow pine 1 1/2 in. thick	1	13	3	5

It would seem probable that the floor of the future would consist of corrugated aluminium plates filled in with some form of composition, such as treated cork, to a sufficient depth to cover the crests of the corrugations by about 1/4 in.

The design of the underframe depends largely upon the weight of the body and upon the size of the motors and the motor bogies. It is very important that the motors should not be so large as to come up within the framing of the motor-car, as it then becomes very difficult to introduce the necessary diagonal bracing in the vicinity of the bogie centre. If this diagonal bracing is to be omitted the sole bars have to be made of a correspondingly thicker section, thus increasing the weight. Up to now the use of a high-tensile steel has not been sufficiently considered in the construction of underframes; such steels have been extensively used in motor-car construction and in bridge building. So far as the author is aware they have not been applied to electric rolling stock. The usual structural steel is that which complies with the British Standard Specification No. 173, having a breaking strength of 28 to

32 tons per sq. in., with an elongation of not less than 20 per cent.

The relative strengths of this steel and two alloy steels used at present, in motor-car construction, but equally available for electric rolling stock, are as follows:—

Steel	Max. Stress, Tons per sq. in.	Elastic Limit, Tons per sq. in.	Elongation on 2 in. Per cent	Reduction of Area, Per cent
Nickel 3%, C 0·2%,	30	19	31	31
Vanadium 0·27%, C 0·2%	44	33	19	41
British Standard Specification for carriage under-frame ...	30	14	20	50

These steels are nearly twice as strong as a steel usually employed to-day, and in consequence the scantlings can

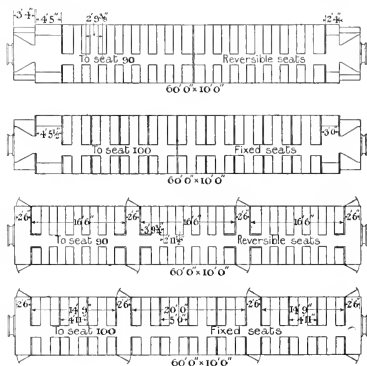

FIG. 6.

be reduced by at least 25 per cent in area, with a corresponding reduction in weight.

The weight of an underframe for a 60-ft. trailer coach is approximately 5 tons. Nearly a ton of this weight might be saved by the use of suitable material. It is recognized that alloy steels are more expensive and are slightly more difficult to roll, but there should not be more than 100 per cent increase in cost per ton of material, while the labour involved in erection would of course be less.

As the first cost of underframe material is low and will never exceed more than £7 10s. per ton, any saving in weight made by the use of more expensive material will easily pay for itself.

The disposition of the weights of the apparatus attached

* Rolled plate.

to the underframe has a considerable effect on its design; and it will be seen from Fig. 7 that the weight per foot-run, and the brake, resistances, and control apparatus of the motor cars should be distributed as far as possible along the length of the body, even if it involves some slight increase in the cost of cabling.

The stresses on the underframe will be relieved if the vacuum pump and motor, or in the case of the Westinghouse brake the air compressor and motor, are made as light as possible. Considerable progress has been made with the design of high-speed compressors for a Westinghouse brake, but a vacuum brake is so much simpler and so much cheaper to maintain that there is a considerable

cars and trailer-cars, and it will be noticed how much more severely the body is stressed, and how important it is to keep the weights as low and as near the centres of the bogies as possible.

The bogies generally may be divided into two broad classes, those arranged with equalizing beams between the axles, and those built on the lines of the ordinary English carriage bogie. The equalizing type of bogie is always the heaviest type, and is quite unsuitable for English railways with their excellent permanent way. It may, however, be desirable on American interurban roads with poor road beds.

The ordinary type of bogie used for carriages on the

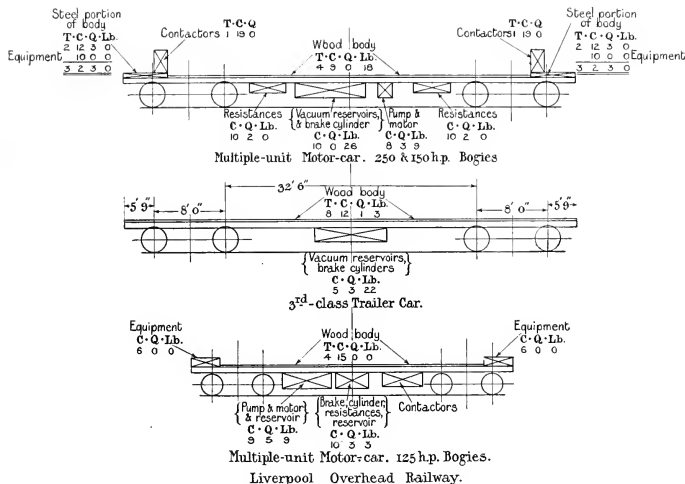

Fig. 7.—Distribution of Weights on Underframe.

field for a high-speed vacuum pump of light weight. A pump somewhat on the lines of a motor-car engine but with automatically actuated valves will probably be used in future for this purpose. The reservoirs which are essential to the vacuum brake should be made of aluminium.

In order further to reduce the weight of the body, the use of aluminium cable should be considered, though the difficulty in jointing introduces a serious fire risk, and in many cases renders its use inadvisable; and in connection with the contactors, wherever it is possible to use bar connections aluminium bar should be used rather than copper, and wherever castings are subjected to light stresses aluminium castings should be used.

Fig. 7 shows the approximate distribution of the weights, and the bending moments caused by them, for both motor-

steam railways of this country may be built with elliptical or spiral bolster springs, either outside or inside the wheels. There is a considerable advantage in putting the springs inside the frames, as this enables the bolster to be made wider and the bolster spring to be put farther away from the centre-pin of the bogie, thus tending to diminish rolling. There is a considerable saving by using spiral bolster springs instead of elliptical bolster springs; nearly 0.75 ton per coach can be saved in this way.

In the author's experience elliptical bolster springs are quite unnecessary for the purpose of steady riding. The best results are obtained by having short, stiff semi-elliptical springs over the axle-boxes with assistant helical springs at their ends.

The wide frame involves an increase in weight; but on

† With bogie.

* Without gear

account of the steadier riding obtained by the wider centres of the bolster springs it is worth having.

Cast iron is very usually used for axle-boxes, but cast-steel axle-boxes and cast-steel axle-box slides will enable the weight of these parts to be reduced by 22 per cent.

In connection with the weight it is very important to consider the arrangement of brake-blocks. It is very usual in modern designs to arrange for blocks to press on either side of the wheels with a view to eliminating the stresses due to a one-sided application of the brake. The double brake-block arrangement involves, however, a very considerable increase in weight, amounting to nearly one ton per coach. The increased stresses, however, will mean increased diameter of the axles, increased bosses on the wheels, and an increase in the size of the motor housings,

Better results can be obtained with independent blower sets, but the complication of having an additional small motor to maintain, and the necessary air ducts do not compensate for the saving effected. Generally speaking, a light motor means a high-speed motor, and a high-speed means a large gear ratio; but it will be found cheaper to renew gears than to carry a standing charge of moving an unnecessary weight.

The tables accompanying this paper give particulars of the motor and trailer coaches used by the leading electric railway companies in England and the United States, and it will be realized that the question of weight has not had the same attention given to it as the question of equipment.

Many of the electric railways which were pioneers in

Square feet per ton (total)	23.0	27.4	21.0	19.28	—
Kilowatts for heaters	4.8	—	—	4.8	—
Kilowatts for lighting	1.5	—	—	0.76	0.80

which will amount to a greater weight than that saved by the single brake-block arrangement.

Fig. 8 shows the latest motor bogie as adopted by the Lancashire & Yorkshire Railway.

The scope of this paper does not permit a full discussion of the weights of the motors, controllers, and resistances, but it should be pointed out that the totally enclosed railway motor has not been found really necessary in this country. The motors operated by the Lancashire & Yorkshire Railway Company are run continuously with as many ventilating openings as possible, and no trouble has been experienced except on one occasion when very fine snow was being blown horizontally in large quantities, and even in this case the trouble arose more with the resistances than with the motors. In order to get a light motor it should be of the self-ventilating type, and the movement of the armature should produce a powerful draught through the motor.

this country and in America will in a few years be reaching the period when, in the natural course of affairs, the gradual renewal of their rolling stock will have to be undertaken, and it is to be hoped that the general considerations outlined in this paper will assist in directing the attention of electric railway engineers to increasing the capacities of their systems and decreasing their maintenance by the provision of lighter rolling stock.

The principles outlined in the paper are equally applicable to electric tramway systems, light railways, and high-speed suburban services operated by steam engines. Owing to the greater "train resistance" of trams the energy consumption in this respect is not exactly proportional to the weight; but on account of the great frequency of stopping and starting, the acceleration component completely overwhelms the other aspect of the case and lightness of construction becomes a matter of the first importance if economical working is to be attained.

DISCUSSION BEFORE THE INSTITUTION, 12TH MARCH, 1914.

Casson

Mr. W. CASSON: I think there can be no doubt as to the importance of the question of weight which the author has put before us to-night, and the much more direct effect that it has on the operating costs of electric railways than on those of steam railways. I cannot help thinking, however, that he has gone rather far in estimating the probable effects of small reductions in weight on the maintenance costs, when one considers the rough and ready conditions that obtain in operating. There is one question that I should like to ask. Should not the horizontal scale in Fig. 2 be "time in seconds" and not "speed"? So far as Fig. 3 is concerned, I am not quite sure whether the percentage there is the percentage that the accelerating energy bears to the energy input of the train or to the energy output of the motor. If it be the former it seems to me to be about correct; but if it be the latter I think it is more like 80 per cent with stops half a mile apart. With regard to Fig. 4, I hardly think it would be found in practice that with such a small number of trains as 56 one would get anything like unity for the ratio of the maximum to the mean load. The number of trains on the underground system supplied from Lots-road power station is very much more than 56, and we should be only too pleased if we could get a figure of 1 for the ratio of the maximum to the mean load. Moreover, it is always necessary to provide against the contingency of an unusual number of trains starting at once. That is the kind of consideration that prevents these calculations being carried too far. If that were done we should be liable to have the whole arrangement upset by a slight change in the next month's time-tables. The same thing occurs to me in regard to the question of reckoning maintenance cost per ton of car. It seems to me that there are other considerations, which may be quite small and yet may have such an effect as completely to swamp the consideration of the weight in regard to maintenance, even if the weight is all put in the right place. For instance, the rolling stock on the Central London Railway is much lighter than that on the London Electric Railways; but from causes which I need not go into, its maintenance cost is considerably higher. The first electric rolling stock on the District Railway in which wood and aluminium were used is lighter than the more modern steel rolling stock, but it is more costly to maintain.

With regard to first cost, the original wood and aluminium stock was actually more expensive than the steel stock; it was cheaper, however, than our latest steel stock which is just being put into service, but it is difficult to make a correct comparison owing to the great general advance in the cost of material and labour for rolling stock.

The seating diagrams given by the author are of great interest, especially as showing the different views held by various people on what constitutes adequate seating room. People in the north country are supposed to be built on a larger scale than southerners, but I am quite sure that all our passengers would strongly object if they were placed in the seats that the author has provided on his trains. The seating room on the author's coach compares as follows with that on the District Railway:—

	Mr. O'Brien	District Railway	Mr. Casson
Longitudinal seats ...	just under 18 in.	20 in.	
Cross seats ...	approximately 16 in.	19½ in.	
Distance between centres of cross seats ...	4 ft. 11 in.	5 ft. 8 in.	

I cannot help thinking that with the very large number of stops per mile on the District Railway there would be considerable difficulty in getting the passengers in and out of the cross-seat cars, especially with the comparatively small door openings that are provided. The other day I was told by a traffic superintendent of one of the railways that "railway engineers are much too fond of trying to crowd too many seats into the cars, whether they are comfortable or not. It would be better to have fewer seats, so that they can be made more comfortable." I certainly think that with the arrangement of seats and the small doors shown it would be difficult to handle passengers fast enough for stops half a mile apart. But so far as seating is concerned, as long as we provide the traffic department with floor area it is for them to say how they want to divide it. With regard to the question of vacuum brakes, the simplicity and the low maintenance costs must be admitted, but I do not know of any system operated with vacuum brakes that is running a service of the same sort that there is on the underground railways of London and New York. I do not say that such systems do not exist, but merely that I do not know of any. In any case I think there would be difficulties. I quite agree with the author as to clerestory roofs, and I fancy everybody does at present, but fashion seems to have a lot to do with this question. For rolling stock for use in the Tubes, however, where there is no room for outside ventilators, the elliptical roof introduces some interesting problems in ventilation. The author's remarks about bogie design and construction agree exactly with our experience on the underground railways, particularly as to its not being necessary to use elliptical springs on the bolsters. As a matter of fact one very satisfactory trailer bogie that we use has no elliptical springs at all; it has two helical springs over each axle-box, and helical bolster springs. I agree as to the weight of the equalized type of bogie and as to its being unnecessary for anything like that sort of service. As to its weight, the District Railway bogie, mentioned above, which has cast-steel side frames and a 7-ft. wheel-base, weighs less than an equalized bogie having a much more flimsy construction and only a 5-ft. wheel-base. The 7-ft. wheel-base bogie rides very much better and is far cheaper to maintain. With regard to the question of wheel-base, there is considerable difficulty in practice in reconciling the use of a long wheel-base with the placing of the motor masses near the centre of the bogie. That is one of the difficulties experienced by designers in reconciling the requirements for a satisfactory bogie. The outside frames shown in the author's design are interesting, and where the positive conductor rail is far enough away to give room for the bolster swing links in that position it must be a great advantage. Unfortunately we have not got that. With regard to the question of motor bogies in general, I cannot help thinking that

Mr. Casson. engineers do not take into account to anything like a sufficient extent that they are giving that bogie the work of a locomotive to do; in fact, as far as tractive effort is concerned, it does more work than a good many locomotives. I do not think the motor bogie receives anything like the attention that it ought to do. If we took a lesson from the locomotive engineer and went more on the lines of a locomotive in building motor bogie-frames it would be much better. With regard to the question of cast-steel axle-boxes, I agree with the author, but we do not find cast-steel axle-box slides are very good. They save an almost infinitesimal amount in weight and they wear themselves and the axle-boxes out very rapidly. We prefer cast iron. With regard to the table on page 453, I cannot help thinking it would have added very much to its interest and the amount of information that we get from it if instead of taking the motor car as the unit for comparing weights, we had what I may call the traffic unit, that is to say, the motor car and the trailer car or cars, $1\frac{1}{2}$ or $1\frac{3}{4}$, or however many trailer cars go with each motor car. For instance, I recognize No. 2 in Table 1 as the Central London Railway Standard motor car. We have reduced the number of cars per train now since the motor omnibuses became so aggressive, but when these motor cars were originally introduced there were two motor cars to a 7-car train. It alters the whole question of relative weight if that is taken into account. I have here the figures of the latest steel rolling stock on the District Railway which is just being put into operation. They are as follows:—

Trailer cars per motor car	1
Motors per motor car	2
Horse-power per motor	230
Temperature rise at which horse-power is taken for 1-hour run... ..	135° F.
Gear ratio	3/37
Diameter of driving wheel	36 in.
Diameter of trailing wheel... ..	30 "
Weight of each motor	6,100 lb.
Weight per rated horse-power	26.5 "
Bogie wheel-base (motor)	7 ft. 3 in.
Bogie wheel-base (trailer)	7 "
Weight of car complete (motor)	33 tons
Weight of car complete (trailer)	22 "
Weight of motor bogie complete	11.4 "
Weight of trailer bogie complete	3.8 "
Weight of motor bogie without motors	6 "
Weight of car body complete and equipped (motor)	18.2 "
Weight of car body complete and equipped (trailer)	14.4 "
Weight of equipment complete including motors but not compressors	7.3 "
Length of car	49 ft. 9 in.
Width outside	8 ft. 8 in.
Length of bogie centres	34 ft. 1 in.
Floor area	320 sq. ft.

The whole of this is passenger space, except that in the front car of the train a space 3 ft. x 8 ft. is shut off for the motorman. The space available for passengers is

thus 99.1 per cent of the total floor space in an 8-car Mr. Casson train.

Square feet per ton for motor and trailer car ...	11.6
Square feet per ton for motor car only	9.7
Square feet per ton for trailer car only	14.5
Horse-power per ton of train	8.4

The most severe continuous service on which these trains operate is about 17 miles per hour schedule speed with stops about $\frac{1}{2}$ mile apart.

Mr. H. W. FIRTH: The author emphasizes on page 445 the importance of the question to which Mr. R. T. Smith recently called attention in connection with locomotives, and to which I also referred in the discussion, namely, the characteristic curve of the motor. Mr. O'Brien shows that that is again important, not only in connection with the question of locomotives or the utilization of suburban rolling stock on non-suburban services, but even in suburban traffic where a certain amount of non-stop running is necessary. He refers to the question of strength as regards collision, and his remarks seem to show the importance of keeping down to the lowest possible limit the weight on the underframe—that it is much more important to keep that down than to keep down the weight on the bogies. If that be so, it certainly seems to show that single-phase equipment, which requires very heavy apparatus on the underframe, would be less satisfactory in this respect than systems which place most of the weight on the bogie. The author also gives the capital cost of motor coaches as £70 per ton, and of trailer coaches as £45 per ton. I take it that the difference is entirely accounted for by the electrical equipment. I should like him to tell us whether this is so or whether it costs more per ton to build a motor car than to build a trailer car, excluding the equipment. The light car design which the author has shown is very interesting, but I think it does not give as great a seating capacity as side-door compartment cars do. Thus, the light trailer car of the Lancashire & Yorkshire Railway, if my figures are correct, provides a seating capacity of 1.62 seats per foot-run of train, whilst a side-door compartment car gives a seating capacity of at least 1.8 seats per foot-run of train; moreover, this light car gets that seating capacity per foot of train (which is less than that of the side-door compartments) only by increasing the width of the car to 10 ft., or at least 1 ft. more than usual. I should like to know whether these 10-ft. wide coaches are operated over the same road and at the same platforms as ordinary narrower stock. If this be the case, how are the platforms arranged so as to deal with both types of coach? The author makes a point that the gauge of the rolling stock should not be restricted to the limiting point of the loading gauge of the line. That is all right in case the limiting point of the loading gauge is in some out-of-the-way portion of the line, but there are a large number of places in the very centre of the heaviest suburban traffic in London where 10-ft. cars could certainly not be run. I think the seating capacity per foot-run of this car does not show up as favourably as I thought it might compared with the side-door arrangement. As regards the weight per seat, or number of seats per ton,

* R. T. SMITH. Some railway conditions governing electrification. *Journal I.E.E.*, vol. 52, p. 203, 1914.

this car is, so far as I know, far ahead of anything that has ever been built. The author points out that the side-door car is much less inherently strong than the end-door car. I should like him to tell us the time that it takes to empty a full car of this description on its arrival at a terminus. I think it will be found that quite a long time is taken to empty one of these cars. It may be all right with the frequency of service with which these cars have to contend, but in some cases the frequency of service is so great that the utmost speed is required in loading and unloading passengers. I notice in Fig. 6 that the author shows two designs with additional doors in the sides of the car as well as those at the ends. Does not this increase the weight of the car over the weight of those with end-doors only? Also, is there any advantage from the point of view of the passenger in this arrangement over the arrangement shown in the first two diagrams? It seems to me that they can be unloaded more quickly, but I wonder whether the author can give us any results from actual operation. With regard to the question of bogies, I notice the wheel-base of the new bogies is 10 ft. I think I am right in saying that the original Lancashire & Yorkshire bogies had an 8-ft. wheel-base. Has this increase in wheel-base been due solely to considerations of providing satisfactory running for light cars? In a paper²⁵ read last month by Mr. Willox before the Institution of Civil Engineers the very great importance of wheel-base in regard to the question of rail wear has been pointed out. I wonder if the author could give us any information as to rail wear with relative wheel-bases, and tell us whether the question of rail wear influenced the choice of wheel-base. Or was it chosen solely with a view to improving the riding of the cars?

Mr. J. B. SPARKS: In discussing methods of reducing the weight of motor coaches, the author presents much information of value, but I consider that the calculations which he gives on page 447 largely exaggerate the importance of such a reduction in weight, and, moreover, are worked out on a wrong principle. The author has assumed that the costs of energy, and of repairs, maintenance, etc., vary *pro rata* with the weight of the coach, but I submit that these costs will not vary in any such proportion, and that the cost per ton will increase for any reduction in the total weight. Further, I believe I am right in saying that the weight of all types of electric rolling stock has largely increased since electric traction was first introduced, it having been found that the more substantial construction obtained with an increased weight reduced the maintenance. Provided the required strength is obtained, it is certainly advantageous to avoid excessively heavy cars, but I submit that it would not pay to increase the cost of rolling stock by 10 per cent in order to save 4 per cent in weight, as the author suggests. With regard to the importance of weight reduction as affecting energy consumption, I have made the following estimate as to what reduction in total cost of working a railway would result from reducing the weight of the motor coaches by as much as 10 per cent. Taking the cost of locomotion (that is the cost of operating the trains) as 30 to 40 per cent of the total cost of operating the railway, and the cost of energy as 50 per cent of the cost of locomotion, the energy accounts for from 15 to 20 per cent of the total cost of working the railway. Owing to the various losses in the

electrical system and the energy required for overcoming wind resistance, etc., we may assume that a reduction of 10 per cent in the weight of the rolling stock will only reduce the energy consumption by 5 per cent. This saving of 5 per cent in energy consumption would probably reduce the generating costs by not more than $\frac{2}{3}$ per cent. As stated above, the energy cost amounts to from 15 to 20 per cent of the total cost of operating the railway, so that if this be reduced by $\frac{2}{3}$ per cent the reduction on the total cost of operating the railway amounts to only 0.375 or 0.5 per cent. This reduction of less than 0.5 per cent in the total cost does not seem to bear out the author's figures. I should like to know if I am right in assuming that he takes the expenditure on energy consumption, maintenance, etc., *pro rata* with the weight of the coach. [Mr. O'BRIEN: Yes, that is quite correct. I estimate that if the weight of the coach be reduced from 10 tons to 9 tons the cost of repairs should be reduced from £50 to £40 per annum.] I submit that this is a wrong principle on which to estimate this saving, and that the reverse to what the author suggests is more likely to occur.

Mr. R. H. BURNETT: A similar subject was discussed at the Institution of Civil Engineers only the other day when a good deal was heard about the great wear of rails, although nothing was said about the tyres. I fancy there must also be a great wear of tyres. In the papers that were read before the Institution of Civil Engineers the authors had investigated most carefully—I may say microscopically—the proper composition of rails to withstand the wear that takes place. I ventured to point out in the discussion on those papers that I thought the ingenuity displayed in determining the chemical composition of rails might be better expended in investigating the cause of their wear, as in my opinion it was due to a very great defect in the gear through which the electric force is transmitted to the wheels. I will confine my remarks to-night to only a few points, and I may start by mentioning that my experience of 40 or 50 years ago on the Metropolitan Railway enables me, I think, to speak on the very points that are being raised by the paper to-night, because of my having had charge for eight years of the rolling stock and the permanent way in steam locomotive days. We did not then work the length of line that is being operated now; the total length of the Metropolitan Railway, the District Railway (which we also operated and maintained), and the other branches of the Metropolitan Railway, was then only 25 miles; but I had some experience of what I may call the intense traffic that is peculiar to electric traction, because of the short distances between the stations, and such questions as starting and stopping quickly, rounding curves, etc., were even then very much to the fore. I wish in the first place to emphasize Mr. Casson's remarks with regard to the need for solidity of the bogies through which the electric force is transmitted to the rails. My observation of the rolling stock of the Metropolitan and District Railways has made me feel that in the attempt possibly to get lightness the very large amount of work that is being done by these bogies has not been taken into account. Taking the analogy that the first speaker made about the bogies of steam locomotives, although they have no driving to do they would soon go to pieces if they were constructed in the more or less—I do not like to use the phrase—dimmy way that I observe. It is very important

* W. WILLOX. Rail-steels for electric railways.

Mr. Burnett

that the bogies should be substantial in view of the enormous force that is given out in propelling the train. I think any saving in the weight of the bogies themselves is quite a mistake. The direction in which one should go is rather to make them more solid to stand the wear and tear upon them. Another important question is the length of wheel-base. To my mind the wheel-base is too short. Theoretically a short wheel-base is the right thing, because it tends to reduce what I may call the "scissor" action between the guiding flange and the high rail. I watched very carefully the action of the various types of bogies running over the Metropolitan Railway in my time, because the wearing away of the rails and flanges was a very important question, and I am satisfied that a long wheel-base is infinitely better in practice than a short one, because it compels the bogie to set itself more correctly to the curve and reduces the flange friction and the wear on the side of the rail. I notice that various figures are given in the table on page 454 for the bogie wheel-base, under the heading of "Trailer cars." I am glad to see that the bogie wheel-base in No. 1 is 10 ft. as compared with 5 ft. in No. 2, and 5 ft. 6 in. in No. 6. I am quite sure that the bogie with a 10-ft. wheel-base is better than a bogie with a 5 ft., or 5 ft. 6 in. wheel-base; in fact I think one need not be afraid of going up to 12 ft. With 40-ft. carriages we had a 20-ft. steady wheel-base—a most important feature for ensuring steady running on the *straight* portions of the lines—and the cars went round the curves with perfect ease when properly guided by radial axles in front and without any wear on the wheel flanges.

The other point that I should like to mention is the diameter of the wheels. The larger it is the better. Mention was made at the Institution of Civil Engineers the other night of the sacrifice of seating accommodation if larger wheels are used. We had wheels 3 ft. 6 in. in diameter and did not sacrifice any seating capacity. I really do not understand why at least 3 ft. 6 in. wheels should not be used on electric rolling stock. Even if it meant sacrificing some seats I believe it would pay. Who would ever think of running a locomotive—of course there is the reciprocating action with it which I admit does not occur in electric traction—with small wheels like those under an electric train? Such a locomotive would knock itself to pieces in no time. It is therefore very important to use wheels as large as possible even if it means sacrificing some seats or raising the floor of the carriages. What does it matter if people have to step a few inches higher than they have to do at present? Another point emphasized in the paper read before the Institution of Civil Engineers was the difficulty of carrying the motors on springs. I am not an electrical engineer and it is not for me to suggest how the thing should be done; but why not attach the motors to the bodies of the vehicles and drive the axles of the carriages through gearing or in some other way, the weight of the motors being carried, not on the axles, but on the body of the car? The weight would then be carried on the springs, which cannot be the case when the motors are attached direct to the axles of the driving wheels.

Mr. Mason

Mr. C. L. MASON: As a representative of the carriage department I have been very much interested in this paper. In particular I was astonished to see the figure that was given for, the saving that is effected by doing away with the superfluous weight of carriages. The trend

Mr. Mason

of modern carriage design is always towards a heavier vehicle, and I think the reason for this is that a lighter coach built on the present lines will not stand up to modern traffic conditions. Secondly, the public demand greater comfort, which means less seating capacity per vehicle or greater weight per passenger, and there is also the steadier riding that is obtained by a heavier vehicle. In designing a lighter coach the carriage superintendent would have to be careful not to increase unduly either the first cost or the cost of maintenance, as it is by these figures that he is judged. The saving in haulage, etc., effected by reducing the weight, referred to by the author, does not show in the balance sheet as such, and would not perhaps be so apparent to the general manager and the directors, and by them credited against the increase in first cost. Naturally, therefore, if the carriage superintendent finds that the lighter vehicle causes the maintenance charges to increase, he is apt to build a heavier vehicle in order to make sure of keeping down his departmental costs. I should like to ask a question with regard to the paragraph at the bottom of page 447, to which a previous speaker has referred. I have not been able to follow the statement that "it becomes therefore a commercial proposition to spend as much as £185 per motor and £145 per trailer in labour and material in order to save a ton in weight." As I understand it, it should be the total saving per annum by omitting this ton of weight, multiplied by the life of the coach; that is to say, so much is saved in first cost, so much in the wear of the permanent way, and so much in hauling the vehicle, and the annual saving multiplied by the life of the vehicle will give the amount that might be spent in getting rid of the unnecessary ton. If we take, say, the £19 per trailer and divide it into the £145, or the £255 and divide it into the £185, it gives a figure of somewhere about 7 or 7½, which from my reasoning would appear to be what the author assumes the life of the electrical coach to be, so that I can only presume I have misunderstood his calculations somewhere. Further, he says on page 446: "It is not a difficult matter so to design the ends of the underframe as to prevent over-riding of one underframe upon another." I should like to ask him whether he knows of a suitable device that will prevent the over-riding of an underframe fitted with buffers, such as we have to use on the London & North-Western Railway.

Mr. Bowden

Mr. J. BOWDEN: Comments have been made on this paper by locomotive, carriage, and electrical engineers, which suggests that this series of papers on electric railway work is bringing together that combination of experience in the development of electric rolling stock which has hitherto been rather conspicuous by its absence. On page 454 the author states that "it will be realized that the question of weight has not had the same attention given to it as the question of equipment." There can be little doubt of this, mostly due to the new conditions and problems raised by electric traction apart from the design of motors and control gear. The design of rolling stock for heavy electric working has been largely a question of trial and error; this paper points out a better way and also the importance of weight saving, to which the remarks of previous speakers suggested opposition. Surely the factor of intrinsic strength which the paper so strongly emphasizes has escaped their notice. We cannot be content with anything but rational design, and we are led thereby to use

viden, only such materials as make for weight reduction. If strength efficiency be thereby sacrificed, the design is not rational. Materials have so far progressed during the last 10 years that alloys of steel and bronze can now be made with such physical properties, that but for their use the hulls of large ships like the *Maurelana* could not have been built within the tonnage limits now common to that class of ship. On similar lines the operating costs of electric traction can be economized. I am in accord with Messrs. Burnett and Casson as to the desirability of following locomotive practice in regard to design, materials, and workmanship of trucks. Early locomotive engineers soon found it necessary to construct frames which, in addition to being suitable as a carriage, were sufficiently rigid to take the stresses of the engine itself and of starting and stopping. The motor truck mentioned in the paper is equipped with two motors of 250 h.p. normal rating, and capable, no doubt, of 50 per cent overload on occasion. Thus the truck may have to stand stresses incidental to 750 h.p. at starting, and equally heavy stresses on stopping. For such service a mere carriage truck is not sufficient, and failure to appreciate this has proved expensive, as many of us know. Judged by the heavy service conditions which obtain in London the truck shown in the paper appears to be light. The vacuum brake is used, and this affirms the suggestion. I would ask the author whether that brake retards so heavily as is required for the Metropolitan and District Company's services where short runs and 20-second station stops are required to meet the time-tables of to-day. The large vacuum reservoirs suggest difficulty in this respect. In truck details I notice that the journals are without button heads, side thrust being taken on the ends of the axles by bearings provided with means of adjustment. This arrangement is comparatively new in this country, though common in Continental practice and in America, but without the adjustment. As Mr. Burnett said, the longer wheel-base eases the side pressure on axles, and end wear is particularly troublesome on short-wheel-base trucks. The gear wheel is bolted to an extension of the wheel boss—I presume in halves. [Mr. E. O'Brien: It is pressed on.] If bolts are used why not take advantage of split gears and avoid pulling off wheels when renewing gears?

Seating and door arrangements have been discussed at some length, and I would refer to experience of both car and compartment stock working together. Car stock only was installed on the electrification of the Metropolitan Railway, and later Mr. C. Jones converted several existing compartment trains built for steam service and of comparatively recent construction; the trailers were fitted with train lines and the end vehicles were mounted on new underframes and motor trucks; fireproofed compartments were provided for control gear and motormen. These trains are greatly appreciated by the traffic department and travelling public alike. Compared with car trains, even those fitted with centre doors, the side-door train loads and unloads faster, the public prefer the privacy, there is less difficulty with draught, and the doors being fitted with slam locks and suitably hung give no trouble or delay in opening and closing. These compartment coaches are easier and quicker at stations than the car trains working on the same service, and the superiority of the old side-door arrangement has been fully demon-

strated on the Metropolitan Railway. There is, more—Mr. Bowden. over, the advantage of utilizing existing stock which by obsolescence might become a heavy charge against electrification.

Dr. S. P. SMITH: On page 445 the author draws attention to the very important matter of the different services for which motor coaches have to be equipped, such as low-speed city traffic and high-speed suburban traffic, which makes it troublesome to obtain the best conditions for both classes of traffic in one and the same vehicle. The result is that a compromise has to be accepted both in the motor characteristics and in the gear ratio. Now this is probably the cause of a lot of the trouble that is experienced on the suburban service, owing to the excessive strains that are set up thereby. It would be far better if there were more elasticity in the method of speed control, for we could then suitably meet the various conditions of working. At present the standard method is to use the series-parallel method of control and quickly bring the train up to a fairly high speed; it is then allowed to coast a certain distance, depending on circumstances, and is finally brought to rest as quickly as possible. This is doubtless rather bad for the equipment, but as long as we are limited to the series-parallel method of control we cannot well avoid working in this way. If, however, we can get more elasticity into the speed control we can get characteristics which are more suitable for both low and high-speed traffic. The recent developments in the design of traction motors tend to show that instead of having only two economical running speeds we can have any desired number, though probably only three or four would be used owing to the complications of the controller. This elasticity is obtained by means of field control produced either by placing the poles in parallel or by diverting the field current. The possibility of field regulation is a consequence of the introduction of interpoles in traction motors. So long as interpoles are not used, one of the most important things that the designer has to bear in mind is commutation, which practically determines the flux; but as soon as the interpole is introduced he can vary the flux as he pleases. The result is that the same heavy starting is no longer necessary to produce a high acceleration, because a much stronger field can be used. It is then possible to run up to whatever speed is suitable and to remain at that speed for a longer period, instead of running to a high speed and then coasting. In this way there are not the same heavy demands on the station either when starting or running. On reaching the suburban line the driver can then notch up to a higher speed when required. By thus taking full advantage of the interpoles, which at present seem to be advocated chiefly for producing good commutation, it is possible to improve the service very considerably by increasing the number of economical speeds; at the same time the starting losses, the maximum electrical demands, and the mechanical stresses will all be reduced. The future will probably show that series-parallel control alone is but one step in the right direction.

Mr. F. W. CARTER: There are only a few matters that I wish to mention in connection with the paper. The first has reference to Fig. 1, which shows the resistance to motion of a two-coach train. Train resistance is a subject on which no two people ever seem to agree, and I must

Mr. Carter, say that I consider the curve given in the paper is very high. At 35 miles per hour the resistances are shown as approximately $18\frac{1}{2}$ lb. per ton; I think this is higher than would be expected even for a single coach of 40 tons weight. I wish therefore to ask the author what is included in the train resistance, because there are practically two train resistances that appear in electric railway work. One is train resistance when power is on, and the other the train resistance when the train is coasting. In the latter, the motors are being driven, and in addition to the true train resistance there is axle-bearing friction, gear friction, armature-bearing friction, brush friction, and wind friction in the motors, all of which appear as resistance to the motion of the train. This may amount to a large percentage of the whole, and in one case that I recently investigated, viz. that of a heavy interurban car of the American type, weighing about 25 tons, having a 4-motor equipment, and running at about 20 miles per hour, the effect of the friction due to the motors when the car was coasting was about 4 lb. per ton. If, then, the train resistance as deduced from the slope of the coasting curve is, say, 16 lb. per ton, only about 12 lb. per ton of this is true train resistance, and the rest is friction which only appears when the car is coasting, since all this friction is attributed to the motor when power is "on." It would not be practicable to attribute the motor friction to train resistance when power is "on," as the gear losses necessarily depend on the power that is passing through the gears. I wish, therefore, to ask the author whether in Fig. 1 the motor friction has been subtracted, leaving the true train resistance, or whether the motor friction is included, which may account for the curve being so high.

I have long contended that unnecessary weight should be saved in trains intended for suburban services, and am therefore gratified to find that the author takes the same view. The value of the saving does not amount to much for long-distance services, as it is only the fact that frequent stops are made that makes a saving in weight result in a commensurate saving in energy. As I read the paper I do not think the author is suggesting that weight should be saved at the expense of strength in the coach, as many speakers seem to have assumed. I am sure the author fully realizes that the saving must not be such as will diminish the strength, but must be effected by more careful choice of material, or by cutting down weight where it is not necessary for strength. Any saving in weight that can be obtained in this manner is justifiable and good economy, but a saving which results in a sacrifice of necessary strength would probably cost more in maintenance than is saved in power. In common with several other speakers, I do not quite appreciate what the author intends to convey by the paragraph at the bottom of page 447 on the subject of the yearly saving due to a saving of weight. It seems to me that it is not right to take maintenance at so much per ton when the question of weight itself is under consideration, because the saving in weight will not necessarily result in a saving in the cost of maintenance. I should say the only saving to be expected would be the power saving of £12 10s. per annum. The only other point to which I wish to make reference is in connection with motor weight. This is a matter that has come forward during the last few years, and it is now usual to design motors with this feature strongly in view, and to

Mr. Carter arrange induced ventilation to carry away the heat in order that as light a motor as possible for the power may be obtained. This is done with the special object of doing away with unnecessary weight, and it is quite in accordance with the author's views on the subject.

Mr. W. A. A. BURGESS (communicated): Although the Mr. Burgess author has dealt rather fully with the reduction of dead weight, he does not refer to the importance of reducing to a minimum the proportion of the motor weight that is directly borne by the axle. This proportion of course very considerably affects the hammering action at rail joints and crossings, and therefore the upkeep of both track and tyres, and to a less extent that of the rolling stock as a whole. The "wheelbarrow" method of motor suspension shown in Fig. 8 is undoubtedly preferable to suspending the whole of the motor weight from the axle, but even so more than half the weight of the motor has still to be carried by the axle. It appears very desirable therefore to aim at the suspension of the motor from the sole plates at a point as near as possible to its centre of gravity, and even though this is by no means easy owing to the necessity for keeping the motor as far as possible below the underside of the car floor, I consider that it will be found practicable in many cases. As the sliding movement of the motors would be doubled by this method, owing to the radius being halved, it would probably be found most satisfactory to suspend the motor by pivoted links which would allow this movement to take place without the necessity for a special bearing sliding in guides on the sole plates. As to the ventilation of coaches, an objection to the method of introducing fresh air at the bottom of the coach and there warming it is the amount of dust that would be kept in suspension in the air; for as users of some of the types of domestic radiators now on the market are painfully aware, there is always an insupportable dust which only the frequent use of a vacuum cleaner can keep down, and which is very perceptible in the rising current of warm air from radiators standing directly on the floor. I therefore suggest that the process be reversed and the air extracted from the carriage at the floor level, fresh air slightly warmed and properly diffused being admitted at the top of the carriage. The heat required by varying outside temperatures should preferably be provided by heaters suitably distributed under the seats or in the foot-board and controlled by the passengers. With reference to carriage lighting, owing to the proximity of the roof to the level of the eye, semi-indirect lighting seems particularly suitable, and with a matt-white roof-surface a plain inverted conical shade of white opal glass suspended directly below the lamps will be found to give a pleasing effect with lamps of moderate candle-power.

Mr. W. Y. LEWIS (communicated): In my paper before Mr. Lewis the Society of Engineers in May, 1912,² I emphasized the desirability of (1) low weight of rolling stock per seat provided; (2) graduated acceleration and deceleration so as to permit of mean accelerations and decelerations several times greater than was customary; (3) regeneration during deceleration. I welcome Mr. O'Brien's paper as dealing with (1), and hope that forthcoming papers relating to electrification problems will discuss the evidently more promis-

² W. Y. Lewis, Intermittency: its effect in limiting electric traction for city and suburban passenger transport. *Society of Engineers, Transactions for 1912*, p. 121.

ing fields, (2) and (3). It seems a pity that the author has not summarized the possibilities in the field that he had explored, by indicating, if only approximately, the extent of the weight reduction attainable by resort to the refinements described. Perhaps he would in his reply state this for the case of the latest Lancashire & Yorkshire Railway train comprising, say, two motor and two trailer cars, which presumably would be capable of the 30 miles-per-hour schedule speed with one stop per mile service mentioned in the paper. It would also be useful if the tables were amplified, especially as regards average weight per seat in a given train with or without refinements. From the paper one might expect that a saving of at least 10 per cent in dead weight per seat is attainable; but this is misleading. The allowance of only 4 sq. ft. per passenger is too low to ensure the comfort which the public demands and which engineers should strive to give. Recently the Midland Railway introduced a new train on the Southend service having six-seats-per-side compartments on approximately this basis, and the patrons of the line are strongly protesting against this bare allowance. If the wide coaches suggested would involve track slewing and platform widening, the capital cost thereof might easily become a sufficiently serious consideration to outweigh the advantages to be gained by saving weight. Analysing the paper, I have found it difficult to account for anything like a 10 per cent saving of weight by the refinements set forth. Assuming that the advantages of extra wide coaches be offset by track widening, etc., I deduce the following results:—

Item	Weight Saved	Extra Cost
Al. roof instead of steel ...	0·5 ton	£60
Al. panels instead of steel	0·5 "	£36
Al. seats instead of cast iron	0·75 "	£70
Special steel underframe	1·00 "	£48
Sundries, say	0·25 "	£25
Totals	3·0 tons	£239

Against this there is the possibility of an increase of dead weight on account of bows, double brake-blocks, etc., amounting to at least $1\frac{1}{2}$ tons and involving extra cost; but other items not included above, owing to insufficient data being given in the paper, may possibly balance these. Assuming this to be the case, it seems therefore that in the 67-ton Lancashire & Yorkshire motor coach costing £70 per ton the dead weight could be reduced to 64 tons (a $\frac{1}{2}$ per cent weight reduction) at an extra capital cost of say £220 (4·7 per cent extra), allowing £19 for the saving in labour cost due to lighter material. This means an increase of the cost per ton from £70 to £77, or 10 per cent. The author appears to suggest that the saving of 3 tons of dead weight would warrant an increase in capital expenditure from £70 per ton to—

$$\frac{(67 \times 70) + (3 \times 185)}{67 - 3} = £82 \text{ per ton}$$

(i.e. a 17 per cent increase). His argument taken in the case of a trailer car is even more startling, since a similar 3-ton saving of weight would, according to the paper,

VOL. 52.

warrant an increase of the rate per ton from £45 to £71 (i.e. 57·5 per cent). The deductions on page 447 do not seem to be sound, and it is to be hoped that they will be satisfactorily explained or modified in the author's reply. The tendency in the design of electrically operated rolling stock is towards increased rather than decreased weight, and it is significant that the latest example of Lancashire & Yorkshire rolling stock described in the paper and presumably tabulated in column 1 of the tables is exceptionally heavy. It remains incumbent upon traction engineers to reduce both the weight and the capital cost. To reduce only slightly the dead weight and thereby considerably increase the capital cost will not help matters at all. In conclusion, I may perhaps be allowed to point out that the prospect of much improvement in the direction of weight-saving cannot make one very hopeful of finding the better solution of traffic problems in the electric train system. I have indicated in the above-mentioned paper that by resorting to the continuous plan of operation (or, if need be, semi-continuous plan) as against the present intermittent plan, the weight per seat can be reduced from 1,200 or 1,400 lb. (as instanced in the Lancashire & Yorkshire rolling stock) to about 400 lb. in the electro-mechanical system recently put forward by me. As to this, I may say with Mr. Hobart, who had deeply investigated it, that a schedule speed of 30 miles per hour with one station per mile in the outskirts and a 16-miles-per-hour schedule speed with 4 stops per mile in urban districts, can be far more easily and cheaply attained than by the electric train system.

MR. C. A. BAKER (*communicated*): The author refers on Mr. Baker page 447 to the question of a railway company producing its own electrical energy, and he puts forward some reasons in favour of its doing so. I should like to remind members that in the recent paper by Mr. Roger T. Smith it was pointed out* that "the generation of electrical energy and its supply is a business in itself," continuing generally to prove that it is more advantageous for a railway company to purchase than to generate electrical energy. I entirely agree with Mr. Smith's opinion, and would condemn the establishment of the two new generating stations now under construction for London railway companies as being encumbrances for many years to come upon their respective proprietors. In neither case has it been possible to select a site that may be considered ideal or even mediocre; electrical energy could be purchased in any quantity that the companies might respectively require, from established undertakings which have reputations for reliability and economy, and at prices that, with the available diversity factor, must be better than those at which a solitary station can in the long run produce. No better object-lesson is necessary than the case of London with its 50 or more generating stations which 15 or 20 years ago were established with the guidance of the most enlightened expert advice and commercial knowledge that could be obtained, and now the question arises what is to be done with them. History will for ever repeat itself, developments in electrical generation have been and will be rapid, and unless it is impossible for a railway company to purchase the energy that it requires, there can scarcely be sufficient justification for the equipment

* R. T. SMITH. Some railway conditions governing electrification. *Journal I.E.E.*, vol. 52, p. 207, 1914.

Mr. Baker. of a generating station and the establishment of a new staff in connection therewith. The author further adds that "the operation of generation, etc., falls naturally within the province of the Chief Mechanical Engineer's Department"; here again I disagree with him. The electrical department should be independent and in charge of a responsible electrical engineer with the right to put forward his own views from his own standpoint, having primary regard to the utmost efficiency of the undertaking unhampered by considerations which a mechanical engineer, who is dealing primarily with duties of another character, may or may not see fit to endorse. As to "the changes of policy that occur with municipal stations" to which the author refers, I fail to recognize what undertakings he has in mind, those stations of the classification suggested in and around London having nearly all progressed most favourably from their earliest days.

Mr. H. E. O'BRIEN (*in reply*): Mr. Casson suggested that in Fig. 2 the horizontal scale should be "time in seconds" instead of "speed in miles per hour." That is quite right, and the suggestion will be carried out. In Fig. 3 the energy is the energy input into the car and not the output from the motors. With regard to Fig. 4, Mr. Casson suggested that an even load would not be obtained when there are 56 trains running. I must admit that he is correct in that. It would be possible to have 1,000 trains and not obtain a level load. What I wished to indicate was that when one gets as many as 56 trains on a system one is beginning to approximate to a level load if batteries are not used. He is quite right in raising that point, and I should have added that explanation to the paper. Mr. Casson and various other speakers have queried the propriety of basing the cost of repairs on the tonnage. Different engineers have different experiences, but our experience in the North of England has tended to show that the repairs do depend very largely on the tonnage of the cars.

Replying to Mr. Mason at the same time on that point, I should like to say that I speak as a carriage and wagon man and as a locomotive man more than as an electrical engineer, and taking the period of the last seven or eight years the very light cars have shown themselves to be exceedingly economical in maintenance, and the heavier cars, even though the design has been strengthened, have proved heavier in maintenance. It is to a certain extent a matter of design. One designer places his material in one position and another designer in another position, better results perhaps being obtained in one case than in the other. I quite understand that under certain special conditions it may be otherwise, as for instance on the Central London Railway.

Generally speaking, the maintenance does depend entirely on the weight; and the weight of the body is the most important part of the weight of the car, because on it depends the weight of all the other parts. I agree that as far as the body itself is concerned a very heavy rigid body will require less maintenance than a very light flexible body, but a light body can be designed which will still be very rigid, and the maintenance of which will be practically the same as that of the heavier body.

Supposing that the weight of a car is increased from 30 tons to 40 tons, in the first place the axle loads are increased; that means to say that larger bearings are

necessary. Even if the bearings are enlarged so as to obtain the same bearing pressures, they will only run the same length of time as the smaller bearings, and when they are renewed it is a larger bearing that has to be renewed. The same remark applies to the tyres.

The cost of tyre renewals will increase even more in proportion, because the tyre has practically line contact with the rail, and consequently the greater the intensity of pressure (we are limited practically to four wheels per coach on an electric coach) the quicker the tyres wear out. When it is necessary to re-tyre, the old tyre has to be scrapped, so that the cost of repairs increases more than proportionately. The same remark applies to the armatures. There is a larger coach and a larger motor, consequently a larger armature with more copper in it. The life of the insulation will be just the same in both cases; but when it comes to rewinding, larger coils and more insulation have to be renewed, so that I do not feel inclined to recede from the position that I took up, namely, that the cost of repairs is very nearly proportional to the weight of the cars.

In the next place Mr. Casson complained of the small seats provided in Fig. 6. I think it is a good point that where passengers are getting in and out every one-third or half a mile a little more knee room is probably required than when the stoppages are further apart; but I hope Mr. Casson will pay us a visit in the North. It is a rather out-of-the-way place and difficult to get to, but I think if he will get into these cars he will find that they are not as uncomfortable as they seem. I consider 16 in. is quite a reasonable accommodation for anybody, and I think that if the 4 ft. 11 in. centre is actually tried it will be found that it allows one to sit quite comfortably.

Mr. Firth pointed out that the side-door car gives greater seating capacity. That is perfectly correct. I think that about 20 per cent more seats are obtained in a side-door car; but if passengers are to be taken 20 to 25 miles out from the terminals, which is what is wanted if possible, as Mr. Roger Smith recently pointed out in his paper, I do not think the side-door car is suitable. It may be suitable in certain districts—it certainly is not suitable in the North of England, with an exposed coast like the Lancashire coast, and it is found that when once accustomed to it the public prefer the corridor car; so much so, that we actually have complaints when corridor cars are removed from a service for repairs and compartment stock has had to be substituted. The circumstances are different in the South, and it is possible there, with the shorter distances between stations, the milder climate, and the shorter runs, that the side-door car would give satisfaction from the point of view of comfort.

It certainly does not give the management of the railway satisfaction as regards the platform staff that they have to keep, because if there are 8 doors per car to open and shut every time, unless this is left to the passengers, it involves keeping a considerable number of men on the platforms for the purpose of doing that work. The time taken to empty one of these corridor cars with end doors when it is crowded is a smaller time than it takes for the motorman to get out of his compartment at one end and walk to the other to reverse the train; and unless the traffic has become so dense that a motorman will be waiting on the platform to step into the other end of the train—that may be the case in London, but it is not the

case as yet with us in the North—unless that point has been reached, the train can be emptied without involving unnecessary delay at the termini.

It was stated that the doors in these corridor coaches were too narrow. The doors are not narrow but exceptionally wide—sufficiently wide, in fact, to allow two people to enter or get out abreast. The door opens in the direction of the exit traffic, and the results obtained in practice are very satisfactory.

The question of the vacuum brake was raised by several speakers. There is no reason—if there is, I should like to know what it is—why the same retardation should not be obtained with the vacuum brake as with the Westinghouse brake; and the retardation on the Liverpool & Southport line is actually greater than on the London lines.

In the case of the vacuum brake a lower pressure, 11 or 12 lb. per sq. in., is used. It is purely a matter of cylinder diameter. In the case of the vacuum brake one has a 21-in. brake cylinder, compared—I am not familiar with the dimensions of the Westinghouse brake—with probably an 8-in. cylinder in the case of the Westinghouse brake. The question of the rapid production of the vacuum is certainly a difficulty. That is why I said that there was a field for a high-speed vacuum pump. The vacuum pumps that are used at present are low-speed and more or less inefficient machines, but even with them it is quite possible to produce a vacuum on a 5-car train within 15 seconds so that 20-second stops are quite practicable. The rapid raising of the vacuum is effected partly by the use of the high-speed valve on the train pipe—which incidentally ensures graduated application of the brakes—and also by having vacuum reservoirs to which the pump is connected while the train is running between the stations, the vacuum in the reservoirs being then used for re-creating the vacuum in the train pipe.

The table on page 453 would have been very much more useful if the names of the railway companies had been given; I was anxious to give those names, and received a general consent with one exception; consequently I had to leave the table as it stands.

Mr. Firth drew attention to the importance of the motor characteristic. I am very glad that he did so because it is one of the things that wants to be very carefully considered in designing rolling stock for suburban services, where it is very difficult to meet the varying requirements.

Then as to the question of collisions, the weight of the underframe should be a minimum. I do not think it is possible to prevent telescoping, but it is possible to go a long way towards preventing it by providing very strong pillars at the ends of the underframes, and by so doing the effect of the telescoping will in many ways be minimized. Collisions at high speeds, I believe, will always cause telescoping, no matter what we do; all that I wished to point out was that the rational way to meet the possibilities of collision was not to increase the weight of the whole car, and thus introduce a perpetual charge, but to try and design ends so that the underframes would not lift over one another, as far as could be done without seriously increasing the weight; and also to do what is being done in America, that is, fasten the underframe on to the bogies so that part of the energy of the collision will be absorbed in tearing away the bogie from its attachment to the underframes. As to the saving effected by weight reduc-

tion, I said "it becomes therefore a commercial proposition to spend as much as £185 per motor and £145 per trailer in labour and material in order to save a ton in weight." I think I should have omitted the word "commercial." I should have said "no loss will be involved if one spends as much as £185." I look at it from this point of view: that one could borrow £185 at 5 per cent and could provide a 5 per cent depreciation fund for renewing that £185 in approximately 17 or 18 years. That would cost £185 per annum, which was exactly the saving which would result by reducing the weight by one ton. Of course it would not really be profitable to spend £185, but one would not lose by spending that sum.

Mr. Mason suggests that the life of a coach should be taken into account, but he will see that it is done when the transaction is looked at in this particular way.

Mr. Sparks seemed to say that because the saving effected was only a small percentage of the total cost of traction, it was therefore not worth considering. That of course is a proposition to which nobody engaged in the practical maintenance of rolling stock could assent. It is only by grasping at every little economy which can be effected at not too great a capital cost that the cost of operation could be reduced in such a way as to produce satisfactory results.

In answer to Mr. Firth, the 10-ft. rolling stock operates over the same roads and platforms as all other stock, and there is no difficulty in effecting this.

Mr. Firth and Mr. Burnett mentioned the long wheel-base. The 10-ft. bogie of which a drawing was given in the paper was designed partly to minimize the rail wear and partly to provide for larger motors. Those objects were not entirely attained by that bogie, because the greater weights of the motors negated the increase in the wheel-base; and the wear on the tyres, and also presumably on the rails, with that particular bogie was just as great as on the shorter wheel-base bogie that preceded it.

Another speaker criticized the bogie as being apparently of too light a construction. It is difficult to judge from a drawing, but actually the bogie is of too heavy a construction. It is quite correct as an example of design as far as it is shown in the paper, but it is not correct in the matter of weights; that is to say, the frames, the transoms, and the bolsters, could all have been made much lighter, and will be made lighter in subsequent bogies. This bogie was constructed throughout with the ordinary mild steels hitherto employed in bogie construction; but by the use of high-tensile alloy steels, properly heat treated, a saving in weight of probably not less than 25 per cent could have been effected.

In order to design a satisfactory electric bogie, as was pointed out by one speaker, it is not a matter of getting a heavy bogie, it is a matter of placing the material in the right place. What is wanted is to get ample bearing surfaces on the journals and ample bearing areas on the faces of the axle-boxes, so that there will be no heavy wear on the horns. It is a question of using one of these high-tensile steels and placing the material in the right place, seeing that the bogie is well trussed and that proper diagonal pieces are introduced so as to secure its rigidity.

I quite agree with Mr. Burnett that the bogies must be of strong construction and that the wheel-bases should

Mr. O'Brien, be as long as possible. There is no doubt that the larger the diameter of the wheels the better.

Though it is not referred to in this paper, I do not see why in the case of electric locomotives the bogies should not have wheels as large as 4 ft. 6 in. or 5 ft., or even a little larger. It is practically impossible to have such large wheels on passenger stock, because the loss of seats would be serious. The wheels would interfere with the body of the coach to such an extent that I think more revenue would be lost by the lack of seats than would be gained in maintenance with the large wheels. But with the electric locomotive I see no reason why the bogie wheels should not be very much larger than they are at present.

One of the speakers asked how much of the cost of the cars was due to the electric equipment and how much to the actual coaches, *i.e.*, he wanted to know whether the trailer coach cost as much as the motor coach to construct. The motor coach is more expensive to construct than the trailer coach, because it is necessary to provide accommodation for the tractors, attachments for resistances, and heavier bogies; but as far as the actual carriage work is concerned, the cost is approximately the same.

Dr. Smith pointed out the objection to series-parallel control, and suggested that by using field control the peaks on the power station could be very largely reduced. I am not a motor designer, but I thought that we already used practically as strong a field as was possible during the acceleration period, and it certainly had not occurred to me that by the use of interpoles we could enormously strengthen the field and reduce the starting current correspondingly.

The proposal to make the motor cars more flexible, that is to say, more adaptable to different services by means of field control, is worth considering, and in many cases it will pay to adopt it.

Mr. Lewis suggests that there is a more promising field in graduated acceleration and regeneration during deceleration than in reducing the weight of the rolling stock. He further suggests that weight reduction is attained by resorting to refinements. I cannot admit that the plain straightforward substitution of lighter and stronger materials is in any way a refinement; it is merely proceeding on rational lines. He is mistaken in assuming that I have stated that the actual instances which I have given where weight could be saved meant a saving of 10 per cent. It is not stated in the paper that 10 per cent in weight can be saved in this manner, and, as a matter of fact, in constructing the trailer car there is no difficulty in saving considerably more than 10 per cent by the methods indicated.

In replying to Mr. Carter, I should like to say that I am much obliged to him for drawing attention to that point about the resistance of the motors. The curve is not obtained by means of readings of the speed, but from the readings of a pendulum in the dynamometer car, which gives the total actual resistance of the train in a very much more correct way than it can be obtained by the speed readings. It is the total resistance, so that if he is correct in his figure of 4 lb. per ton for the resistances, which might properly be attributed to the motor itself, and which are absorbed in the motor when running, that would bring that curve down to a figure which approaches the curves with which we are more familiar.

Mr. O'Brien, Several speakers seem to think that it was suggested in the paper that the strength of the car should be diminished as the weight was diminished, but that is not the intention. As Mr. Carter pointed out, I thought we ought to save unnecessary weight, and that where we could use stronger and lighter materials without any sacrifice of strength, that should be done, but that it did not seem to have been carried out.

Coaches have very generally up to the present time been built of mild steel, or mild steel and wood, and little attention has been paid to the importance of closely investigating the possibility of reducing their weight. It can be conclusively shown that to introduce unnecessary weight is to throw money away in perpetuity; and I should like again to emphasize the fact that the body which carries the passengers is the most important part to consider from the point of view of weight-saving. But the weight of the body reacts throughout the whole equipment. A light body and underframe means light bogies to carry them; light bogies mean light motors; light motors again mean that the electrical equipment which has to be carried on the body will be light, which again in its turn permits of a slightly lighter body. Our knowledge of the strength of materials has greatly advanced in the last 10 or 15 years, and it is most important that we should turn that knowledge into advantage in connection with rolling stock construction.

Mr. Bowden notes that in the bogies the journals are without button heads; this arrangement has proved very satisfactory in practice. The gear wheel is not split because the solid wheel is both cheaper and stronger. The average life of the gears on the Liverpool-Southport line is over 250,000 miles, and consequently it is not worth while making a special arrangement for renewal purposes.

In answer to Mr. Burgess, the "wheelbarrow" method of suspension has survived as being the simplest and cheapest. As to ventilation, I agree that a downward movement of the air produces the most sanitary results, but it is a very difficult system of ventilation to carry out in a railway carriage. The system described produces fairly good results.

Where a bulk supply of current can be purchased cheaply I agree with Mr. Baker that it is far better for a railway to purchase its electrical energy. On the North-East Coast waste-heat stations and a varied load with a magnificent diversity factor make it possible to supply energy so cheaply that no municipality or railway company could hope to do the same. Elsewhere, however, small stations with a poor diversity factor are universal, and while this is so railway companies do well to build their own generating stations; for a railway load has an excellent diversity factor of its own, and the magnitude of the load is such—on a successful scheme it will seldom be less than 20 million units per annum—that the standing charges per unit will be less than in the case of municipal stations which are notable for their extravagance in buildings and plant. The changes in policy which occur in municipal stations are partly due to the fact that the latter are controlled by political parties and partly to the fact that the poor salaries paid by the corporations cause perpetual changes in the staff. Liverpool, Manchester, Newcastle, and the London County Council are all cases in point.

The directorate and chief mechanical engineer of a railway company change infrequently, and the policy is continuous. The problems connected with the generation of electricity are mainly mechanical; the chief mechanical engineer is usually a man of broad views and wide experience, and in the ordinary operation of his department he has the assistance of experts in each particular branch—electricity, marine engineering, cranes, stationary boiler plant, etc. He is therefore eminently fitted to deal with the problems of a power station. The railway will already possess a staff for dealing with coal analyses and purchase properties of oils, and water, etc., and for testing purposes, and hence a generating station can be operated with an economy unknown among municipalities or in most companies. I do not dispute Mr. Baker's contention that the 50 generating stations in London are wasteful and that it is a problem to know what to do with them; on the con-

trary, I am pleased that he should have adduced this argument to prove the wisdom of the policy adopted by the London & North-Western and London & South-Western Railways. It is of course a matter for regret that there is not a central supply authority for the whole of London; as soon as such an authority is in being no doubt the railway companies will be in no two minds about purchasing their current. I should like to say further in answer to Mr. Baker that in my opinion in order to get the best results in a very large organization like a railway company it is essential that the whole of the mechanical engineering and transport problems should be grouped under one authority. Many hard things have been said recently about the Great Eastern Railway, but the Company has shown very great wisdom in appointing an engineer as general manager, who will be able to co-ordinate the various mechanical problems now divided between departments.

DISCUSSION ON

"SOME RAILWAY CONDITIONS GOVERNING ELECTRIFICATION."*

SCOTTISH LOCAL SECTION, 17TH FEBRUARY, 1914.

Mr. W. W. LACKIE: The main point in this paper about which I wish to speak is the statement that the electric tramways compete directly with the railway services in many large towns, and that railway companies have been obliged to reduce their fares owing to tramway competition. I thought it was quite agreed that a tramway is a distinct benefit to a railway, in so far as the tramway acts as a feeder to the railway and increases its traffic. It is true that the tramway undertaking uses the streets, but it also bears the cost of paving in a very substantial manner, viz. to the extent of two-thirds of the area of those streets, an expense that would otherwise fall upon the rates. The tramway department further pays rates on the full value of its permanent way, whereas the railway companies only pay rates on one-third of the value of their permanent way. The extension of tramway lines to suburban areas has had the effect of stimulating the building trades in those areas, and of developing a residential population, both of which results undoubtedly react beneficially on both goods and passenger railway traffic. It has been shown on the railways in several districts that the traffic has increased when the tramways have been extended. The motor omnibus acts similarly in favour of the railway. The author indicates in the paper that what is wanted in suburban traffic on electric lines is either an increase in the fares or the ability to purchase electrical energy at $\frac{1}{4}$ d. per kilowatt-hour. It seems to me that the running of a railway is very much like the operation of an electricity supply undertaking, inasmuch as standing charges are an important feature in both. In my opinion, instead of being increased, the fares should be reduced. Our experience in Glasgow is now well known. Instead of carrying a passenger half a mile for $\frac{1}{4}$ d., the Corporation increased the distance to 1 mile for $\frac{1}{4}$ d. The increase in revenue from this cheaper fare has more than covered the

cost of the reduction. Would it not pay the railway companies to reduce the first-class fares and so increase the number of persons who travel first-class? In the case of the Glasgow Electricity Department, which showed a deficit of £4,000 on one year's working, the tariffs were reduced and the deficit was turned into a surplus in the following year. The author states that cheap coal is a hindrance to the electrification of the railways; but the price of coal in America, where electrification has been adopted, was only half the price of coal in this country. It is stated that the difference between the heat value of the coal in the bunkers and the work done at the draw-bar of the electric locomotive is only 6 per cent. I do not see why this should not be 12 or even 15 per cent. It may be of interest to recall that in February, 1909, I read a short paper before this Local Section in which I gave an account of an experimental electric locomotive which was run between Glasgow and Edinburgh as early as 1837.

Mr. C. E. COCKBURN: Whilst I am in favour of electricity as a motive force, I do not think the time is yet ripe for its introduction for long-distance traffic. There is a considerable difference between the working of electric tramways and underground electric railways in London and the operation of the steam-worked overhead railways. With regard to the difficulty of handling long-distance and short-distance traffic in the limited area inside big terminal stations such as those in Glasgow and London, I consider it to be better for the railway companies to leave the local traffic in short-distance areas to the electric tramways, and to concentrate their attention on the long-distance traffic, which can be more successfully dealt with for the present by steam railways. As an example of the difficulty of handling traffic to places on the Clyde, in the case of a steamer capable of carrying 1,000 or 1,500 people, with the

* Paper by Mr. Roger T. Smith (see pp. 293 and 398).

W. W. LACKIE. Early experiments in electric traction. *Journal I.E.E.*, vol. 42, p. 629, 1909.

present electric rolling stock three or four trains would be required to convey a boat-load of passengers; with long block sections this would result in the passengers being kept waiting too long between the arrival of the first and last trains to permit of such a system being feasible, when by a competitive route which had steam-hauled trains an equal number of passengers would have been conveyed perhaps in one or at most two trains. Consequently, it is impossible at present to contemplate the introduction of electric traction to handle such traffic as this. In justification of my views I would call attention to the fact that on busy days when such events as football matches take place in Glasgow and the crowds have to reach a given point by a given time, the tramways are unable to meet the whole of the requirements, as they cannot provide a sufficient number of cars to carry the public when the latter present themselves in a body; neither can the public be induced to travel during a longer period in order to suit the system of car working. The public therefore have to fall back on the railways at the last moment in order to be carried to the match before the game commences. I am therefore convinced that until heavier loads can be carried it would be unwise for the railways to contemplate the introduction of electric traction as their only means of haulage. I am a great believer in electric power, which can be made use of on a railway not only for haulage but for lighting, signalling, block working, and the manipulation of points, in a way which was impossible with any other form of power. In fact, I consider electricity will naturally be the power of the future; but until it can be produced more cheaply I am of opinion that the moment has not yet arrived for its introduction on railways, where it is really wanted more for handling long-distance than short-distance traffic, inasmuch as the latter is competitive with the tramways, which are able perfectly well to handle this traffic. The railways would not be compelled to reconstruct their big terminal stations if this short-distance traffic were dealt with by the tramways as at present, the existing railway stations being large enough in most cases to handle the long-distance traffic without any further additions.

Mr. J. M. SCOTT MAXWELL: I think the author's introduction is an admission that all is not as it should be in this country with regard to the question of railway electrification. He says that it is much easier to change "things" than to change the habits of large bodies of men; but surely in order to change a single thing some man has to be changed in some way or other. Is it not a much greater task to change the attitude of parliament, government departments, railway directors, and general opinion, than it is to change the daily routine of railway operatives? I have always thought that the engineering profession is very greatly to blame for the present lack of progress, because they ought to seize every possible opportunity that will enable them to make a little headway against the inherent conservatism of the travelling public and more especially of railway directors; but this they have not done. I spent some years in the United States just at the start of heavy electric traction, and I had considerable experience of the electrification of the New York Central Railroad. Since then I have endeavoured to follow the American developments as closely as possible, and these developments are worthy of full consideration by British engineers. Many

American engineers have had to repeat over and over again to some of the very enthusiastic advocates of electric traction that the first big schemes were not due to the proved economy of electrical working in comparison with steam working. Public opinion, expressed through the authority of the City of New York, compelled the New York Central Railroad to abandon steam locomotives owing to the danger arising from the smoke in the tunnel entrance to their New York terminal. The New York, New Haven & Hartford Railroad, using the same terminal, came under the same condemnation. The American engineers were sharp enough to seize that opportunity as a start and are now pressing forward electrification in a thoroughly business-like fashion. How about the engineers in this country? Six years ago I read a paper on the "Problem of Heavy Electric Traction" before the Iron and Steel Institute of Scotland. Before reading it a newspaper reporter asked me for a synopsis of it. I pointed out to him the disgraceful condition of the underground sections of the Caledonian and North British Railways in Glasgow and, as Mr. Roger Smith has said in relation to underground railways in general, I told him they ought to be electrified. I told him what New York City had done and what other American cities were doing, and pointed out that the Glasgow Corporation did nothing, the only reason which I could discover being the fact that such electrification would reduce the revenue of the Corporation tramways and increase the railway revenue. Six more years have passed and these underground sections are still tolerated by an unenlightened and apparently helpless and apathetic public.

Turning to the financial factors, Mr. Smith says that directors can only be expected to spend money which will help to increase the revenue. That is a sound argument; but at the same time it is difficult to see, for example, how the heavy expenses incurred by the Caledonian Railway Company at the Central Station (Glasgow) can increase the profits. Perhaps the profits were not expected to increase, but the expenditure was nevertheless considered necessary. This proves that railway directors are willing to spend money in such orthodox ways as building a bridge and a station, but that expenditure on electrification, even though it may greatly increase terminal facilities, leaves them indifferent or lacking in courage. We all know that the Board of Trade standards are in many cases only impeding progress. Electrical engineers are almost justified in thinking that steam engineers are responsible for the creation and maintenance of these excessively severe standards. The longer they exist the longer will steam traction manage to survive. It is for the electrical profession to educate the government and the people to a better sense of proportion. As for the difficulty of dear money, it is likely to get cheaper, temporarily at least, in the future, and is it not cheaper here than in any other country? As for higher labour costs, wages have risen considerably in America, but the American government are not inclined to allow the railroad companies to raise freight charges or passenger fares. Such contemplated increases seem regrettable in this country, where freights are already so abnormally high.

Turning to some of the engineering factors, American engineers seem to have reached the decision that railways should no longer generate their own electric power, but

Mr. Maxwell.

should purchase it from power companies. This has been the evolution of electric power in the industrial world, and it seems natural that it should also apply to railways and especially to the electrification of terminals in large cities. This does away with the greatest part of the new capital expenditure and should do much to lessen the fears of the directors. Surely there is enough enterprise in London, for example, to raise money for generating electric power to supply all the London railways within, say, a 30-mile radius. By giving power companies a right of way along the railways further economy could be effected. While we are obliged to accept the small headway and clearances on all British railways as a serious handicap which even the future will probably never remove, it seems all the more essential that we should have stronger and not weaker draw-gear than on American railways so that we may have still longer trains. When the long overdue question of automatic couplings and automatic brakes is finally faced, it is to be hoped that electrical engineers will see that the draw-gear is then made amply strong enough for the future possibilities of electric haulage.

While this paper does not raise the still very vexed question of systems, it is, I take it, an introduction to later papers in which this point will be discussed, and a few words as to American tendencies may therefore be of interest. Mr. Smith seems to think that the single-phase system is at present the most promising because of the possibility of using different running speeds. Now, some American engineers very strongly condemn the adoption of the single-phase system as being the greatest cause of the slow development of heavy electric traction. They claim that the cost of operation and upkeep is very much higher and that many single-phase systems are being replaced by continuous-current systems at 2,400 volts. Such systems are really the same as the older 600-volt system except for insulation, and there is every reason to expect the voltage to rise, as indeed has been decided upon in this country. This claim is not only applicable to interurban railways but also to the heavy electric traction on the main railroads. The advocates of the single-phase system have still to solve economically the serious trouble experienced in telephone and telegraph circuits which are in close proximity to the heavy current of a single-phase trolley system. There are other engineers and other interests who strongly defend the single-phase system. The controversy, I am afraid, has been rather bitter at times, but it looks as if the advocates of continuous current will win. This will mean three-phase transmission to rotary-converter sub-stations. Here economies may be effected in the future by the substitution of mercury arc rectifiers in place of rotary converters; but, so far as I know, this is not a commercial fact as yet, although I believe I have reliable information that it may be in the near future. The American tendency in locomotive design is to build 100-ton locomotives with four motors direct on the axles for high-speed passenger service. These locomotives are used singly or in pairs, and have usually three running speeds—series, series-parallel, and parallel. The author does not think that electric locomotives with series motor characteristics can do what certain types of steam locomotives can easily accomplish in this country. Is it not possible that with electrification it will be easier to maintain schedule time? The electric locomotive can stand

adverse weather conditions better and is not subject to the drawbacks of poor coal and tired firemen. When we tested the large continuous-current locomotives for the New York Central Railroad along a part of their main-line system between New York and Buffalo, we used at times to race the fastest steam trains in America. With a 300-ton train we could run up to over 80 miles an hour. This we accomplished with the greatest ease, because the man in the sub-station would see the situation and boost up the voltage. I only relate this as an interesting possibility of getting over the trouble of the series characteristics. If a train in a certain sub-station section got badly behind time, the voltage could be raised, perhaps by the exact amount, so as to ensure the train making up the time; and if other trains on the same section got ahead of time they could slow down.

With the possible exception of Ireland, Glasgow is the most retrograde part of the United Kingdom in respect of electric railways. We have a large local population but not a single mile of electric railway in the district or anywhere in Scotland. Nevertheless, I believe that in spite of the general pessimism there is a suitable field in the Glasgow district, and any sign of such development would in all probability attract some of the great initiative and enterprise which is so conspicuous in our shipbuilding industry and so lacking in our railways.

MR. S. MAYOR: I should be glad if the author would give in his reply a definition of the term "load gauge." The context does not seem to explain the term quite clearly. I should also like to ask him how the draw-bar pull in long trains is affected as the train passes round curves, and whether in the case of a long goods train driven electrically he would suggest, instead of one powerful leading locomotive, the use of two or more locomotives distributed along the train and controlled from the leading locomotive. I think, as the author says, that cheap coal in this country is one of the factors hostile to railway electrification; but he may take encouragement from the certainty that coal will in future be dearer. In attacking a problem of this kind electrical engineers have the great advantage, which supports them in attacking nearly every other problem of the kind, of possessing facilities for the exact measurement of power. This enables them to deal with problems with greater precision of method, and it has enabled them, as the author has pointed out, to state definitely the prospective costs under any given conditions.

MR. J. A. ROBERTSON: It would be very interesting if the author would give further details showing how the relative costs of 7½d. for electric locomotives and 10½d. for steam locomotives have been determined; it is stated that the difference would not be sufficient to pay the standing charges on the cost of electrical equipment, a statement which is probably true with existing conditions. For comparison with these figures, I find that Mr. Vaughan in a discussion before the Canadian Society of Civil Engineers states the ascertained cost of steam working to be 20d. per train-mile, and of electric operation 12½d., that is to say a difference of 37 per cent in favour of electricity, compared with Mr. Smith's 30 per cent. The overall efficiency of the electric system is given as 6 per cent; this seems very low, and I should like to ask the author to give the relative proportion of losses in the power station and in the transmission line and locomotives. A

power station efficiency of 16 per cent should be attainable with the load factor from a railway system; and one generating station at least in this country claims at present to be obtaining an overall efficiency of 18½ per cent. It would therefore appear that there is a very great loss between the power station and the energy delivered at the axles of the locomotive. I also think that the author is too pessimistic about the design of electric locomotives, and that English designers will have no difficulty in providing him with an electric locomotive capable of developing 1,200 h.p. at 70 miles per hour. I agree with Mr. Lackie that the railway companies have themselves largely to blame for being unable to face the expense of electrification. There has been too much overlapping and unnecessary competition in the past, and if the railways were organized under one authority they would be in a better position to face electrification than under present conditions. Take the route from London to Manchester, for example. Here there are three competing railways running trains at intervals of two to three hours. None of the companies are in a position to electrify, but if the whole of the fast traffic from London to Manchester were dealt with on one line, the increased traffic density would in all probability justify the expenditure. The problem should really be considered with a view to future requirements rather than to existing conditions. If the inhabitants of London make six times as many journeys by rail or tram now as they did ten years ago, surely it is not too much to expect that with better facilities a large increase may also be looked for in long-distance traffic. I understand that the increase of traffic on the electrified portion of the London, Brighton, & South Coast Railway has been so great that the Directors propose to electrify the line right through to Brighton.

Mr. R. T. SMITH (*in reply*): Mr. Lackie referred to the competition of electric tramways with railways as a blessing to the railways, and this view was dealt with at some length by Mr. Cockburn. It may be a blessing in disguise, and I agree that that railway is on the whole the happiest which, like my own company the Great Western Railway, has comparatively little suburban traffic. Mr. Lackie compared a reduction in railway fares to secure more traffic as equivalent to a reduction in the price of electricity in order to increase its sale, or of reduction in tramway fares. Although the increase to the traffic would add greatly to the peak load, that may be satisfactory if the railway is not already congested; but if accommodation is hampered by non-paying traffic, a considerable chance is run of injuring the paying traffic.

Mr. Cockburn dealt with the difficulties of suburban traffic and tramway competition in a most refreshing manner. I did not quite follow him, however, as to the difficulty which he suggested occurs in moving large crowds by electric traction. As an example, take the race traffic to Aintree on the Lancashire & Yorkshire Railway's Southport electric service. Each 60-ft. coach seats 90 or 100 passengers, and half the 1,500 passengers can be taken in one 8-coach multiple unit train. It is agreed that the underground railways of London are like glorified tramways, but some sections run out for long distances into the outer suburbs, and on the busiest sections 44 trains each way are being run per hour. Nothing like that can be done by steam where station stops are of the order of half a mile

apart. I am heartily in sympathy with Mr. Cockburn's view that it is an advantage to do everything on a railway—traction, signalling, point moving, power, lighting, etc.—electrically.

Mr. Maxwell pointed out that the bulk of the railway electrification in the United States was carried out—for its tunnels and terminals—as the result of the pressure of public opinion and not from any ideas of economy. He also referred to the substitution on certain lines of continuous-current equipment for single-phase equipment where the latter had been installed. I believe that I am right in saying that this has occurred on street and interurban railways, and not on what Americans call railroads, which correspond to our railways. The railway is mostly run, as in our tramways, by means of single cars, and this shows the single-phase system at its very worst. A long and heavy train shows the single-phase system at its best and that may in part account for the way in which single-phase electrification is going ahead on the Continent of Europe, where main lines rather than terminals are being electrified. Mr. Maxwell's comparisons between what is being done in the way of electrification in the United States and over here is interesting and stimulating, but needs no comment from the author except to recommend it to the careful consideration of everybody.

Replying to Mr. Mavor's questions, the influence of curves in increasing the draw-bar pull is most difficult to measure with the dynamometer car, and the results given do not agree very well. A train is generally out of the curve before the effect due to the later on the train ceases to be neutralized by the effect due to the curve on the engine. Mr. Mavor also inquired as to load gauge. The load, or loading, gauge may be defined as a profile within which every vertical section through the rolling stock—whether locomotive or carriage or wagon—must be contained. No portion of the side, top, or under surface of a coach or locomotive, or of the load carried on a wagon, must be outside this profile. The load gauge fits inside the minimum structure gauge with several inches' clearance, this clearance varying on different railways. The small size of the structure gauge on British railways is a great difficulty in electrification with overhead conductors where the current collectors must violate the rule and be outside the load gauge in order to touch the conductor which is inside the structure gauge. The available space between the two gauges is often quite inadequate for overhead construction. Mr. Mavor asked whether a train was best hauled by one or two electric locomotives. The matter is one for experiment. It may be preferable to keep down the number of types of locomotive and double bank them for heavy trains. This is the method proposed for working the electrified circular railway in Berlin, the two locomotives (one at each end of the train) being controlled from either end. With the cost of electric locomotives as high as it is at present I think single locomotive units will chiefly be used. Mr. Mavor also referred to the cheap and easy measurement of electrical quantities. There is no doubt that if measurements with the steam locomotive were not so difficult it would have advanced more quickly than it has to its present state of development. The steam locomotive is still being improved, and

Smith, superheating has been stated recently to be the greatest improvement in the last 30 years.

Mr. Robertson, referring to the comparative annual costs of an electric and steam locomotive, asked what efficiency had been assumed between the heat in the coal and electrical energy delivered to the outgoing cables, stating that efficiencies as high as 18½ per cent had been obtained. Mr. Robertson does not state if that is the overall annual efficiency or the maximum. For the efficiency of 6 per cent stated in the paper between coal in the generating station and draw-bar pull, an annual heat efficiency in the generating station of 11 per cent was assumed, as this was the highest annual efficiency that the author had seen stated for any generating station connected with railway work. The efficiency of the locomotive, between the current collection and the draw-bar, was taken (for fast service and few stops) as 73 per cent. The efficiency of the sub-stations as 70 per cent. The efficiency of the transmission line to the sub-stations was taken as 95 per

cent, and from sub-stations to train as 93 per cent. The Mr. Smith, efficiency between the coal and the supply to feeders, averaged over the year, was 11 per cent. As to railway electrification under present conditions, I am entirely in agreement with Mr. Robertson's clear statement of the case, that its economy or otherwise is dependent on the density of traffic. He pointed out that it was the fault of the railways in their early days that the density was now so low, owing to unnecessary lines having been built for competitive reasons; but Parliament, which has always insisted on competition, must take its full share of the blame. In the treatment of passenger traffic costs a low density was taken in the paper, and the form of analysis permits of any increase in density being taken account of. It is when the density has increased to such an extent that steam working has come to the end of its tether that there is no question about electrification being the proper thing, as it adds to the capacity of the existing permanent way and stations.

MANCHESTER LOCAL SECTION, 24TH FEBRUARY, 1914.

Dr. E. ROSENBERG: In order to introduce electric traction on railways it has first to be shown, according to the author, that the electric locomotive will do what the steam locomotive does. Perhaps the author did not wish to give too optimistic a view of the situation by showing that electric traction can achieve results which the steam train cannot achieve. When he states that no electric locomotive has yet been built which can give 1,100 h.p. at 70 miles per hour, if it were designed for hauling only such maximum loads as obtain on British railways, he is of course right. The statement must not, however, be understood to mean that there are still very difficult problems to be solved in order to comply with such conditions. I am convinced that if any railway company were to ask for tenders for an electric locomotive to comply with such a specification they would receive reliable quotations from every responsible manufacturer. There are no new fundamental problems to be solved in this respect. So far back as 1903 the problem was solved of running electric trains at 130 miles per hour. At that time it was thought that electric traction would mean a fast service, and demonstrations were made on an ordinary steam line which was adapted for electric service to run electric cars between steam traffic at a speed of over 200 kilometres per hour. At that time it was thought that only motors without commutators could be relied upon to run such a service, and the experiment was made with three-phase current. I do not believe, however, that anybody would now hesitate to run absolutely the same service with commutator motors, whether of the single-phase or continuous-current type. We now have 50 \sim rotary converters which have a normal commutator speed of 60 miles per hour. The author has referred to the capacity of the steam locomotive to give constant output at various speeds. It is, of course, true of the plain series motor that there is only one speed for a given load and a given voltage, but the shunting of the series field has been developed during the past few years, and on the large Pennsylvania locomotives such shunting is used with excellent results, 50 per cent of the armature current being shunted from

the field coils. For starting and accelerating an extra strong field is provided, but after reaching a certain speed a normal field is used. On the Pennsylvania locomotives the shunting is done in a single step. The motors have commutating poles; the commutating conditions are excellent, even with the normal field, and not the slightest difficulty is experienced. If instead of one step the shunting is effected in two or three steps, several economical speeds can be obtained for the same work. The author mentioned the possibility of using separate excitation. This is an extremely interesting problem. It was suggested that for ordinary tramway service a compound motor should be used instead of a series motor. I am afraid that it would not be practicable to use an ordinary separately excited motor, and that every endeavour to get such a speed regulation would have to be in the direction of compound excitation, for the extremely good qualities of the series motor should not be abandoned entirely. We may possibly assist it by means of a shunt winding, or by sending through the series winding current from another source, or by using a kind of booster in parallel with the series winding. With regard to the traffic conditions that allow of electrification, the author rightly mentioned that it is first of all a financial problem to find out whether the additional traffic to be obtained will give a reasonable return. Those who have to solve this problem must, however, have some imagination, because if they want first to see on paper proof that every penny spent will be refunded, I am afraid it would be an impossible problem. It is strange that one of the most promising suburban lines in the Manchester district is still operated by steam locomotives, although we have heard during the past ten years that it was to be electrified. I am sure that no line would lend itself better to electrification, having a length of only 9 miles and a large passenger service, and it is very disappointing to hear that the railway authorities have again abandoned the project. I understand that in order to determine whether the electrification would pay, inspectors were sent to count the tramway passengers on the competing lines; and it was eventually decided that electrification would not pay even if all the tramway pas-

sengers could be marshalled into the electric trains. I wonder what the result would have been if, before building the first railway from London to Manchester, inspectors had been sent out on to the roadway to count the number of travellers.

Mr. E. ROTHWELL: I was particularly interested in the point that the author raises that if the cost of electrical energy cannot be reduced to $\frac{1}{4}$ d. or $\frac{1}{2}$ d. per unit, electric traction on railways will not come to the front, and it seems to me that if we have to depend on current being sold at $\frac{1}{4}$ d. per unit there is not very much hope for electric traction on railways. The author mentions the shunting engine. At the present time we do not find steam shunting engines undertaking the work that the better engines are built to take, and it would only be a matter of the electric shunting engine being designed for that particular class of work, and special engines for the heavier traffic. The author suggests that the generation of electrical energy is a trade in itself, and he thinks that it would be better if the railway companies bought the current which they require. I differ from him there, as I think the railway companies know their own conditions best, and are in a better position to deal with the different problems that will arise. With regard to the method of operating electric railways, I certainly think that if there are to be electric railways in the future we shall have conditions growing up to cope with the same. If all our railways were, for instance, at present electrified on the overhead single-phase system, there would be a scarcity of men to operate them, as the men would all be too busy looking after the line.

Professor E. W. MARCHANT: There are several facts in the paper which I think are very interesting. The first is that the largest suburban service is that from the St. Lazare Station in Paris. I was one of those who regarded the railway systems in France as very much behind those of England, and it is therefore surprising that the largest service should be from one of the Paris stations. With regard to the future of the electrification of railways, a line showing very clearly what may happen in developing traffic is that of the Mersey Railway Company. When the line was working under steam the number of passengers carried was just over 5,500,000 per annum, whereas after 13 years electrification the number has increased to 13,240,000 per annum, excluding season ticket holders, and is not stationary at that figure. The cleanliness and comfort of electric trains compared with steam trains are to my mind two of the strongest arguments in favour of their use. It is my misfortune to have my laboratory near to a half-open tunnel on the London & North-Western Railway, and the amount of dirt and dust we get from it is evidence of the accuracy of the statement made by the Chicago city smoke inspector that 43 per cent of the total smoke and over one-half of the total dirt that collects in such a town as Chicago come from the railway locomotives. It may be of interest to record some results that we have obtained in tests made with the Wimperis accelerometer as to the actual rates of acceleration and deceleration on some of our electric railways. Tests made on the North-Eastern Railway of the actual acceleration at starting give 1.5 ft. per sec. per sec., afterwards falling to a steady value of 1 ft. per sec. per sec. until the period of acceleration is nearly over. The braking effort observed on one train was 300 lb. per ton, while

in another case, when the train was pulled up very quickly, the braking effort rose to 350 lb. per ton, which is the greatest value observed. On the Liverpool-Southport line of the Lancashire & Yorkshire Railway, where we have also made some tests, the maximum acceleration is 2 ft. per sec. per sec. The normal initial acceleration is usually 1.3 to 1.5 ft. per sec. per sec., after which the acceleration gradually diminishes to about 0.5 ft. per sec. per sec., again rising to 1.5 ft. per sec. per sec. as the train gets up to full speed, presumably when the controller is moved over to the parallel notch. The maximum deceleration is about 250 lb. per ton, corresponding to 3.2 ft. per sec. per sec. The last railway on which we made tests was the Liverpool Overhead Railway; and this line is interesting because it gave the largest acceleration which we observed. The maximum acceleration with the present service is 2.7 ft. per sec. per sec. At one time motors were installed which gave an acceleration of 4 ft. per sec. per sec. This acceleration gradually falls to 1.5 ft. per sec. per sec. As far as braking goes, the maximum effort for braking is 300 lb. per ton, corresponding to a deceleration of about 4 ft. per sec. per sec., the normal braking effort being about 200 lb. per ton.

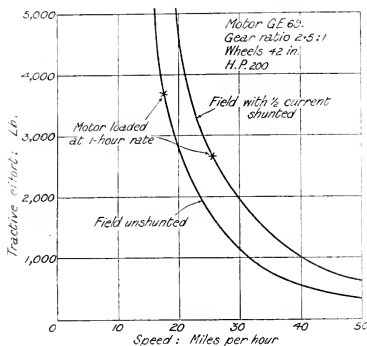

Mr. J. L. MOFFET: I think electrical engineers cannot insist too strongly or too often that comparisons between electric and steam traction can only be made when the two services are working under the same conditions. Usually when a line is electrified the schedule is very much increased and then comparisons are made between running costs under the old system and the new. As is only to be expected, the costs after electrification are at times higher than they were before, although, if the new installation had been designed for the same schedule as with steam working, the costs would have been considerably reduced. The working cost increases as the square (or higher value) of the schedule speed, and where the speed has been increased it is because the management has decided that the advantages accruing will more than pay for the extra expenditure. Mr. Aspinall in his presidential address to the Institution of Mechanical Engineers in 1909,² illustrated the effect of an increase in speed. He showed that on the Liverpool-Southport line, during the transition period while the steam trains were sandwiched with the electric trains, the steam trains were speeded up with the result that the coal consumption reached the high figure of 100 lb. per train-mile. A usual figure with normal speeds is 50 to 60 lb. per train-mile. I should be interested to hear what density of traffic the author considers necessary in order that the savings effected by electrification may give a reasonable return on the extra capital expenditure. I recently worked out the cost for operating electric trains under steam conditions, taking as a typical case a 100-ton train (exclusive of the locomotive portion) running at an average speed of 25 miles per hour with a stop every $1\frac{1}{2}$ miles, and found that the saving would pay 8 per cent interest and depreciation on the extra capital expenditure when the density of traffic reached an average of $1\frac{1}{2}$ trains per hour. On page 302 Mr. Smith claims as an advantage of electric traction that "any driver can work any locomotive, which is not the practice in this country with steam locomotives." I think that on some railways in this country drivers are now changed from one engine to another, although passenger

Professor Marchant.

Mr. Moffet.

² Institution of Mechanical Engineers, Proceedings, p. 423, 1909.

Met. drivers will be kept as far as possible to passenger engines in order to ensure safety, this grade only consisting of tried men who have proved themselves reliable on other classes of traffic. Dr. Rosenberg points out that by shunting the field of a series motor a higher running speed can be obtained; I think, however, the same variation cannot be obtained in this way that could be obtained by weakening the field of a shunt motor. This can be seen from the accompanying diagram for a G.E. 60 motor, which shows

that supposing the necessary tractive effort be constant at 3,000 lb. the speed will only be increased from 20 miles per hour to 24 miles per hour by shunting half the field current; whereas if the motor had been shunt wound so as to have the same strength of field as the series motor at 20 miles per hour, then reducing the field current to one-half would increase the speed to 30 miles per hour. Dr. Rosenberg also mentions that electrical engineers could now build a locomotive that could give the draw-bar pull stipulated by Mr. Lydall, viz. $3\frac{1}{2}$ tons at 75 miles per hour. I think the real difficulty is to obtain a locomotive that will give this large power at a high speed and also give this or a smaller power at any lower speed. As the author indicates, the steam locomotive is a very flexible machine. Any desired load can be hauled at any speed, within the power of the engine, and also very large overloads can be obtained at any speed (at the expense of efficiency) by working with a late cut-off and forcing the boiler. One speaker stated that he did not think there was any prospect of obtaining electrical energy at $\frac{1}{3}$ d. per unit, but Mr. Wollaston at a recent meeting of the Chemical Society showed that by using a fairly good quality of peat with recovery gas-plant, not only could power be obtained for nothing, but that a clear profit of 21 per cent per annum on the capital expenditure could also be obtained.

Mr. R. T. SMITH (in reply): Dr. Rosenberg stated that little reference had been made in the paper to the things which the electric locomotive can do but which the steam locomotive cannot do. The North-Eastern Railway Com-

pany's electrification of their Shildon and Newport mineral line, referred to in the paper as now in progress, is a very good example. There is a heavy mineral traffic downhill to the Middlesbrough district, and the steam locomotive which now takes the full trains down can only take half the empties up. The electric locomotives that I saw today in various stages in the railway company's workshops at Darlington will be able to take full trains of empties up the steepest gradients and greatly increase the capacity of the line. Dr. Rosenberg very properly referred to the high speeds that were obtained in the Zossen experiments, and instanced the Pennsylvania locomotives, where the series fields are shunted by a diverter for the higher speeds. The actual result of this in tractive effort at the wheel rims and in speed is shown for one of the Pennsylvania locomotives in Fig. 2 of the paper. It is surprising that this method has not been more used with continuous-current locomotives. It will be satisfactory to railway men if designers of Dr. Rosenberg's calibre will take up the question of improving the characteristic of the continuous-current series motor in one or other of the ways that he suggested. For the North-Eastern Railway locomotives referred to above there are 20 control notches, and I believe only 2 of them are running speeds; this is not satisfactory. Dr. Rosenberg also referred to the need of imagination in railway men. Railway men have often been alarmed by the wealth of imagination in electrical engineers, and an average between the two should be struck over the railway electrification business. As far as the paper goes I have endeavoured to confine myself to present conditions only. When it is remembered that one of the best engineered and managed concerns in the world—the London tubes—only pays about 1 per cent on its stock, it is not to be wondered at that railways hesitate to spend capital on such lines as the Manchester-Altrincham, referred to by Dr. Rosenberg, with a maximum of 6 or 7 trains each way per hour instead of the 40 per hour on the London underground railways.

Mr. Rothwell did not agree that it was best for a railway to buy its electricity, and stated that if electrification depended on a price of $\frac{1}{3}$ d. per unit there was little hope for it; but it must be remembered that price applies to fast passenger service only. He suggested that if a railway were entirely equipped with overhead conductors the time of the whole staff would be taken up in maintaining it. No railway man would have overhead equipment if it could be avoided, but the advantages may be more than worth the disadvantages.

Professor Marchant was surprised to learn that the St. Lazare station in Paris had a bigger suburban movement than any other European station; but the figures prove it. It is fortunate that he mentioned the Mersey Railway, for it is probably the best example in this country of electrification, resulting in the turning of a financial failure into a financial success by doing what steam could not do. The paper² that was read before the Institution of Civil Engineers in November, 1909, by Mr. Shaw, the engineer of that line, gives the most complete comparison between steam and electric working that has ever been published. It must be remembered that the physical conditions of the Mersey

* J. SHAW. The equipment and working-results of the Mersey Railway under steam and electric traction. *Minutes or Proceedings of the Institution of Civil Engineers*, vol. 179, p. 10, 1909-10.

Railway favour electricity and handicap steam; but its success should be studied by all interested in the question. Professor Marchant further referred to the cleanliness of electricity—which I find is much appreciated on the Tyne—and instanced the terminal electrifications in the United States forced on the railways by public opinion or the presence of long tunnels. Perhaps the same reasons may suggest terminal electrification in our own country; but the effect of the domestic hearth and the factory in blackening the air must in this country completely swamp the effect of the steam locomotive.

The acceleration and deceleration rates actually measured for suburban service in the North are most interesting. On the London urban and suburban electrified lines accelerations are mostly from 1.5 to 1.7 ft. per sec. per sec. with decelerations of rather more than double this rate.

In claiming that electric and steam services must be the same to be compared, Mr. Moffet instanced the high coal consumption of steam locomotives when drawing trains over the Liverpool-Southport line sandwiched between electric trains. The difficulty of steam measurements has I think limited the other measurements which might have been taken by steam locomotive engineers in the past. Especially the cost of quite a small increase in

acceleration was not understood until the simple and continuous measurements possible with electricity showed it. I am glad Mr. Moffet has worked out the paying train density, which, with $1\frac{1}{2}$ miles between stops and 20 miles per hour average speed, he makes 14 trains per hour in order to pay with electricity. A rather higher figure was suggested by Mr. Sparks in the discussion in London, and whatever the constants assumed may be, I welcome the method of analysis, for I am sure it is the correct way of showing the economies of electrification. It would seem, however, that the more convenient unit is the number of trains per mile and not the number of trains per hour.

I agree that, as the price of coal increases, the cost of steam traction will increase relatively to the cost of electric traction, but steam locomotive engineering is not by any means standing still. Superheating effects a coal saving of from 15 per cent in well-designed locomotives to 25 per cent in badly designed locomotives using saturated steam, and if it is remembered that the locomotive coal bill of the London & North-Western Railway for last year was over one million pounds sterling, savings of that order have great importance. The chief object of the paper was to induce electrical engineers not to under-estimate the difficulties to be overcome.

FURTHER CONTRIBUTIONS TO THE DISCUSSION.

Mr. H. E. O'BRIEN (*communicated*): As a railway and locomotive engineer who for some years had to operate one of the suburban electrifications referred to in the paper, I should like to congratulate the author on the most reasonable contribution yet made to the subject of railway electrification. The point made by him as to the long-distance fares having to make up for the far greater cost of the short-distance stopping service is very apt; it is too often forgotten that high speed means long-distance fares, because it extends the distance radius of the electrification and takes the electrification outside the competitive omnibus and tramway zone. As to the operation of fast passenger services by electric locomotives, the idea at present is visionary in this country: the adoption of high superheat for locomotives, the introduction of the four-cylinder balanced simple or compound engine, and the prevalence of wiser ideas in boiler design have placed the steam locomotive far ahead of the electric locomotive for some time to come. It is erroneous to suppose that under modern conditions there is any necessity for a passenger locomotive to stand idle during 75 per cent of its time: if it does, the blame must partly and primarily rest with the traffic department for providing unsuitable workings involving periods of idleness; and partly with the engineer who fails to provide mechanical coaling appliances and arrangements for rapid washing out of the boiler. The average mileage per engine even on a line with a large amount of shunting should not be less than 20,000 miles per annum; and on passenger services the mileage per annum obtainable from a steam and an electric locomotive would only differ by the difference in mileage due to the electric locomotive spending about six weeks less in general repairs than the steam locomotive. It is stated in the paper, with reference to goods services, that nearly one-third of the engines are away under repairs: if this is the case on

any railway, it points to incredibly bad management. It is not difficult to conceive railways where every driver can work every locomotive; in fact, no modern railway should have locomotives which it is not possible for every driver to work. The inflexibility of the electric locomotive is not sufficiently emphasized by the author; Mr. Lydall's paper, to which he refers, is practically entirely devoted to emphasizing this fact. It is pointed out quite correctly on page 300 that after making the rather large assumption that electrical energy could be bought at $\frac{1}{3}$ d. per kw.-hour, the saving in coal, which is the only saving possible, would only represent capital charges equal to £2,100 per mile of route, whereas the cost per mile of route for any electrification would be at least double this figure. It is estimated that the cost of the electric locomotive will be reduced when there is sufficient demand for it, but it is not stated on what grounds this assumption is based. Frames, cab, wheels, axles, axle-boxes, brake-gear, and in some cases connecting rods, are all common to both types of locomotives, and are the cause of no inconsiderable portion of the maintenance. The assertion made in the paper therefore amounts to stating that 1,200 h.p. of electric motors, with the necessary cabling and control gear, will eventually be less expensive than a locomotive boiler, cylinders, and motion capable of doing similar work. The 4-cylinder superheater locomotives on the London & North-Western Railway are capable of exerting 1,200 h.p. continuously over long distances, and it will be an agreeable surprise to locomotive engineers to learn that four 300-h.p. continuous-capacity motors, with their necessary control gear, could be purchased for the same price as a boiler, cylinder, and motion of one of those engines. It is also not realized that a heavy repair to a large electric motor is quite as expensive as the repairs of a boiler of similar capacity. The question of the electrification of sidings has not been very

O'Brien fully considered, and it is a very serious matter, particularly on those railways which have such an amount of traffic as to render them specially suitable for electrification. In a particular instance the total miles of running line are 880, and the total sidings amount to 480 miles, or 54·54 per cent of the total mileage of the railway. The majority of the sidings are very infrequently used by engines, sometimes not more than two or three times a week, but it is necessary that every siding should be traversable by an electric vehicle if electrification of the whole line took place. To electrify all these sidings with overhead wires would involve an enormous and unremunerative capital expenditure, and probably it would be better to provide storage-battery locomotives at all groups of sidings where shunting is continuous.

There are on nearly every railway specialized services which could be profitably worked electrically, but—and the platitude cannot be repeated too often—each case must be carefully considered on its merits. It is probable that in certain cases these special cases will be sufficiently numerous eventually to warrant the conversion of the whole railway to electric traction.

The author has most commendably avoided any show of bias towards particular systems of electric traction, and it is to be hoped that this may help to dispel the idea that those who have advocated in our present state of knowledge continuous current for suburban traction in any way feel committed to it as a solution of other problems. In cases where one system is suitable for suburban and another for interurban or main-line traffic, each involving a different system of collecting the current for the trains, it is possible that it may be a commercial proposition to keep the motor vehicles each to their own system of collection, but to equip the line in the smaller area with both types of track distributor. It was probably considered superfluous to emphasize in the paper the extreme flexibility of modern electric supply, but I think it would have been advisable to do so for the benefit of many railway engineers who are not conversant with the ease and security with which current can now be generated, distributed, and converted to alternating or continuous current of any voltage. Some of these remarks do not strictly apply to railway conditions governing electrification, but they apply to the converse, which is so nearly related to the subject of the paper as to be a good excuse for apparent irrelevancy.

Brook. Mr. R. V. C. BROOK (*communicated*): In connection with the author's figure for the cost of energy, if the electric locomotive is to compete with the steam locomotive, in order to produce current at 3d. per unit exceedingly large power stations must be built, preferably at the pit's mouth, and they must have a very high load factor. I should like to know whether the author has considered the possibility of the railway companies combining together to lay down power stations in various areas to supply the whole of the current required by the lines running in those areas. As a compromise between steam and electric traction, can the author tell us anything about the turbo-electric locomotive on the Reid-Ramsay system. Is such a system where the locomotive carries its own generating plant likely to be more efficient and more economical than the present all-steam system? In considering the cost of steam locomotives as compared with electric locomotives, the author states that taking an average cost of the average

steam passenger locomotive, the figure is £1,175 per annum for each steam locomotive, this sum including capital charges, maintenance, coal, wages, etc. The corresponding figure for an electric locomotive is given as £1,250 per annum. The figures seem to be rather in favour of the steam locomotive, whereas one would have imagined the electric figures do not take into account the extra mileage that the electric locomotive would be able to run on account of its requiring less attention in the repair shops or running sheds. If this is taken into consideration the electric locomotive should have a decided advantage over the steam locomotive.

Mr. R. T. SMITH (*in reply*): It is gratifying to find that Mr. O'Brien, with his large experience of the fastest electric suburban service to be found anywhere, as well as of the high-tension continuous-current service between Bury and Holcombe Bridge, is on the whole in agreement with the principles which the paper endeavoured to lay down. As a locomotive engineer he points out that the recent advance in the design of the steam locomotive makes it now far more unlikely than it might have been some years ago that high-speed passenger services should be worked electrically.

There is considerable danger of being misunderstood in dealing with the time that a locomotive is idle, but Mr. O'Brien makes out a worse case than the author, since he gives his locomotive only 20,000 miles per annum, while in the paper it is given as 27,000. Now 20,000 miles at an average of only 20 miles per hour is 1,000 hours per annum in service out of 8,760, or 80 per cent of its time idle; but that figure is misleading. Yet from such figures as are available it does not seem possible to make the time out of the shed as more than 75 per cent of the total number of hours in the year. Any driver can work any electric locomotive, and such "pooling" may result in a very considerable increase in mileage, but it was assumed in the paper that this was an advantage not shared by the steam locomotive as far as this country is concerned, and it is interesting to gather from Mr. O'Brien that "pooling" ought to be general. With regard to the cost per ton of the electric locomotive, the paper did not suggest that it would ever be reduced to the same cost per ton as the steam locomotive. The electric locomotive is only now being made experimentally, and no parts are standardized for stock manufacture. That alone raises the price, and it is quite reasonable to expect the cost per ton in time to become much less than double the cost per ton of the steam locomotive. When the locomotive as a whole is considered, for the same adhesion the electric locomotive is 30 to 40 per cent lighter than the steam locomotive, while the whole cost of the tender (which Mr. O'Brien omitted from his comparative list) is saved.

Mr. O'Brien's case of the electrification of a line for which sidings formed 55 per cent of the total length, is the best example that could have been given of the difficulties of electrifying some main lines. With all that he says as to choice of system and the possible need of equipping the same lines with two systems, the author is in hearty agreement. It is appropriate that in this connection Mr. O'Brien emphasized the flexibility of electricity supply and the ease with which it could be changed from one form into another.

With reference to Mr. Brook's remarks, the author has

given no consideration to the question of railway companies combining to erect power stations, as such station can supply nothing but the railway, while for a power company the railway demand is but one item in their supply, and the diversity of load may be expected to increase with time. No information, so far as the author knows, is available as to the working of the Reid-Ramsay turbo-electric locomotive.

The annual costs of a locomotive, steam or electric, consist of costs which vary with the mileage (coal and

water) and those that do not. To obtain the former the annual mileage for each type must be assumed, which for the passenger locomotive has been taken as the number of train-miles hauled per annum—27,000 miles steam and 40,000 miles electric, as stated in the paper—and it must be remembered that not only the costs given per train-mile, but the actual lump sums given as the annual cost, are dependent on the mileage run in a year by each type of locomotive.

STEAM BOILER WORKING IN ELECTRICAL POWER STATIONS.

By J. W. JACKSON, Associate Member.

(Paper received 7th April, 1913, and read before the NEWCASTLE LOCAL SECTION 10th November, 1913.)

A very great deal has been written in the past about steam boilers; so much so, in fact, that it is extremely difficult if not impossible to talk on any new subject under this heading. Fortunately, however, owing to the wide field covered there is sufficient scope for frequent discussion without exhausting the subject.

Re-arrangements of boiler drums, tubes, etc., are of course continually taking place, and in some cases definite advances are being made, but very many of these are only the bringing together of various old ideas.

It is of course granted that better work is being done to-day both in the way of manufacture and operation than was the case 20 years ago. The above remarks should be considered quite general, and the progress made in the steam engine and the steam turbine must not be overlooked. There we see enormous strides. One direction in which progress has been made in steam generation is the superheater. This has recently been developed to meet the requirements of the modern steam turbine. Here highly superheated steam is required because of the increased turbine efficiency.

An important consideration in the case of boilers for electric power stations is the liveliness of the boiler for dealing with variations in the load. The result of this is that the water-tube boiler has been adopted almost universally; and there is really small wonder at this when it is remembered that at least eight of the leading makes of water-tube boilers will permit of steam being raised from cold water to the full working pressure in about 30 minutes, whereas with the big cylindrical type of boiler several hours are required for this purpose.

Circulators have been developed to overcome this difficulty with the cylindrical boiler and are undoubtedly doing good work, but even with circulators the boiler is still very much handicapped, while the ordinary Lancashire type of boiler does not permit of forcing to the same degree as the water-tube boiler.

It will be remembered that in a previous paper* I touched upon this subject. In that Paper the vertical or only slightly inclined straight tube was advocated. Nothing has happened since that time to alter this view.

The designing of boilers to fulfil this condition of straight vertical tubes is by no means a simple matter, some difficulty being experienced in designing the drums so as to accommodate the requisite number of tubes without at the same time having to press the drum ends or sides into bad shapes.

It has been seen that where the metal is at all strained in obtaining these deep seatings or facings an irregular stress is permanently put upon the metal, with the result that irregularity of expansion causes local working and ultimately fracturing of the metal at these positions, although the utmost care had been taken in the annealing of the boiler plate at the time of manufacture. This annealing undoubtedly relieves some of the original straining, but it is the shape of the metal that allows the action to be concentrated usually at the sharpest angle of the indentation.

In connection with the design of superheaters, modern competition appears to have called for a superheater of smaller area but placed in a much hotter portion of the boiler, with the natural result that the superheater tubes are overheated and will therefore have only a short life. In addition to this, difficulty is experienced in keeping the tubes in position. This is undoubtedly a mistake, especially after we have got used to superheaters which were designed ten years ago but are free from this objection, as in Fig. 1. These superheaters having ample surface were fixed in the boiler at a distance much further removed from the furnace, with the result that they are much steadier to work and of almost everlasting wear. They also have the advantage that the amount of superheat can be reduced without overheating the tubes. In this latter case, with the superheater in normal full temperature working, the whole of the gases pass through the superheater after having passed so many rows of water tubes. If it is desired to reduce the superheat, a by-pass damper can be opened immediately before the superheater, thus by-passing the superheater with the gases.

The more modern superheater (Fig. 2) does not usually vary the path of the gases at all, but shunts more of the saturated steam past the superheater. This calls for a smaller quantity of steam passing through the superheater, with the result that a lesser degree of heat is transmitted to the steam, thereby allowing the superheater-tube tempera-

* *Journal I.E.E.*, vol. 49, p. 220, 1912.

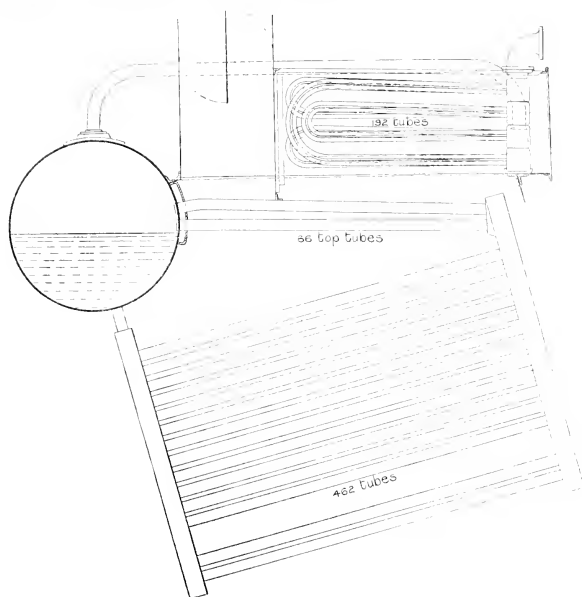

FIG. 1.

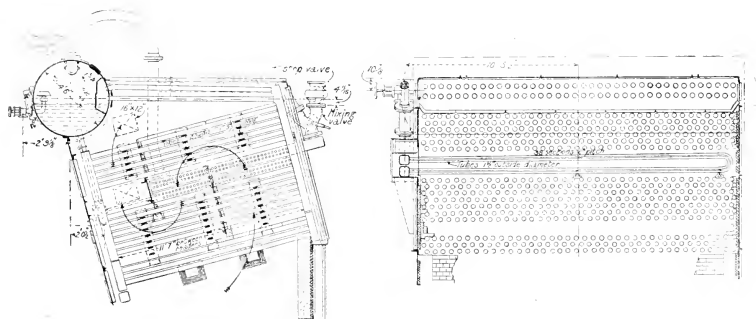

FIG. 2.

ture to rise so high that corrosion or oxidation occurs inside and outside the tube.

It would appear that the reason for fixing the comparatively small superheater in such a hot position of the boiler is due to first cost; the new superheater can of course be made considerably cheaper, but the difficulties in operation are increased as regards maintenance, reliability, and control. The scheme usually means that the modern superheater is fixed between the main water tubes of the boiler, with the result that "sooting" of the boiler becomes a difficult matter; also such a number of small tubes being bunched together in such a hot position may allow of the soot clogging up certain portions of the path of the gases, the degree of superheat being thereby affected considerably by the cleanliness of the boiler, that is to say the freedom from soot. When certain portions of the path of the gases become clogged with soot, the gases are then concentrated on the narrow passages, with the result that a greater amount of heat is brought to bear on those portions, which causes more rapid oxidation of the metal, and so shortens its life.

This clogging of the gas passages continues until the amount of superheat falls to a comparatively low figure, by which time the gas passages throughout the boiler have become so clogged with soot that a thorough "sooting" is necessary. This trouble is one that requires most careful consideration when the lower grades of fuel are handled, such as dust coal, etc. In such cases a considerable amount of soot or dust is blown through the gas passages, and causes trouble from the clogging of the passages in perhaps a quarter of the time that would be experienced with a higher grade of fuel.

The more generous superheater fixed beyond the first bank of tubes being of ample size for its work because of the lower temperature of the gases, is much less sensitive to the fouling of the passages by soot, the reason apparently being that the boiler becomes choked up with soot amongst the first four or five rows of tubes from the fire; in fact, with certain grades of fuel clinker is burnt on the tubes until there is scarcely a passage left at all. Under these conditions it will be seen that the superheater is subjected to about the same gas temperature as before, and continues to give almost the full superheat.

It has just been mentioned that higher superheat is used now than was required a very few years ago. We are undoubtedly at the beginning of the period when really high superheated steam is coming into use, and steam temperatures of from 700° F. to possibly 900° F. at the turbine stop valves are likely to be required before very long. Under these conditions it will be seen that if the superheater of the future is fitted in such a hot position of the boiler as in the case of some existing superheaters, troubles will increase somewhat alarmingly. Again, several superheaters are made with bent tubes. There does not appear to be any serious disadvantage in using such superheaters so long as the water can gravitate to a header. If a superheater tube is bent so that it cannot drain itself at the bottom, as in Fig. 3, serious corrosion or possibly complete clogging of the tube is liable to occur; but even this trouble can be lessened if the superheater is kept well up in the boiler so that it does not normally become flooded when the boiler is at rest. Here again, however, Fig. 1 offers a good solution, as owing to the gas

by-passing the superheater there is no danger of the latter being flooded or of its being overheated when starting the boiler. Fig. 4 is a good design when kept well up above the water level. In this connection attention may be called to the fact that there is always a considerable amount of risk with a superheater that has to be blown out before the boiler can be put on load; and from this point of view alone it is advisable to stipulate that the superheaters be kept well up above the boiler water-line and also that the superheater be considered, so far as operation is concerned, a portion of the main steam pipe, that is to say, that the boiler should not be fitted for the main steam with a main saturated steam pipe arrangement.

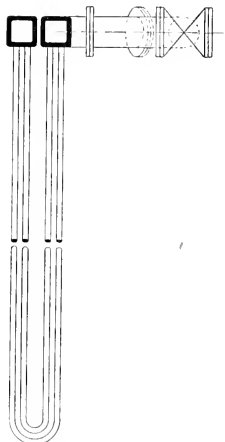

FIG. 3.—Type of Superheater adapted to a Lancashire Boiler.

Another trouble with the modern superheater is that owing to its comparatively small surface a considerable drop in pressure takes place when the boiler is being worked at its normal full load, this drop amounting to as much as 10 to 15 lb. per sq. in. at the normal full-load rate of working, whereas with the older superheater a drop of about 5 to 7 lb. takes place. The difficulty of overhauling and cleaning the exterior of the modern superheater is also considerable, this being due to the narrow space provided, it being almost impossible for a man to get into the space and carry out the necessary work. The older superheater being fixed at the top of the boiler allows of the superheating casing being dismantled entirely, so giving very thorough and complete access.

With regard to the position of the main steam drum or drums, some consideration is required as to the position at which the water-gauge fittings are to be attached. If the drums are placed parallel to the path of the gases then

the front of the drum should be set at a higher level than the back of the drum, while if the drums are at right angles to the flow of the gases the front drum should be elevated and the back drum lowered in comparison with the level of the centre drum. In actual practice in the case of a boiler with three drums set at right angles to the flow of the gases, the length of the boiler from the front to the back being about 16 ft., there is a difference in the water

water; and, further, friction is set up in the water-circulating tubes by the water flowing from the front drum to the middle and back drums to repeat again the cycle of circulation. There does not appear to be any disadvantage whatever in elevating the front drum by as great an amount as that indicated. In elevating the front drum by 12 in. above the level of the back drum it will of course be seen that a fairly long water-gauge glass is required to cover

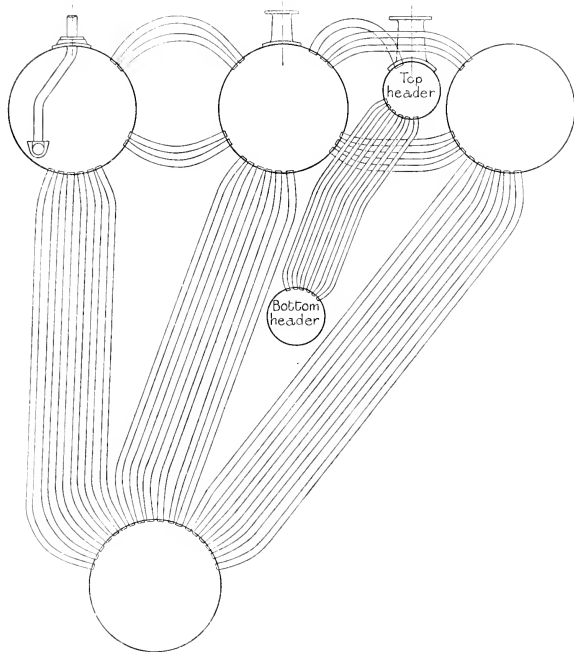

FIG. 4.

levels between the back drum and the front drum of as much as 12 in. when the boiler is being steamed at normal full load. The reason for this is not difficult to see. It will be remembered that nearly 75 per cent of the total evaporation of the boiler takes place in the front two or three rows of tubes. The bubbles of steam rising up the tubes at a fairly high rate displace the water in the tube, and so set up a rapid circulation; moreover, the water in the front drum is quite full of large and small bubbles of steam which have the effect of lowering the density of the

fully the variation in water levels. This, however, is an advantage rather than otherwise, and in following this scheme out a lower water level can be maintained with much greater safety than is at present experienced; that is to say, by elevating the front drum the water level throughout all the drums will be the same mean level under working conditions, and by carrying as small a quantity of water in the drums as is reasonably safe, greater freedom from priming, when dirty water is carried, is obtained. This question of priming is of great importance,

whether the steam is required for reciprocating engines or turbines, and any scheme that can be put forward for reducing this difficulty must receive attention.

Another difficulty in connection with priming is the corrosion of the steam space of the drums and of the steam and superheater tubes. The steam rising from the water surface heavily charged with moisture comes in contact with the heated surfaces of the upper portion of the drum and steam-connecting and superheater tubes, and is liable to set up very serious corrosion, which in a comparatively short time will completely destroy the tubes. It is quite easy to overcome this trouble, so far as the drums are concerned, by painting the internal surfaces of the drums with any of the first-class bitumastic paints that are now on the market. This process of painting with bitumastic paint has now been carried out on boilers for at least five to six years with completely satisfactory results, and if the paint could be easily applied to the surfaces of the cross-over steam and superheater tubes there is little doubt that the trouble would be got over by the same means. From the above remarks it will be seen that comparative priming is undoubtedly the real cause of the trouble, and this priming is quite possibly due to the comparatively small steam space available in the drums.

BOILER FURNACE.

One of the most notable advances made in the present-day steam boiler is that of smokeless working with ordinary bituminous and low-grade coals. In a very short time it ought to be possible for the British Navy and the large shipping companies to run their boilers on ordinary bituminous coal, the first cost of which is so much less than that of the higher grade Welsh coal. It is of course admitted that bituminous coal can be obtained of equal value to the best Welsh steam coal at something like half the cost. The only real difference in the value of the two coals is the smokelessness of the one with a particular type of boiler furnace. One reason frequently advanced against the old Lancashire boiler for electrical power stations was its smokiness, and the same difficulty applied to some of the early water-tube boilers—that is to say, the water-tube boilers built about 15 years ago. In these cases the space between the fire grate and the tube surface was extremely small, with the result that the gases were chilled before combustion was completed. To obtain a good combustion a temperature of about 2,500° F. to 3,000° F. is required in the combustion chamber, while the temperature of the outside of a water tube or the furnace side of a Lancashire-boiler tube rarely exceeds 400° F. Therefore once the gases became chilled there was little possibility of smoke being avoided.

Experiments were made some years ago with the Lancashire type of boiler by lining the first part of the furnace with firebricks; this gave very much improved results so long as the firebricks lasted, but being subjected to a high temperature at very close quarters they had only a short life.

With the modern water-tube boiler a very large combustion space is provided, and a great deal of this combustion space is lined with a refractory material, high-grade firebricks usually being employed for this purpose. The firebrick becomes heated up to a fairly high temperature, but being sufficiently far removed from the heart of the

flame it does not suffer at a prohibitive rate and so allows combustion to be almost completed before the heated gases are allowed to come in contact with the comparatively cold metal surfaces.

Another important reason for the smokelessness of the modern boiler is of course the mechanical stoker, where the fuel is gradually heated up at a comparatively slow rate or in comparatively small quantities so that there is no great rush of gas into the furnace at any moment. This scheme of making the furnaces with refractory linings becomes of considerable importance when low-grade fuel has to be employed, as unless the furnace temperature is maintained this fuel cannot be dealt with. One of the best illustrations of this is the ordinary refuse destructor. The ordinary refuse employed has a very low B.Th.U. value, but yet it is possible completely to destroy all organic matter by utilizing refractory linings in conjunction with heated air supplied under pressure. The refuse destructor should therefore be almost the starting-point wherever low-grade fuels are to be employed.

Air leakages into the furnace are of very considerable importance, and this question probably requires the largest amount of attention in boiler working from the point of view of efficiency. With the ordinary induced-draft system, which is very generally employed, air leakages can occur over very wide areas, and it is often an extremely difficult task to ascertain the starting-point of the leak. One of the best illustrations of the effect of air leakage on boiler furnace brickwork can be seen on boilers using gas firing, where practically the whole of the furnace brickwork is heated up to almost the same temperature. Those places at which air leakage occurs show up as black spaces over the brickwork inside the furnace. These places are of course readily inspected by means of the usual furnace inspection doors. Again, in the case of a chain-grate stoker using coal with a calorific value of something less than 10,000 B.Th.U.'s per lb., an air leakage into the furnace towards the front end of the boiler has such a bad effect on some grades of coal as quite to put the fire out if an attempt is made to drive the boiler at even the normal rate of working.

The CO₂ indicator is of course of great assistance in locating air leakages, but it only indicates that a leakage is taking place. It is of great value, especially when it is of the recording type, not only to the officials but also the firemen, and firemen after having worked with this apparatus for a very short time very much appreciate its uses and gain such information by its use that considerably improved results are obtainable. Wages for the firemen and others connected with some steam plants are controlled by the amount of CO₂ indicated by the recorders. This is a scheme that has a great deal in its favour, although at the same time other features have to be closely watched. It is quite possible to get a very high percentage of CO₂ in a furnace, and so earn a big bonus, without effecting any real improvement in the coal consumption of the station. This would of course occur where the ash was allowed to leave the station without proper supervision, the reason being that with reasonably good brickwork it is possible to show a fairly high percentage of CO₂ without going to great trouble by allowing a rather large quantity of fuel to go over the back-end unconsumed. This difficulty, however, would in some power stations be

very easily got over by the amount of noise made by the workmen handling the ashes, as in the event of such an extreme case of negligence such men would have an extremely difficult task.

A new page in boiler history was recently opened by Professor Bone and Dr. Nicholson. The particular line of research adopted by Professor Bone has been that of surface combustion. In this case the ordinary furnace is eliminated, but at present the apparatus has only been designed for use with the cylindrical type of boiler of very short length, combustion taking place within the fire tubes. This scheme calls for a very high rate of evaporation per square foot of heating surface, thus requiring that very suitable feed water be supplied to the boiler.

So far as can be seen at present, the field for this scheme is somewhat limited, the fuel employed being cleaned gas. The great point in its favour that makes it so much worth consideration is the high thermal efficiency. It is claimed that boilers working in commercial practice are giving over 90 per cent thermal efficiency, while the evaporation per square foot of heating surface has been raised to 35 lb. Apparently the power required to drive the auxiliaries such as the fan, etc., is somewhere in the neighbourhood of from 4 to 6 per cent of the total power developed by the boiler.

Dr. Nicholson's scheme can apparently be applied to any of the usual commercial boilers by re-arranging the gas paths. The furnace remains much the same as before, the chief idea being to pass the gases after combustion over the heating surfaces at a very high rate of speed. In the case of Lancashire and Cornish boilers the furnace tube for a portion of its length is fitted with a firebrick plug, leaving a very narrow space between the plug and the heating surfaces for the gases to be forced through. In passing the gases over the heating surfaces at this high rate of speed a considerable number of eddies are formed, with the result that the film of comparatively cold gas is driven away from the heating surface, thereby permitting a more ready transference of heat. The other great advantage of this scheme is that owing to the high speed at which the gases flow it is possible to reduce the temperature of the outlet gases to below 200° F., with the result that the latent heat of the steam contained in the gases is recovered. With some types of coal this is a very considerable amount.

It is stated that owing to the gases being carried over the heating surfaces at such a high rate of speed no corrosion due to the condensation of sulphuric acid takes place in either Professor Bone's or Dr. Nicholson's schemes. So far as can be seen at the present time it is possible for the overall efficiency of a commercial boiler to be improved by from 2 to 7 per cent over the best modern boiler practice. Dr. Nicholson's scheme like Professor Bone's scheme requires a very considerable amount of power in producing the necessary draught. Of the two schemes perhaps Dr. Nicholson's is the more promising, as under this arrangement it is possible to use coal in the ordinary boiler furnace. This in turn means that the usual ash-handling arrangements can be adopted, whereas in Professor Bone's scheme it would be necessary that a gas producer be built before the boiler could be got to work in a very great number of steam-raising plants; and those who have had experience with gas producers know that their working is by no means simple, while the

efficiency of the gas producer is such as would quite eliminate the saving to be effected on the steam boiler unless a by-product recovery plant is used in conjunction with the gas producer.

The selection of firebricks is one that naturally requires very careful attention. The particular make of firebrick to be used depends not altogether upon the quality of the brick but to a great extent upon its character. Some firebricks with great reputations run to slag very quickly indeed, while again other firebricks practically unknown do excellent work with the same coal. There is of course no great wonder at this when it is remembered that the sulphur content of coal varies very considerably, while again some coals contain a fairly considerable amount of impurity such as fireclay. This fluxes some makes of bricks very badly, and on examining the furnace after quite a short run it will be found that the molten firebrick or slag has run down the underside of the furnace arch, cutting quite deeply into the firebrick and practically making rivers running down the side walls and on to the grates, with the result that the fires quickly get into a very bad condition and need to be cleaned by means of a long slice as frequently as once per hour.

The above is undoubtedly one of the explanations of the variable reports received from time to time regarding the various makes of firebrick; therefore it seems that when difficulty is experienced, experiments must be made with various firebricks until a suitable make is discovered. In some cases natural stone, very high in silica content, taken direct from the stone quarries has been used with very good results.

It will generally be gathered from the above remarks that a good furnace is one that allows plenty of room for combustion and is well lined with a refractory material, as undoubtedly the theory is being more and more appreciated that the boiler has the function of absorbing the heat delivered to it from the furnace, while the function of the furnace is to produce the heat, and the requirements of both must be kept in view if good results are to be obtained.

The important idea to keep in mind when arranging furnaces is to surround the fire as much as is necessary with refractory lining, so as to permit of the high temperature being obtained through complete combustion before the flame or hot gases are allowed to come into contact with the heating surfaces, and that is almost the only value, but a very important one, that firebricks have in the furnace.

STOKING GEAR.

Boilers have for a great many years been fired by hand, and this still appears to be the case with marine boilers in both the mercantile marine and the Navy.

In view of the success that the machine-fired stoker has met with on land boilers, it is very difficult to explain why marine boilers are still fired on what should be called an old-fashioned principle. Hand firing has undoubtedly some serious disadvantages, one of these being the frequency with which the fire-door needs to be opened, thereby admitting a great rush of cold air, which more or less cannot be utilized to advantage, but which for the time being lowers the efficiency of the furnace.

It may of course be that one of the reasons why hand firing is still used is that a very great number of the old-

fashioned cylindrical boilers are still in use, which type of boiler offers some difficulty to the principle of the machine-fired stoker. Those, however, who have had experience with boilers on land with hand firing must realize that for the amount of steam required an exceedingly high cost of labour is involved, but it is only when a fairly large battery of boilers becomes necessary that this point may be really appreciated. On the other hand, those who have a number of machine-fired boilers to attend to, realize that firing under the new conditions with many of the modern stokers is a very much easier task, although giving an output of from 10 to 20 times as much steam as was the case with the hand-fired boiler. An important consideration in favour of machine firing is the regularity with which the fuel can be fed into the furnace, and this generally means that a high percentage of CO₂ can be obtained under equal conditions as compared with the hand-firing scheme, the liability to form smoke being at the same time reduced.

In populous districts, and also in the Navy, smoke commands considerable attention. Some of the largest boiler installations in the country have been fired for many years by machine stokers under very variable loads and conditions, and it is very rarely that smoke is seen to issue from the chimneys. The author has also a particular instance in mind where a good-class machine stoker now at work under some boilers replaced a stoker which was supposed to be a machine-fired stoker, but which was so erratic in its general conduct as practically to amount to a hand-fired stoker, with the result that violent smoke was emitted over considerable periods. This was due to the firemen having continually to pull the fire about in order to get steam at all, and even after all this labour only about half the steam was available that should have been obtained, and which was obtained with the better type of stoker. Machine firing is of course of the greatest service where coal is used in a somewhat finely divided state, and coal in this state is of course the most difficult to deal with by hand firing. It is possible now to handle coal in the finest possible state of division without causing smoke or encountering any other than the usual difficulties, that is to say that "duff" coal can be as easily handled as "nuts."

Years ago mechanical stokers were made of the "sprinkler" type. These did very good service, but were often accused of causing smoke. In almost all cases where smoke was experienced with this type of stoker no firebrick lining was fitted to the furnace, therefore the stoker was unfairly charged with that disadvantage. The "sprinkler" stoker was followed by the "coker" stoker. This also did good work and was more suitable than the "sprinkler" for certain classes of coal, but it also caused smoke when the furnaces were not lined with firebrick. The "coker" was in turn followed by the "underfeed" type, which caused as much smoke as any of them when it was fitted in furnaces not lined with firebrick, and running parallel with some of these stokers was the chain grate, made by various manufacturers. There are some chain grates working in neighbouring collieries that were made by a firm of ironfounders near Durham which have given most excellent service for nearly 20 years, and although somewhat rough they are working under just the same main principle as we see to-day in the modern

chain-grate stoker. This stoker has also given very good service, but will smoke under unsuitable conditions. Some of these stokers are much more suitable for certain types of fuel than others. It is undoubtedly a fact, however, that all stokers may be good, but that some will do much better work under certain conditions than others. It is of course the usual thing for the designer to claim that his stoker is the best all-round stoker, and in his own particular line he is possibly correct.

One particular advantage of the chain-grate and step-grate stokers is that they allow the ash to be handled more or less automatically, that is to say the ash is delivered by the stoker on to or over the dumping bars at the back end of furnace. With the old pattern chain-grate stoker a considerable amount of labour was required to pull the ash and clinker over the dumping bars on to the dumping doors; this is owing to the fact that dumping bars of considerable thickness and length are necessary with the old type of chain-grate link. This length is used with a view to covering up the openings in the link at the time that they begin to go round the back sprocket. Links have recently been developed which allow of a dumping bar being fitted as short as is desirable; the determining factor in this latter case being that a slight click to the ashes, etc., is necessary to allow of complete combustion occurring at the back end, otherwise good fuel may be carried over in fairly considerable quantities. A fairly big boiler plant is of course fitted with the usual ash conveyers for loading up the ashes into the railway trucks or barges.

It is of course of considerable importance that the ashes should be handled mechanically, as otherwise very high costs for labour and other labour difficulties will occur. This automatic principle is equally necessary for putting the coal into the bunkers. Nobody would suggest for a moment that the appliances required for this class of work are capable of operating without trouble from breakdowns, etc., but the trouble and cost of operation is nothing compared with what would undoubtedly be experienced with hand labour. A better scheme than the ash conveyer has been developed and is now being solely relied upon for some large boiler plants, and it is giving a very considerable amount of satisfaction. The principle roughly is that a large cyclone chamber is fitted above an ash bunker; the cyclone chamber is connected up to an exhaustor of fairly large capacity which will create a vacuum of as much as 4 in. of mercury. Another pipe is taken from the cyclone chamber and has a number of openings in it, the openings corresponding with the number of ash hoppers under the boilers. An ash crusher is fixed on wheels and is capable of being moved from one ash hopper to another; it is driven by an electric motor and crushes the ash as the latter is allowed to issue from the boiler ash chute, in which condition it is allowed to fall into the suction pipe. The draught created by the air exhaustor at this pipe is so great as to cause the ash and clinker to be drawn up the pipe to a considerable height, where it is ejected through the cyclone chamber into the ash bunker. A very important advantage that this scheme has over any other ash-handling plant is its freedom from dust. The only place where dust can be met with is at the point where the ash is loaded up into the railway trucks from the ash bunker, and even this can be dealt with by fitting spraying pipes inside the ash bunker.

A somewhat similar method of dealing with ashes has been in use for several years, more especially for marine work, and in a few instances for land work. In this case water pressure is used for ejecting the ashes. The apparatus is usually spoken of as Secs ash ejector. In one particular case two equipments have been placed in series, and ashes are being delivered through the discharge pipes as far as one-quarter of a mile away from the boiler-house. This scheme is a very good one indeed in many positions, but it is not as free from dust nor is it as easy to handle as the pneumatic type of plant.

Feed-water treatment has always received a considerable amount of attention. There is a very good reason for this, and it is extremely difficult to lay down any hard-and-fast rules for treating feed water; but wherever the opportunity presents itself of roughly analysing the solid matter in the boiler water and the amount of hardness of the make-up water, the simple system of treatment, generally with soda ash and lime, should be adopted. A multitude of makes of boiler compounds are on the market, which will soften the water more or less as claimed, and possibly allow more abuse of the boiler than the simple scheme of soda ash and lime does; that is to

say, the water can possibly be much more overtreated with compositions without such bad effects. It should be borne in mind, however, that very few boiler compositions can deal with the softening of feed water at anything approaching the cost of that of the lime and soda system.

Boiler corrosion has always been a most difficult subject, and it is possibly not much nearer being solved now than ever it was. One of the most formidable reasons for this is the impurities in the metal of which the boiler shells and tubes are made. Various methods of treating the interior of the tubes with some paint that to some extent will electrically insulate the water from the metal have been introduced. Such painting will undoubtedly reduce the trouble in that respect, but on the other hand it prevents the efficient transference of heat through the plate. Very frequently a compromise has to be made between two or three evils.

Various electrical schemes are now being tried for overcoming the local action on the boiler tubes and plates, by concentrating it on renewable plates located inside the boiler. This promises well, but it must be applied with the utmost care or the troubles may be much increased.

DISCUSSION.

Mr. C. TURNBULL: The author wonders why much use has not been made of mechanical stokers at sea. The great difficulty is that mechanical stokers nearly always use small coal. At sea the coal is mixed—some is small and some is big—and if it had to be broken up the additional expense incurred would be greater than the saving effected by the use of mechanical stokers.

Mr. H. H. BAKER: In dealing with the question of superheaters the author shows a strong preference for the arrangement illustrated in Fig. 1. No doubt this is a very satisfactory arrangement, but I do not think it is quite fair to assume that it is solely the cost of manufacture that has brought about the change in position to that shown in Fig. 2. The necessity of obtaining a larger output per boiler, the fact that the width and depth are limited by the stoker, and the increase in the temperature of the steam to 650° or 700° F., have, I think, made it necessary to place the superheater lower in the furnace. The author considers that the arrangement illustrated in Fig. 1 is much cheaper as regards maintenance. I doubt whether this will be borne out in practice.

Mr. W. M. SELVEY: As regards the variation of the superheat with the condition of the boiler, I think Mr. Innes and the author are both correct. I should expect a clean boiler to give a lower superheat, which would gradually rise as the boiler tubes nearest the fire got dirty, and finally fall again as the superheater tubes got dirty. With reference to the proportion which the author has given for the concentration of the evaporation in the front tubes, I should be inclined to put this a little lower, probably not greater than 60 per cent, having in mind the actual temperature of the gases impinging on the tubes, as measured in our tests. I feel inclined to protest against the view that the Bonecourt boiler and the work of the late Dr. Nicholson have opened a "new era" in boiler practice. I think this statement is due to a want of appreciation of what has already been done. Outlet tem-

peratures, certainly within 100° F. of the lowest proposed Mr. Selvey. in these schemes, are being obtained with plant such as that outlined in the paper. The result is practically within 3 per cent of the efficiency proposed, and these boilers use raw coal of a very low grade. The extra fan power will more than account for the gain to be expected. The Bonecourt boiler uses a fuel which is mainly hydrogen, and it is therefore proposed to condense the steam in the flue gases so as to render its latent heat available. Apart from coke-oven gas, which has only a very limited application, I take it that such a boiler involves the use of a producer. A producer without by-products means sacrificing 15 per cent of the efficiency. With by-products the conditions are so different that it would be quite impossible to go into them now. There is an impression—which I probably shared—that if the outlet gases are cooled below 212° F. part of the steam in them is condensed. On looking closely into the matter I find that with good combustion of Mond gas no condensation would take place above about 120° F., and with the products of combustion of coal which is burnt in an ordinary manner the temperature is nearly as low as 90° F. This led to a conclusion which was new to me. Those who have read Professor Dalby's paper* on heat transmission before the Institution of Mechanical Engineers will be familiar with the idea of a cold film of gases next to a metal surface. What the above calculation leads to is that the temperature of the metal surface, i.e. the economizer tube, must not fall to the "dew point" of the gases if condensation is not to occur; that is to say, in order to prevent corrosion the temperature of the feed water is the important matter. This is generally known in practice, the working temperature being kept at 90° F.; but the additional information is, that provided the feed temperature be kept up there is no objection, certainly in the case of coal-fired boilers,

* W. E. DALBY, Heat transmission. *Institution of Mechanical Engineers, Proceedings*, p. 921, 1909.

Mr. Selvey. to having the outlet temperature as low as those proposed in the new schemes. The problem resolves itself into a question of the value of the extra steam raised and the cost of raising it. Moreover, by baffling existing economizers so as to make them more "contralto" by the help of a little extra draught, say another 1 in., the present temperatures can easily be further reduced. In connection with brickwork the sulphur that the author speaks of is accompanied by iron, and it is the fluxing effect of the iron-oxide on the bricks which produces the result described. For this reason common bricks (which if of purer clay are less easily fluxed) are sometimes found to be more satisfactory than expensive bricks. I do not know why a mechanical stoker has not been developed for marine work, but I suggest that this is partly because the "ideal" has always been an oil-fired boiler.

Mr. Baxter. Mr. W. BAXTER: I think it is generally admitted that where steady steaming is all that is required the Lancashire boiler is very satisfactory. It would be interesting to know what type of turbine blading the author would recommend for use with the highly superheated steam which he prophesies will come into use in the near future. With regard to the author's remark that a refuse-destructor design should be the starting-point wherever low-grade fuels are to be employed, it is a well-known fact that the earlier destructors were not a success simply because the theory of combustion was not properly understood. It is surprising what a large amount of air will leak through ordinary well-joined brickwork; and while this is a point that receives every attention in power stations, it is very frequently neglected in collieries and small works. I note that the author has a good word to say for the "sprinkler" type of stoker, but other conditions being equal it seems impossible for this type of stoker ever to be as good as the "coking" type, as the gas given off by the fuel which is thrown towards the back of the furnace never has time to be consumed properly and simply produces smoke. The use of soda ash and lime appears to give excellent results with some waters.

Mr. A. R. CLEMITSON: The author's advocacy of vertical straight-tube boilers is more significant when one bears in mind the considerable experience that he has had with boilers of various types. It must be admitted that the majority of boilers working in this country are not designed on those lines; but on the other hand there is a sure tendency among not only power-station engineers but also engineers of commercial undertakings to get rid of horizontal tube boilers, all of which are designed on more or less wrong principles, and of boilers with bent generating tubes, and to go in for vertical straight-tube boilers. The design of a superheater and its position in the boiler depend of course very largely upon the amount of superheat that is desired; but as there is certainly a tendency towards high-temperature superheated steam, the superheater must be placed in such a position that the temperature of the gases will be in the neighbourhood of 1,500° F. It has been suggested by a previous speaker that it is not desirable to by-pass any of the superheated steam, since with a change in the output of the boiler the amount of heat on the furnace side would likewise vary, and thus whether the boiler is working on light or heavy loads the temperature of the superheat would not

Mr. Clemitsen vary to any extent. While this is practically correct, it must be remembered that it is very often the condition and arrangement of the steam engine which determine what the final temperature of the steam should be; and it will therefore be necessary to have means of controlling the temperature under all conditions of load. The regulation obtained by by-passing some of the saturated steam is quite satisfactory. I should like to ask the author what amount of saturated steam could safely be by-passed with the arrangement shown in Fig. 2 without causing any damage to the tubes, assuming the superheater is designed under normal conditions for 200° F. superheat. The author has made a point of the clogging up of the superheater tubes, which must occur more particularly with design No. 2; this inconvenience, however, is reduced to a minimum in the Woodeson superheater, which is much more accessible. Reference is made in the paper to highly superheated steam, and the author points out that temperatures of 700° F. to 900° F. are likely to be required before long. It may be of interest to mention that Messrs. Clarke Chapman & Co. are at present making two large boilers for Luton Corporation, and also one for Loughborough Corporation, where the temperature of the superheated steam is 700° F. I do not see any necessity for the large drop in pressure that the author says takes place in the modern superheater; it appears to be only a question of arranging a sufficient area through the superheater tubes for there to be no appreciable drop at all. I quite agree with him that large combustion chambers are essential if high furnace temperatures are to be obtained. In Lancashire boilers and often in horizontal water-tube boilers the gases are chilled before combustion is completed, and therefore the temperature of the furnace never rises sufficiently to give the high efficiency that can be obtained with water-tube boilers designed with large combustion chambers. As pointed out by the author, much importance should be attached to the percentage of CO₂ found in the escaping gases; and as this can be so much affected by air leakage through the brickwork, I should like to ask him whether he has found much improvement in this direction in boilers enclosed in a steel case.

Mr. C. VERNIER: Not only does the Bonecourt boiler Mr. Vernon suggest the possibility of making better use of our fuel, but compared with present boilers it appears to save considerable space, which I think is an important point in connection with power stations. I should like to ask the author what are his views with regard to the future possibilities of gasifying coal. I have recently given a good deal of attention to the subject, and it seems to me that it might pay to adopt this method in some cases, in view of the high value of the by-products recovered. Any of the following methods of gasifying coal with recovery or by-products could be used: (1) The coal might be coked into furnace coke in by-product-recovery regenerative coke-ovens and the surplus gas utilized for burning under steam boilers; (2) the coal could be destroyed in gas producers; (3) a combination of these two methods might be used, the coal being first coked at a low temperature so as to recover the more volatile constituents, and the coke being then finally destroyed in gas producers. In each case the by-products would be recovered. I assume that in each of these

errier. cases a good coking coal of 15,000 B.Th.U. per lb. (33,600,000 B.Th.U. per ton) would be used. The cost of this I have taken at 13s. 6d. per ton. In order to ascertain the value of the gas recovered, I have taken the thermal value of the gas when burned under boilers as only 60 per cent of that of the coal if burned direct. In the former case one would have to get 124,500 B.Th.U. for one penny, whereas coal would yield 207,400 B.Th.U. for the same sum. The price obtained for the sulphate of ammonia has been taken at £11 10s. per ton, which allows about 50s. per ton for working expenses (sulphuric acid, bagging, etc.). The first method is limited in its application to those districts where there is a demand for furnace coke. The by-products recovered would be approximately as follows:—

	s.	d.
10 gallons of tar	3	0
30 lb. of sulphate of ammonia	3	0
13 cwt. of furnace coke at 21s. per ton	13	6
5,500 cub. ft. of gas of 650 B.Th.U.		
(3,474,000 B.Th.U. at 1d. per 124,500 B.Th.U.)	2	4
	21	10

The second method is that which is more suitable for use with gas engines, of which an interesting example is the plant installed a year or two ago by the Corporation of Accrington. In this case it is possible to quote some actual figures from the published results. The plant is by no means a large one, consisting of only two 1,000-h.p. gas engines, and its cost is stated to be £1875 per kilowatt, including some special work in connection with difficulties encountered on the site. About 85 tons of coal are gasified per week, and the by-products recovered per ton of coal are:—

	s.	d.
08 lb. of sulphate of ammonia	10	0
2½ cwt. of cheap tar at 10s. ton	1	3
	11	3

The fuel consumption is 1·6 lb. of coal per unit, costing 0·125d., and the value of the by-products recovered is equivalent to 0·07d. per unit. The third method, which is likely to prove of the greatest value, retains the more volatile constituents of the coal in the tar and tar oils. One of the chief difficulties in the way of gasifying coal, unless it is completely destroyed in a gas producer, is to find a suitable market for the surplus coke, as there is already a glut of coke from the gas-works. The final destruction of the coke, which on account of the low coking temperature retains the greater part of the nitrogen, disposes of this difficulty, however, while at the same time enabling the maximum value of the by-products to be recovered. Alternately, of course, the coke might be used direct to fire steam boilers. The value of the products recovered in this case would be somewhat as follows:—

First low-temperature carbonization:—

	s.	d.
(1) 20 gallons of tar and tar oils	6	0
(2) 12 lb. of sulphate of ammonia	1	2
(3) 13 cwt. of tar-free coke	—	—
(4) 5,500 cub. ft. of gas of 650 B.Th.U.		
(3,575,000 B.Th.U. at 1d. per 124,500 B.Th.U.)	2	4

Brought forward d
Final destruction of the 13 cwt. of coke (Item 3) in gas producers:—

(1) 50 lb. of sulphate of ammonia	5	0
(2) 150,000 cub. ft. of gas of 130 B.Th.U. (10,500,000 B.Th.U.)	13	0
	27	6

Mr. Vernier.

In the latter case we see that the value of the gas and by-products recovered is greatly in excess of the original cost of the coal, and this should leave ample margin to cover interest, depreciation, and labour on the gas plant. Much depends, of course, on the future stability of the market for sulphate of ammonia; but it is stated on good authority that the present output could at least be doubled without affecting the market.

Mr. J. WRIGHT: There is no doubt that any economies Mr. Wright. that can be effected in the boiler house far outweigh those which can be made on any other part of the plant. I am glad to see that the author advocates the vertical or slightly inclined tube boiler, which has many advantages. Particularly is it suitable for the conditions that exist in this locality, where so much blast-furnace gas is used as fuel and a large quantity of dust has to be dealt with. The vertical type of boiler is much more easily kept clean. I was also glad to note that the author places so much importance on the superheater, as unless the steam is to be used for work where a superheat is not advisable it seems to me that the superheater is an essential part of every water-tube boiler. Superheaters could be fitted with advantage in every case. I see that the author's views on superheating coincide with some notes which I gave last year before this Local Section. That is to say, where only a small part of the steam passes through and necessitates a mixing valve, superheaters are not advisable, apart altogether from the corrosive effect that the author mentioned. While I agree with the author that it is advisable to have a larger superheater baffled by a section or sections of the boiler, I do not think that it is quite the arrangement of superheater which will be asked for in the future. With the high superheat called for at the present time and the still higher superheat that will be demanded in years to come, the ideal superheater will be the armoured type placed in the hot part of the boiler—I refer to a heater such as the Foster superheater, where the armouring takes the form of cast-iron fin rings threaded over the tubes. The protective effect of the cast-iron rings, together with the large heating surface and the accumulative effect of the heat in cast iron, form a superheater for which there seems to be a future. Another good arrangement has been adopted by some of the boiler-makers on the Continent, where the superheater is placed in a chamber adjacent to the combustion chamber and the flow of the gases is controlled. I agree with the author that it is better to control the superheat by means of the gases than by shunting part of the steam. While the modern superheater has its disadvantages, the pressure drop mentioned by the author seems to me excessive, unless of course some of the tubes have been burnt out and plugs fitted. There is something to be said for the elevation of the front drum of boilers, but this only applies to some types, and would have to be taken into serious consideration in designing the boiler. It would be impossible to lay down any hard and fast rule as to how

Mr. Wright. much the front drum should be elevated. With regard to the question of air control in relation to combustion, this is a most important point so far as the efficiency of the boiler is concerned. I should like to ask the author what percentage of CO₂ he would expect to get in everyday working. I think it is impossible to give too much attention to this question of air control, especially when we know that with 8 per cent of CO₂ the losses are three or four times greater than with 14 or 15 per cent of CO₂. I have often thought it would be a very good thing if some permanent form of radio-pyrometer could be fitted to the combustion chamber so that the fireman could observe the effect of air control apart from the amount of CO₂ recorded. What has been the author's experience of the flat arch as against the sprung arch? I have known the combustion to be improved considerably by the fitting of flat arches, owing to the better distribution of the gases across the furnace and to the gas not having the same tendency to draw to the centre of the arch. Has the author had any experience with water backs? I refer to a block mounted on a trunion at the back of the grate and acting as a brake on the fuel. Ordinary small ash can normally get through, and large clinkers are heavy enough to swing the block on its trunion so as to pass through to the ash-pit. The block simply acts as a brake on the fuel and so prevents air leakage at the back of the grate.

Mr. L. TAYLOR: As the author has pointed out, the water-tube boiler has been adopted almost universally on account of the ease with which it deals with fluctuations in the load, and no doubt partly on account of its efficiency. He also remarks that the designing of boilers with straight vertical tubes is by no means a simple matter, some difficulty being experienced in arranging the drums to accommodate the requisite number of tubes without at the same time having to press the drum ends or sides into bad shapes. I should like to point out that the Nesdram water-tube boiler exactly fulfils the author's ideals. The tube plates and the manhole ends of the nests of tubes are dished in the same manner as the main steam and water drum ends to suitable radii so that no deep seatings are required and the metal is not strained. The tube plates and the manhole ends are made from plates $1\frac{1}{16}$ in. thick for working pressures of from 160 to 350 lb. per sq. in. Owing to the fact that the boiler consists of a considerable number of small sections of nests of tubes, it is very flexible and will stand sudden variations in the load without any straining or injury. In proof of this I would refer to a boiler which has been designed for evaporating about 4,000 lb. of water per hour, and which has been worked up to 7,000 or 8,000 lb. per hour for the last six or seven years, and yet has stood the test, and is still at work. It is of course unwise to work a boiler in that way on continuous overload, and I have mentioned this instance merely to prove the suitability of this type of boiler for all conditions of work. I cannot agree with some of the author's remarks in connection with superheaters. For example, he states that if the superheater is placed in the hotter portion of the boiler the tubes become overheated and burn out, and there is difficulty in keeping the tubes in position. There is no doubt some justification in this contention. Superheaters should be designed and worked to meet the requirements, and then no trouble will be experienced even if they are placed in the hotter position

as with Nesdram boilers. They must be so designed that the tubes nearest the inlet and outlet are always full of steam under all conditions; there is now no difficulty in arranging for this. There is no need to flood the superheater or to use mixing valves; both are a source of danger. For instance, if we suppose that the temperature in the front combustion chamber is 2,000° F. under normal conditions, and that when the boiler is forced the temperature will rise to 3,000° F., the result will be that as the temperature of the furnace rises the amount of steam passing through the superheater will increase so that the superheat will remain normal if the superheater is correctly designed for normal and full-load or overload conditions. It must be borne in mind that due to the position of the superheater in the front of the combustion chamber it is only exposed to the radiant heat, and is not in the direct path of the gases, so that it is not so liable to injury as a superheater placed behind the first row of water tubes.

The tendency of the steam to take the shortest passage or least line of resistance to the superheater outlet, thus causing the tubes nearest the inlet to suffer due to the lack of steam to fill the tubes at all times, can be easily overcome by compelling the steam to pass through all the tubes by fitting division plates in the superheater headers, thus dividing up the boxes in a suitable manner. We do not approve of flooding the tubes whilst raising steam, or mixing saturated steam with superheated steam to reduce the amount of superheat. I understand that the author also does not approve of this mixing arrangement owing to the danger of burning out the tubes. With regard to the inaccessibility of the modern superheater, its tendency to become choked up with soot, and the difficulty experienced in "sooting" the boiler itself due to the position of the superheater as shown in Fig. 2, all these objections disappear when the superheater is placed high up in front of the combustion chamber as in a Nesdram boiler. It may be of interest to mention that we have recently quoted for a superheater in this district to withstand a final temperature of 900° F. I would also mention that superheaters are now constructed with cast-iron gills to protect the tubes for high superheat, etc. I refer to the Foster superheater as manufactured by Messrs. Heenan and Froude. In connection with the drop in pressure in modern superheaters we have experienced a drop of only 4 or 5 lb. at most. We have never experienced the slightest trouble with respect to varying water levels or corrosion in the steam space. I do not agree with the author's suggestion to raise the front drum of a boiler by about 12 in., for if the fireman allows the water level to fall owing to not being able to keep the pressure, and the stop valve is closed on that account, the water level in the front drum will drop still further and there will be serious danger of the lower side of the drums and the top ends of the tubes, where the greatest heat is, being bare of water. I agree with the author's remark about a high temperature being desirable in the boiler furnace. A large combustion chamber of a shape such as that in the Nesdram boiler is necessary in order to obtain a high efficiency and prevent smoke. We have obtained from 85 to 87 per cent overall efficiency from such boilers fitted with superheaters and economizers.

Mr. P. S. THOMPSON: I think the author is very rash in saying that at least eight of the leading makes of water-

Mr. Thompson.

tube boilers would permit of steam being raised from cold water to the full working pressure in 30 minutes, although probably he has many a time had to do something like that in order to deal with sudden loads. I also do not think he can reconcile the position of the superheater given in Fig. 1 with present-day practice in boiler operation. I take it that the final temperature of the escaping gases would be about 460° F. If so, the superheat that he fore-shadows would not be obtainable, otherwise the gases would have to be allowed to escape at a very uneconomical temperature. The two conditions seem to be somewhat paradoxical. I do not think it was the question of first cost so much as the demand for a high superheat that brought about the position of the superheater which he criticizes. The "sooting" problem has sometimes to be dealt with by removing a number of the tubes in order to give access to a man so that the soot can be satisfactorily removed. I should like the author to state if possible the amount of dust that is carried along with the flue gases from the low-grade fuel with which he has to deal. The dust question is most important, and has considerable bearing on the operation of boilers. The author says that the Navy could quite easily make use of bituminous coal. No doubt they could, but one of the essential points of the economical burning of such coal is, as he states, that there should be large combustion chambers. Would space permit of combustion chambers large enough to avoid smoking from the funnels? I do not agree that it is necessary to drain superheaters. I have some in mind that are rather complicated in form and which it is absolutely impossible to drain. They form part of the main steam pipe, and when the boiler is shut down the superheater of course gradually fills with condensed steam, the water re-evaporating when the boiler comes into commission. Mr. Taylor has mentioned a superheater that is placed just behind the front wall of a particular type of boiler. This seems to be quite all right as far as it goes, but where boilers are subject to a very variable supply of fuel, as in the case of blast-furnace gas, when the gas goes off the steam also goes off; there seems, however, to be sufficient radiant heat in the brickwork to raise the tubes to something like red heat. It seems to me that there is rather a danger of the tubes suffering, though Mr. Taylor says this does not affect them very greatly. I scarcely agree with the author in wishing to use water-tube boilers with less water, as he evidently intends to do owing to the raising of the front drum. One of the troubles with water-tube boilers is that there is not enough water reserve; it would be a pity to sacrifice any of that. The difficult question of priming should be treated on its merits, particular attention being given to the feed water supplied. I should be glad if the author could give us any figures as to the furnace temperatures necessary for very low-grade fuel, and also tell us something about the cost of cleaning the various types of boilers with which he is concerned.

Mr. R. E. COWELL: The author appears to have definitely made up his mind that the vertical-tube boiler is the most favourable. There are, however, many boilers having horizontal tubes which are doing excellent work. Reference is made on page 476 to soot clogging up certain portions of the path of the gases and to tubes giving out. Does that occur locally where the gases are concentrated or the passage of the gases is obstructed? With regard to

placing the superheater above the water-level, it is customary for consulting engineers to submit a plan and to ask for a quotation for a superheater in a certain space. Mr. Wright mentioned tubes with cast-iron gills. I fear that these would make up very quickly on the outside when firing with blast-furnace gases, but I believe, as he says, that in the case of coal firing this superheater has proved very satisfactory on the Continent. A number of superheaters on the lines of those with which the author has had experience have been installed, some 14,500 integral superheaters and over 100 independently-fired superheaters being at work at the present time. The largest integral superheater has nearly 3,000 sq. ft. of heating surface, and is fitted to a boiler of over 8,000 sq. ft. heating surface supplied to the Kensington and Notting Hill Electric Lighting Company. The largest independently-fired superheater that has been supplied has 5,020 sq. ft. of heating surface. The tendency nowadays is to have very high superheat: on the Continent one frequently finds 700° F. The use of bituminous coal in the Navy introduces the question of mechanical stokers, which up to the present have not proved a success. The advent of oil firing, however, which is now almost universally adopted, has practically settled this question. With regard to water softening, has the author had any experience of the luminator process introduced a short time ago by the Westinghouse Brake Company? It may be of interest to mention that at West Ham small coal is being conveyed from the barges to the coal store on the same system as the ash-handling plant described by the author. No dust is made and a lot of labour is saved.

Mr. W. McLEOD: The high superheater temperatures that are desirable seem to me to be rather too much to ask for, because I think that with a temperature above, say, 550° F. the life of a superheater will not be very long. I can quite see that if such temperatures are desirable, something like the superheater described by Mr. Wright will have to be used. Of course the objection to such a type is the sooting up. If we can improve the combustion so that there will be very little deposit on the heating surfaces, we shall get a higher efficiency. I should like the author to tell us something more about surface combustion.

Mr. A. DAVIDSON: We have had excellent results from Stirling boilers, although we have not used them long enough to come to a definite conclusion. I think it is very necessary that economizers and boilers should be considered together. There seems to be a very great difference of opinion as to the correct size of economizers, and I should be glad if the author could refer to this in his reply.

Mr. A. STONEHOUSE: The boilers that we have are fired with blast-furnace gas and waste gas from coke ovens. Mr. McLeod has remarked about the sooting or deposit of dust on the tubes, which is a great source of trouble. No doubt in years to come some system of dry cleaning the gas will be successfully adopted. In some cases the gas is being cleaned by washing; personally I do not think this is what is wanted. As to water-tube boilers, I agree with the author that the tubes should be vertical if possible. We find that with the large combustion chamber (I am referring now to gas-fired boilers) we are getting good results—far better than in previous

years when we had no combustion chambers. Our Stirling and Woodson water-tube boilers are fired with blast-furnace gas, whilst the Babcock boiler uses the waste gas from coke ovens. I think much better results would be obtained if we had more space among the tubes. I do not know whether it would be an advantage to have the high superheat that the author suggests, although the tendency is that way.

Mr. J. F. SARVENT (*communicated*): Is it not a slight defect in the superheater as fitted to most Babcock boilers of the land type that the superheat decreases when the draught to a boiler is reduced? At light loads the superheat is not so high as when the boiler is steamed hard. Of course, with an independently fired superheater this does not occur, the tendency being for the superheat to increase with the diminished volume of steam passing. Another defect of the ordinary type of Babcock superheater is the process of flooding and draining. A superheater on a boiler evaporating about 25,000 lb. of water per hour takes some 15 to 20 minutes to drain. If such a boiler be required in an emergency it could not of course be put into service for the above period, provided that the steam pressure, etc., were correct. In the case of a boiler that is taken off on a Saturday afternoon and has to go into service again for the lighting load in the evening, would the superheater tubes suffer by allowing the superheater to remain unflushed for 5 or 6 hours so as to be ready for instant service if required? This defect is of course obviated by having a mixing valve fitted, so that saturated steam alone can be drawn off. Can the author give any information as to the height of the bridges in the furnace of a Lancashire boiler? I have noticed that the height of the bridges in different stations varies considerably, although the boilers may be the same size, burn similar fuel, and have about the same draught. It would seem that where the higher bridges are used there is greater economy in the use of fuel. Is this so, and what is the precise effect; has it a sort of throttling action on the air passing into the flue, or does it tend to more intimate mixing of the air and the fuel? The author states that we are on the eve of the adoption of very highly superheated steam. I take it that this remark applies purely to turbine-driven stations and is not a general statement. Due to the carbonization of the oil in the engine cylinders, the adoption of very high superheats would of course be impossible in stations where reciprocating sets are installed.

Mr. T. A. MAWSON (*communicated*): The system of removing ashes by pneumatic or hydraulic means seems to me very good. But might not another refinement of construction be added—I refer to an improved means of removing the dust from below the boiler tubes (in types like the Babcock boiler). Where there is a basement below the boiler-house floor I would suggest that a brick or concrete tube be provided, having its outlet door by the ash doors and communicating with the dust repository beneath the tubes. In addition to saving time this arrangement would allow of the dust being removed if necessary when the boiler was at a temperature too high for anybody to enter it. Again, there seems to be no reason why in the case of gas- or oil-fired boilers the feeding of gas (or oil), air, and water, could not be made almost entirely automatic, and in the case of coal-fired boilers semi-automatic.

Mr. J. W. JACKSON (*in reply*): In reply to Mr. Turnbull, Mr. Jackson, machine firing, although it appears to have been tried at sea in a more or less small way, is without doubt a very attractive scheme, and although possibly the chain-grate stoker is not the most suitable stoker for the work, there are plenty of other machines that would handle the varying grades of fuel fairly satisfactorily. There should be no difficulty whatever in the use of big coal, as coal crushers have been obtainable for some time and will crush the biggest and hardest coal in an entirely satisfactory manner at a very small cost per ton. Altogether the saving in labour to be effected in this direction, more especially on the bigger ships, will receive consideration in the near future.

In reply to Mr. Baker, there should be no difficulty in obtaining a superheat of 700° F. with the superheater shown in Fig. 1 when it is remembered that this superheater is subjected to a gas temperature of about 1,200° to 1,400° F. This design of superheater does not appear to be influenced by the size of the boiler in any way, and it is located immediately alongside the main flue up-take.

Mr. Selvey's figures indicate that much lower temperatures can be used than is the present practice, thereby giving rise to considerable economies; it is from this point of view that the work of Professor Bone and of the late Dr. Nicholson is of such great value. With regard to rearranging economizers so that they work on the "contraflo" system, experiments have been made in this direction, and although the differences are not great they are, however, worth having. In any case it costs no more to have the economizer arranged on this system. So far as can be seen, "nut coal" can never be as cheap as "duff coal," but a considerable amount of duff coal of a high calorific value can be bought cheaply. Alterations have been made to stoker gears so as to allow the finest duff coal to be handled at a reasonable cost per ton, so much so as to make it worth using.

In reply to Mr. Baxter, the reason for the preference that certain engineers have for the Lancashire boiler cannot very well be given in the form of definite technical advantages for general steam-raising work. The large cylindrical type of boiler works against a serious disadvantage, and unless it is fitted with an economizer of great capacity it can never be worked economically. With reference to the type of turbine blading that is suitable for the highly superheated steam, unless turbines of enormous capacity are to be used, where the steam passages are large, the turbine will most probably be arranged for the first stage, at any rate on the Curtis system, and most probably the low-pressure part will consist of the simple re-action blading. There are, of course, refuse destructors that are unsatisfactory. On the other hand, this system has been given a lot of thought, and really satisfactory designs are now at work by which it is possible to consume almost any combustible material.

In reply to Mr. Clementson, it is almost impossible to state a definite figure for the amount of steam that can safely be by-passed in the superheater by means of throttling the steam, since so many other things have to be taken into consideration. It seems to me that where the amount of superheat is to be controlled by means of a by-pass valve in the steam space, it is still more important that the superheater should not be placed in too hot a

position; it should be as far away as possible from the boiler furnace. The reason that a superheater well removed from the furnace will give a more regular amount of superheat than one that is placed near the furnace is due to the fact that as the boiler capacity is decreased owing to the fouling of the water tubes the temperature of the gases rises. In the case of a superheater placed near the furnace, the fouling of the main water tubes also reduces the gas spaces between the tubes, and in effect causes a smaller draught in the furnace, thus allowing the temperature of the latter to rise higher than before. And having none or possibly only a few water tubes to pass, and seeing that the steam flowing to the superheater tubes is somewhat reduced, this causes the superheater in many designs to give a considerably increased steam temperature.

It is well known that the temperature rises in most chain-grate furnaces as the gas passages become fouled. There appear to be two main reasons for this, one being that the boiler is subject to a very low draught, and the other that the tubes being fouled with clinker do not take up the radiant heat from the furnace; this has therefore the effect of increasing the refractory lining of the furnace, thereby allowing the furnace temperature to rise. Under such conditions as these the furnace temperature will rise by as much as 1,000 degrees F., the same class of coal being used. It appears to be the general impression that the steam pressure is not likely to have to be considerably increased in the future. For steam turbines a pressure of 200 lb. per sq. in., or thereabouts, is the limit that is at present being used, and is fairly difficult to deal with; but the designers of steam turbines get a much greater economy by using superheated steam. The overall increase in efficiency of a boiler and turbine plant due to increasing the steam temperature is a very considerable item, and a steam temperature of 1,000° F. is by no means out of the question if suitable metals can be obtained for dealing with it.

The reason for suggesting that the front drum of the particular type of boiler should be elevated 12 in. above the back drum is to allow larger steam spaces than at present. Where there is any tendency to priming, most engineers will agree that it is necessary to carry as small an amount of water in the drum as is reasonably safe, thereby allowing the steam bubbles to become disengaged from the water with the least possible disturbance. These notes were written from the point of view that a man is employed to watch the level of the water in the drum and keep the levels constant, or that an automatic feed-water regulator be employed for the purpose. This apparatus promises well. It is possible to have very serious trouble from boiler corrosion where no trouble whatever is experienced with condensers; this especially applies where the make-up feed water may have a high percentage of magnesium chlorides and sulphates, etc.

As to covering the boiler brickwork with steel casing with a view to reducing the air leakage, this is a very valuable asset to a boiler of any make. Where modern boilers are so fitted it is important to see that the brickwork is kept in intimate contact with the steel casing. There should be no air space. If a passage is left, the

gas will by-pass the main tubes of the boiler, thereby destroying the steel casing and allowing heat to be lost up the chimney.

Mr. Vernier raised a very interesting train of thought in suggesting the use of the by-product recovery plant together with a gas producer. In order to supply the electrical energy for such a large power system as that in this neighbourhood a by-product recovery plant with a gas-producer plant would have to be of such enormous dimensions that the electrical generators would represent only a very small percentage of the total capital outlay for such an installation. The business of a company adopting such a scheme as this would appear to be that of a by-product recovery company rather than an electricity supply company. Mr. Vernier's remarks, however, cannot be dismissed with a few minutes' thought; they require a lot of consideration.

With reference to Mr. Wright's remarks regarding the Foster superheater, it is a type to which I have not given much attention up to now. It certainly seems to have several important advantages, and to be protected against high temperatures. I am a little afraid that the introduction of the gills on the tubes may create collecting spaces for the dust, from which unfortunately we do not seem able to get away. Dust may completely insulate the tubes, and they would then become inoperative as a superheater. With regard to the question of the drop in pressure across the superheater, the figures that I have quoted are actual measurements by pressure gauges, and there is no doubt about their being correct. A number of gauges were used; they were all interchangeable and all subjected to a pressure test afterwards.

With regard to Mr. Wright's point as to the air supply to the boiler, I think the best guide we can have to this is the amount of CO₂ in the outlet gases. If the amount of CO₂ in these gases is correct, the air supply to the furnace is also correct, and there will be no difficulty in that respect. First of all, I assumed that the modern furnace is the furnace under discussion; that means a furnace of ample capacity and size. That being so, we can assume that the furnace will require most of the air that gets there. As to the amount of CO₂ that should be aimed at in good practice, generally about 10 to 12 per cent of CO₂ at the outlet of the boiler appears to be the maximum that can be carried. That seems rather a low figure—low compared with what some manufacturers of stoker gear expect, namely, 14 to 15 per cent. It is quite probable that if this latter percentage of CO₂ were carried the furnace brickwork would collapse very quickly. The furnace brickwork is the controlling factor. We may only have 8 per cent of CO₂ in the boiler outlet and 14 per cent under the boiler arches. It is often difficult to ascertain where the leakage occurs—whether in the furnace or at some point between the furnace and the outlet. If a leakage does occur it must be located and dealt with without delay if a high efficiency is desired. It seems to me that the point is met. That is to say, if one aims at an average of about 12 per cent of CO₂ in the furnace, and allows this to fall to something like 10 per cent, no very serious damage can be done to the furnace anywhere, and a fairly efficient combustion is guaranteed.

Mr. Wright asks about a flat arch in preference to the cambered arch. For reasons of efficiency we all aim at

Jackson, obtaining the highest possible percentage of CO₂ in the furnace. The firebrick will only stand a certain temperature before it collapses: for continuous working that temperature is generally between 2,500 and 3,000° F. As a temperature of 3,000° F. is approached, corresponding to 12 per cent of CO₂, the firebrick usually becomes quite soft; if the furnace arches were flat they would therefore collapse at a lower temperature than if built with a fairly big camber, i.e. with a small radius.

A large number of water-cooled ash stoppers have been introduced by the leading makers, but none has worked satisfactorily, the reason being that the ash-stopper has got choked with scale from the water that has been used for cooling. Some engineers recommend the use of distilled water. Even when that is done, owing to the violent changes of temperature that occur, the greatest difficulty is experienced in keeping the pipe joints tight. Dumping bars of very heavy section allow heat to be transmitted quite readily to the more protected parts, and solve the difficulty without water cooling.

I am pleased to hear that it is possible to dish the drum ends of the Nesdrum boiler without serious straining. I have never heard of any troubles developing with those drums, but I have known of many cases of boiler drums failing where the dishing was no more acute than it appears to be in the case of the Nesdrum boiler. This is a point that will have to be watched very closely indeed, since this dishing allows local working and straining to take place. The particular boilers to which I refer have drums of greater diameter than those mentioned by Mr. Taylor. He also referred to the overloading of boilers. I do not think it is possible to overload a boiler provided the temperature can be taken up in an efficient manner before the back end of the boiler is reached; but if the temperature of the gases is reduced to the lowest possible point, i.e. about 100° F. above the temperature of the steam, then the boiler can be overloaded.

I do not agree with the position chosen by Mr. Taylor for the superheater used with his boiler. It will probably get filled up with dust owing to the eddies set up in that position. The dust is given off in at least two forms. One leaves the furnace as a solid, and the other passes off from the fire in the form of vapour, which condenses again as the temperature is reduced. This latter is the dust that blankets every surface so completely. It settles around the tubes very closely and is not easily blown off. A steam jet or an air jet has to be applied very closely indeed to remove it.

With regard to the corrosion of the superheater (Fig. 3), I know of boilers which have failed in the manner pointed out. In all cases the superheater tube was choked with solid matter, thus allowing violent corrosion to take place internally as well as externally, due to excessive heating and to magnesia and lime scale being deposited in the tubes. I know of another design of superheater where scores of tubes are being replaced; they are not bent, but straight tubes. It is not due so much to choking up as to wet steam given off by the boiler passing direct to the superheater tubes.

With regard to the water level in the drums, my point is that if the drums are left in their existing positions with regard to the water level, the steam space in the main drum is relatively reduced. The front drum collects

between 60 and 80 per cent of the total steam, and the steam space is reduced owing to the relative size of the water space being increased. That being the case, priming takes place more readily than it would otherwise do. My remarks were the result of experience in the matter. I should like to add that I do not think we have sufficient space for the deposition of spray in the water-tube boiler. The water ought to be deposited more readily than it is.

Mr. Thompson mentioned the quick raising of steam. I have on a few occasions seen boilers heated quickly, and they stood the test perfectly satisfactorily. The boilers were afterwards hydraulically tested to a pressure 50 per cent higher than the working pressure, and were found not to have suffered in the slightest degree. This is one of the main reasons why a water-tube boiler is to be preferred to a cylindrical boiler. The latter can only be heated very slowly. I should like to explain by referring to Fig. 1 how it is that the superheater will take up the high temperature without allowing the high temperature gases to escape to the chimney. The gases rise through that section of the boiler that is farthest removed from the steam drum, come down through the superheater through the middle section of the boiler, turn round again and rise immediately behind the steam drum up to the flue. The flue is indicated at the position of the butterfly damper. This particular superheater is subjected to a gas temperature of about 1,400° F. when working at normal load. I believe that temperature is sufficient to give us the whole of the superheat that would be likely to be required, i.e. 900° F.

The large amount of dust from low-grade fuels is very difficult to deal with, especially with the lower grade of fuels. Unless the temperature of the furnace is kept high a considerable amount of dust escapes. There is some difficulty in keeping a high temperature in the furnace, since the air to the furnace must to some extent be cut down to the minimum so as to make the amount of the CO₂ as high as possible; that is to say, the furnace temperature cannot be kept up by using an excess of air. I have seen boilers fired with coal picked up from the waste heaps from the countryside in the form of duff, all of it so small as to pass through a $\frac{1}{4}$ -in. mesh, and with a heating value of only 8,000 to 9,000 B.Th.U.'s per lb. There was very little dust from the plant, because the temperature was allowed to rise so high that dust was thrown on to the back wall of the furnace as molten slag. The boilers were kept on load for several weeks at a time without any difficulty, the temperature not being high enough to cause a breakdown of the brickwork.

Considering the superheater again, I have mentioned that the temperature of the gases impinging on the superheater in Fig. 1 is 1,400° F. I have on several occasions seen cases where the air supply to the furnace has been kept low enough to allow combustion to be again set up in the superheater space. That is to say, the amount of CO₂ in the furnace was about 16 or 17 per cent. There was a little leakage into the boiler space between the first pass of the main tubes and the superheater. I think that is one reason for the fire issuing from the chimneys of ships. The combustion chamber is also sometimes too small to allow combustion to be completed. I have seen many experiments in connection with furnace temperatures. With the amount of CO₂ under the arches at about 12 per cent—the temperature under the arches would be of the order of

Mr. Jackson 3,000° F.—and with the back end of the boiler kept reasonably tight, that temperature would be applied to the furnace tubes without any appreciable drop. Immediately the second row of tubes is passed (Fig. 1 will illustrate the point) there is a drop of as much as 1,000° F. across the first two rows of tubes. The interesting point is that the first two rows cause a considerable drop in the temperature. In the case of the boiler in Fig. 4 the front portion of the first section of the tubes carries the correspondingly heavy duty. These tubes cause the temperature to fall about 1,000° F. The front section performs between 65 and 75 per cent of the total work of the boiler.

Mr. Cowell raises a very interesting point in regard to the advantages and otherwise of a vertical or nearly vertical tube as against a horizontal tube. Both have their advantages. The reason why I really prefer the vertical-tube boiler is that I believe it allows a larger circulation; it therefore more readily takes up the heat that is transmitted to the tube, and for equal heating surfaces gives a higher evaporative efficiency. Also, because of this violent circulation, it does not hold the mud that is deposited in the boiler so readily as does the horizontal-tube boiler. In the case of the nearly horizontal-tube boiler the steam is undoubtedly superheated; this is an undoubted advantage.

I have figures to show that the steam is superheated by as much as 20 degrees F. in the steam drum of a horizontal-tube boiler, and this superheating takes care of any priming that may have occurred in a superheater such as that in Fig. 1. Under these conditions corrosion of the superheater does not take place. The designer of vertical-tube boilers must therefore arrange so that the steam is disengaged without causing any priming; and if he can secure this slight degree of superheat in the main and generating tubes so much the better.

With reference to the corrosion of the interior of the tubes, all the corrosion that I have seen has been local, due to this comparative priming, and in that case the corrosion occurs on the ends of the tube and for the first few inches only; it does not get beyond that point. Where the tube is bent, and suspended in the vertical position, as in Fig. 3, this corrosion occurs inside and outside the tube at the bottom of the bend, the tube having become choked with boiler mud and corrosion. The mud gets wet when the boiler is off load, and when subjected to the higher temperature chemical action sets in, causing further corrosion as well as excessive heating. The tubes of which I have known increased in diameter before they finally burst. The normal diameter being $1\frac{1}{2}$ in., the metal stretched to 4 in. before bursting.

With regard to the temperature of the superheated steam, any degree of superheat desired can be obtained with the arrangement shown in Fig. 1 without any difficulty. I should have shown a more complete arrangement of the by-pass damper. Between the two top tubes and the main generating tubes a by-pass damper is fitted. That damper can be opened as far as is found desirable, therefore completely controlling the superheater.

I have had no experience of the luminator process. I know, however, of one case where it had no effect on the boiler water, but acted very considerably the condenser water. Where hydrochloric acid had previously to be

used to remove scale, the luminator kept the scale soft enough to allow of its being removed by a good strong brush. I have heard from boiler inspectors and official-very favourable reports of the luminator plant. Before the luminator plant was installed the boilers had to be taken off load every three weeks and thoroughly scaled—the scale was very thick by that time—but with the luminator installed they were able to run the boiler for 13 weeks without any trouble. This boiler was opened up and found to be quite clean. It was run for a further three months and was still found to be quite clean. All their boilers are now running on luminator plant and are quite clean. It prevents the soft matter from forming scale and causes it to be deposited in the form of mud. I understand that the luminator will not work at all in some districts, mainly where chlorides are found in the water; that is the main disadvantage. It has been clearly demonstrated that the action is purely mechanical; there is no chemical change whatever. On the other hand, it is stated that the aluminium is dissolved from the plate, gathers round the molecules as they settle out of the water, and covers them with a slippery coating so that they cannot adhere together.

With regard to Mr. McLeod's request, I regret I have had no direct experience with either of those boilers. As I pointed out, the Bonecourt boiler has a somewhat limited field, and when it is coal-fired I think it can never be as efficient as a coal-fired boiler, since where coal is used for fuel a gas producer is necessary, the increased efficiency of the Bonecourt boiler being counteracted by losses in the gas producer. There is a lot of investigation work being carried out on gas-producer schemes and the recovery of by-products. The gas-producer scheme is more or less a failure where used purely for gas firing under a boiler.

Mr. Davidson asked about economizers; as a rough guess I think every boiler should be supplied with an economizer having not less than one-quarter of the heating surface of the boiler. That is a big economizer, but these are very much in fashion to-day. They are much safer to work with in all respects, and permit of a high evaporative efficiency being obtained easily under ordinary service conditions.

In a communication from Mr. J. F. Sarvent stress is laid upon the necessity of draining the superheater of the ordinary land-type steam boiler, it being pointed out that, no matter how great the emergency may be, the superheater, which is normally situated underneath the main steam drums, cannot be drained in anything less than 15 to 20 minutes. This is a very serious objection to this type of superheater. Highly superheated steam, such as may be expected in the future, is of course only suitable for turbines, and therefore these remarks apply to such stations.

In reply to Mr. Mawson, as stated earlier in this reply feed-water regulators have been at work for some time, and are regulating the water level in a most satisfactory manner. There are, of course, conditions where automatic regulators are quite unsuitable, and in installing a regulator consideration must be given to the feed pump. If the feed pump is of a reciprocating type it must also be controlled automatically, but if of a centrifugal type controlled by water pressure it need not be specially controlled in order to make automatic feed-water regulating a complete success.

Mr. Jack

DISCUSSION ON "ELECTRIC LOCOMOTIVES."*

BEFORE THE INSTITUTION, 26TH FEBRUARY, 1914.

Mr. F. LYDALL (*communicated reply*): Mr. Roger Smith has drawn attention to the suggestion for a goods locomotive on page 746 of Volume 51, namely that in which an equipment is provided capable of exerting a tractive effort of about 12 tons at 25 miles per hour, and has remarked that if such an equipment included continuous-current series-wound motors the maximum starting pull would be something like 30 tons. I quite admit that such an equipment would be a departure from the ordinary practice, and I only made the suggestion because it is not self-evident that the usual practice of running traction motors in such a way that their maximum output is only developed at speeds much below the steady running speed of the train, is necessarily the best course to pursue in dealing with the haulage of goods trains. I venture to think that there are no technical difficulties in the way of such an equipment as I have suggested, and I pointed out that it is for the railway engineer to decide whether the advantages of running at relatively high speeds up the gradients are sufficient to warrant a somewhat expensive equipment on the locomotive.

The control apparatus of such an equipment must of course be suitable, and the tractive effort exerted by the motors must not be allowed to exceed the proper value as determined by the strength of the draw-bar, although, of course, continuous-current motors could do so without difficulty. With series, series-parallel, and parallel control, combined if necessary with field control, I believe the speed regulation of such a locomotive would prove all that could reasonably be desired without making it necessary to run on the resistances. In the case of single-phase motors speed control is naturally a very simple matter, as indicated in the paper on "Motor and Control Equipments for Electric Locomotives."

In this connection I may perhaps refer to a doubt expressed on a previous occasion by Mr. Roger Smith with regard to the express passenger electric locomotive suggested on page 747 of Volume 51, more particularly in respect of the tractive effort at 75 miles per hour, viz. 8,000 lb. While he is, I believe, perfectly correct in saying that no such electric locomotive has yet been built, I think a reference to the table of locomotive motors on page 397 of Volume 52 will convince him that, given the demand for such a locomotive, no difficulty will be experienced in meeting the demand and in providing a locomotive capable of meeting all the requirements suggested. For example, suppose the continuous rating of the motor equipment is taken at 1,900 h.p., corresponding to a tractive effort of 12,000 lb. at 60 miles per hour, the last motor in the table, viz. W.B.M. 3,700 s. may be referred to. This motor has a continuous rating of 760 kw. input; that is about 950 h.p. output. A pair of these motors would clearly meet all the requirements of the case, provided the proper wheel diameter be chosen to give the required speed at the continuous rating. The

pair of motors would weigh 26·8 tons, exclusive of motor shafts, bearings, etc., which cannot be regarded as excessive for a locomotive with three driving axles and a leading trailing bogie. With continuous-current motors the weight would probably be less.

Mr. Roger Smith's remark that if such a locomotive could be built and put into service, the working conditions of passenger traffic would be greatly altered, leads one to hope that such an experiment will be made in order to ascertain the effect of the change in conditions. It would obviously be a simple matter to effect a general speeding up of the long-distance passenger service, especially on lines where there are many gradients, and this could be done without in any way exceeding the speed limits at present in vogue, but simply by maintaining a high speed up the gradients where now the best that can be done with steam locomotives is from 30 to 40 miles per hour. Such a modification would not create any difficulties due to lengthening existing blocks. It is, however, for the electrical engineer to bring to the notice of the railway engineer the possibility and practicability of constructing such locomotives, and then to leave to the railway engineer the task of deciding whether such locomotives can be profitably employed.

The figures for tractive resistances of the locomotives assumed in the paper have been questioned. Mr. Roger Smith considers that a difference of 700 lb. between tractive effort and draw-bar pull at speeds of 25 to 30 miles per hour is insufficient. Perhaps I may refer to the tests on the 1—C—1 locomotive equipped by Messrs. Ganz & Co. for the Valtellina Railway, described in the *Revue Generale des Chemins de fer* for March, 1905. The results of a number of tests are given in the form of a curve, from which the following points may be taken:—

Speed. km. per hour	Tractive Resistance. kg. per ton
25	2·3
40	3·5
60	5·5

These figures refer to the locomotive alone, and show that it is reasonable to take much lower values for electric than for steam locomotives. The figure of 700 lb., which is equivalent to about 10 lb. per ton, is well above the value mentioned above, viz. 3·5 kg. per ton.

I think Mr. Roger Smith has misunderstood the remarks in the paper dealing with the combination of gearing and coupling rods. I tried to show that the use of geared motors for locomotives intended for high speeds led to uncomfortably high gear velocities, and in doing so I argued the case for several alternative methods of using geared motors, among others large motors geared to jack shafts, these shafts being coupled by side rods to two or more driving axles. I had no intention of going beyond this argument. Such a method may be quite a good solution of a difficulty, if the conditions do not lead to

* Papers by Mr. F. Lydall (see pp. 381 and 384, and vol. 51, p. 739).

Mr. Lydall. excessive gear velocities; and, as hinted at in the Supplementary Paper, it may even be worth while to make special provision for dealing with abnormal gear velocities in cases in which they are unavoidable.

I am not aware that any other difficulties have been experienced with induction regulators for single-phase locomotive equipments, apart from that mentioned in the paper. I am sorry that I am not in a position to give any information as to the working of electric locomotives on steep gradients and how the question of starting on such gradients is affected by the type of control.

Mr. Carter has evidently misunderstood the purpose of the paper on Electric Locomotives. This purpose is stated in the second paragraph on page 740 (Volume 51), viz. "to refer to certain considerations which in my opinion must be taken into account in settling the design of a locomotive to meet a set of specified conditions." The list of locomotives contained in Part I is intended for purposes of reference.

I will, however, try and meet Mr. Carter on his own ground. First of all, I must draw his attention to the fact that the paper in Volume 51 was completed just about the end of 1912, whereas the quotation that he gives from the *Electric Journal* is dated October, 1913. In the second place, I am convinced that it is better to abstain from criticism unless one is in possession of all the facts of the case. A certain amount of hearsay evidence mixed up with preconceived ideas based on theory is not enough to justify statements that one type has been a failure and other types are bound to be failures. I maintain that what is necessary to enable anybody to form a considered judgment is first a knowledge of the reasons that have brought any particular locomotive or type of locomotive into existence; second, a knowledge of the actual behaviour of the locomotive in question; and, third, if there have been any difficulties, a knowledge of whether these have been due to causes beyond ordinary control, such as collisions, etc., or to trifling causes easily avoided in future, or to some reason inherent in the design.

I am not convinced that either Mr. Carter or the authority that he quotes possess this requisite knowledge.

To deal more specifically with the instances given by Mr. Carter, he mentions that many of the types that I have enumerated have given trouble, and quotes first the experimental 1—C—1 single-phase locomotive for the Wiesenthal Railway. Mr. Carter says that this type is always recognized as one that will give rise to "nosing." He does not definitely state, however, that it has been subject to this complaint, nor do I gather that Messrs. Storer and Eaton say so. As a matter of fact, the makers of the locomotive who have watched its running for several years, have not found any tendency towards nosing. The locomotive is in regular service on the Wiesenthal Railway and there is no intention of withdrawing it or altering it.

Mr. Carter's remark that "the remaining nine locomotives are being built to a slightly modified design" is simply a manufacturer's way of expressing that the first locomotive is a failure, shows that he is entirely ignorant of the facts of the case.

Turning next to the extract from Mr. Hellmund's article on the "Electrification of Trunk Lines in Europe," the breakage of the crank pin on the 2—B—1 locomotive

is referred to on page 762 of Volume 51, and the reason for the breakage is explained. Reference is made to the locomotives of the 0—D—0 type which "have so far given best satisfaction in service, although they are subject to rather pronounced vibrations." The statement that some type of geared locomotive would have been a better solution for this service, may or may not be true, but the reasons for this opinion are not given.

As to the breakage in the third case mentioned, I have no information, unless the locomotive in question was one of those built for the Wiesenthal Railway and referred to in the Supplementary Paper.

Mr. Carter then puts forward his view of the fundamental cause of the troubles to which he has alluded namely, that "the uniform torque of a motor can only be converted into a pair of reciprocating forces in the direction of the side rods by subjecting the frame of the locomotive to very severe stresses." It seems to be Mr. Carter's opinion that these stresses have either been overlooked or insufficiently appreciated by the designers of the mechanical portions of the Continental locomotives. This is not the case, as a study of the technical Press on the Continent would easily prove.

When Mr. Carter states that the reason which he puts forward is sufficient to proclaim the side-rod type of locomotive as a type to be avoided wherever possible, his opinion is not borne out by facts. For example, he remarks that the difficulties due to this cause are greatest in that case in which the angle between the connecting rod and the side rods is a right angle. This is the case with the 2—B—1 locomotive on the Dessau-Bitterfeld line. As a matter of fact, apart from the breakage of the crank pin referred to on page 762 of Volume 51, the 2—B—1 locomotive equipped by Messrs. Siemens Schuckert has run very satisfactorily indeed for three years, and there is no reason why it should not continue to give satisfaction in future. It is highly necessary, therefore, to receive these theoretical propositions and the deductions from them with caution.

Incidentally I may point out to Mr. Carter that for full-gauge main-line locomotives the radius of the crank is not of the order of 8 in., but is usually from 12 to 13 in. The figures of torque and stress calculated by Mr. Carter therefore need revision.

Replying to Mr. Bowden, I do not know of any case in which motor-generator control has been employed in electric locomotives.

The opening remarks by Dr. S. P. Smith have, I think, been fully answered above. In regard to the comparison between the Pennsylvania locomotive motor and the 800-h.p. single-phase motor, it may be that Dr. Smith has access to information which I was unable to obtain. When, however, he asserts that the Pennsylvania motor, if designed for 1,200 or 2,400 volts would weigh much more than it does at present, he is indulging in prophecy, since no such motor has been actually constructed.

Personally, I agree entirely with Mr. O'Brien with regard to the advisability of providing for the driver in an electric locomotive a free look-out all round; but unfortunately this is not always possible, more particularly in those cases in which a large step-down transformer is required.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 12TH MARCH, 1914.

Proceedings of the 564th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 12th March, 1914—Mr. W. DUDDLELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 26th February, 1914, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Messrs. C. F. B. Marshall and A. H. Allen were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Members.

Bille, Harald.
Feldmann, Oswald.

Associate Members.

Fuller, William Payne.
Jennison, Matt.
Tasker, John Herbert.

Graduates.

Allington, Ernest.
Browne, Walter Stephen.
Fernando, Peter Charles.
Hollinrake, John Slater.
Phillips, Walter.
Williams, William Ratcliffe.

Students.

Broadwood, Leopold Alfred T.
Burke, George Bernard.
Burrage, Charles James.
Cam, Alan Noel.
Caspar, Frank Albert Emile.
Cheshire, James.
Croft, Edward Hugh.
Cuerden, Harold Seymour.
Delanoy, M. Lee.
Dixon, Fred.
Dobie, Percy.
Furnival, John Megarry.

Harrison, Roger William.

Lawrence, Frederick Charles.
Norburn, William Henry Joseph.
Norris, Eric Douglas Tobias.
Nyman, Alexander.
Porter, Henry Percy.
Poynter, Hubert Gorringe.
Sinclair, William.
Smith, Lewis Charles Reginald.
Smith, William Balfour.
Symons, Ernest John.
Tolley, Claude Edmund.
Trippe, Sydney Howard.

TRANSFERS.

Associate Member to Member.

Hunter, Philip Vassar.

Student to Associate Member.

Timmis, Arthur Carlyle.
Watkins, Stanley Sylvester A., B.Sc.

Student to Graduate.

Mansell, Laurence Thomas George.

Donations to the *Library* were announced as having been received from Messrs. Alabaster, Gatehouse & Co., The Chartered Institute of Patent Agents, W. Cramp, Sir John Gavey, C.B., The International Electrotechnical Commission, H. R. Kempe, P. D. Leake, Liverpool Corporation Tramways, Manchester Chamber of Commerce, Physikalische Technische Reichsanstalt, The Radcliffe Library, Professor D. Robertson, D.Sc.; and to the *Museum* from Messrs. Edison & Swan United Electric Light Company, Ltd., K. Hedges, and H. C. Levis, to whom the thanks of the meeting were duly accorded.

A paper by Mr. H. E. O'Brien, Associate Member, entitled "The Design of Rolling Stock for Electric Railways" (see page 445), was read and discussed, and the meeting adjourned at 10 p.m.

THE JOURNAL OF The Institution of Electrical Engineers

Vol. 52.

No. 232.

DISCUSSION ON "ELECTRIC BATTERY VEHICLES."

BEFORE THE INSTITUTION, 19TH MARCH, 1914.

Introductory Notes by F. AYTON, Member.

The importance to the central station of the load to be obtained by a general use of electric vehicles can hardly be over-rated. It is in practically all cases an "off-peak" load; and as it will in nearly all cases come on during the night, when the majority of the other consumers have ceased to make any demand on the supply, it will have a tendency to flatten out the generating station load curve in a most favourable manner. Every central-station engineer knows the beneficial effect that such an improvement in the station load factor will have upon the cost of generation, rendering it possible to reduce the selling price to all consumers, and, by the increased demand thereby created, greatly benefiting the electrical industry generally. Little wonder, therefore, that the central-station engineer, now fully appreciating these possibilities, is keen on doing all that he can to popularize the electric vehicle and to facilitate its adoption. The natural outcome of this keenness was the formation, by the Incorporated Municipal Electrical Association, of the Electric Vehicle Committee. The object of this Committee is to promote the adoption and use of the electric vehicle for business and pleasure purposes, and its constitution is framed on co-operative lines. The majority of its members are outside the Incorporated Municipal Electrical Association and consist of representatives of the electric manufacturing interests, the electric power companies, the electric vehicle manufacturers and agents, and others.

At the moment, the most promising opening for the electric vehicle appears to lie in its use for commercial purposes; but it is by no means improbable that the passenger-carrying vehicle, whether for business or pleasure purposes, will eventually be considered from the central-station point of view almost as important as the commercial type of vehicle.

One frequently meets people—some of whom, unfortunately, are engineers—who, at the mere mention of an electrically-driven vehicle deriving its energy from a storage battery, grow sceptical, openly expressing their

doubts as to the possibility of such a method of road traction ever proving commercially successful. They apparently base their opinions upon the failures of past years. It cannot be too strongly emphasized, however, that the electric vehicle of to-day is not to be judged by the experiences of even a few years ago in this country. Since that time great advances have been made in storage battery construction, the design of the motors for electric vehicles has been improved, ball and roller bearings have been brought to a high pitch of perfection, chassis construction has been lightened, and better and more efficient rubber tyres can be obtained. For the improvements in the latter three items, the electric vehicle owes much to the wonderful evolution of the petrol car in the past few years.

The proper sphere of utility for the electric vehicle at the present time is undoubtedly in interurban and suburban districts where its mileage limit per charge is not a drawback. The passenger-carrying vehicles and the lighter pattern of commercial vehicles are generally capable of doing from 50 to 60 miles per charge, and it will be found that in most cases this covers the daily requirements for work in such districts as those mentioned. By a boosting charge during the driver's dinner-hour, the daily mileage capacity may be appreciably increased.

The utility of the electric vehicle in interurban and suburban areas is amply demonstrated by the number of vehicles in daily use in the United States alone. At the present time there are over 37,000 electric vehicles in use in that country, of which more than half are passenger-carrying machines used for business or pleasure purposes. There are said to be about 40 firms engaged in constructing these vehicles in America, and the number of such vehicles is increasing at a rapid rate. In certain cities on the European Continent, also, this type of automobile is rapidly coming into general use, and hundreds are already running and giving satisfactory and economical service.

If we have to admit that there are limits to the scope of usefulness of the electric vehicle; if we have to concede to the petrol vehicle, as we certainly must, some of the merits that it is known to possess; if we must agree that there are certain fields that the latter will probably continue for some time to hold as pre-eminently its own; it is nevertheless true that within its own legitimate sphere the electric vehicle can show a degree of economy, and a record for reliability, with which no other existing type of vehicle can hope to compete. We shall, I think, be wise if we frankly admit the probability that each type of vehicle will have its own distinctive field of use in which it will prove, on the score of suitability and economy, practically unassailable.

In spite of the fact that it has to provide and maintain its own roadway, and that this accounts for by far the greater part of the total capital expenditure, the average cost of operating electric trams in this country indicates that this method of transit is still the cheapest where the traffic to be catered for warrants the outlay. The trolley omnibus, again, has proved a cheaper means of conveyance than the petrol omnibus, in spite of having to bear the additional capital charges of the trolley line and feeders. Both these examples are only instances, out of many, showing that when electric driving can be suitably applied and combined with the supply of electrical energy from a central station, the results as regards convenience, economy, and reliability, are incomparably superior to those of the small independent power plant.

The electric battery vehicle is only another instance of the same kind. It also draws its energy from the central station—not continuously, I agree; but it is able to take it at times which are very convenient to the supplier, and under conditions that properly allow of a low price per unit being charged. There is certainly a loss in charging and storage, but in comparison with the electric tramcar and the trolley omnibus, this loss can to some extent be set off against the loss in transmission in the case of the two latter systems.

I think that these analogies, together with the well-known simplicity of the electric vehicle, its freedom from vibration, and the consequent lessened wear and tear, will go far to explain and make clear to the layman the reason why it proves in actual service to be so economical and reliable.

It is in the displacement of the horse that the real economic future of the electric vehicle lies. For haulage purposes in cities and large towns the days of the horse are numbered. The congested state of our thoroughfares demands his removal, and upon the basis of operating costs the electric vehicle is the only type of power-driven machine that can take his place. The relief of the traffic congestion in the main streets of our large cities and towns is well known to be an acute and pressing question. There is naturally a limit to the number of vehicles that can be accommodated in any street; and in very many cases that limit has already been reached. What is to be done? A general widening of main thoroughfares is economically out of the question. More efficient use must be made of the present street area. One obvious method of obtaining relief, then, is to bar horse haulage entirely. A pair of horses and a large van take up nearly double the street area required for an average motor vehicle of the same

capacity, and for equal carrying capacity the electric vehicle, by reason of the simplicity and compactness of its mechanism, takes up the least space of any.

Considerable further relief of the congestion would follow from the fact that a good commercial motor vehicle can do in the same time more than twice the amount of work of two double-horse teams in city service. If we consider for a moment the serious delays that are at present taking place in the delivery of merchandise in our cities, and also the cost of these delays, which ultimately resolves itself into a tax upon the consumer, we can easily realize the immense saving that would accrue to the business community by the wholesale adoption of motor transport for city service.

But the already extensive adoption of the petrol type of commercial vehicle for this purpose has brought in its train conditions which, I suppose, everybody will agree have not added to the amenities of city life. The noise and smell from that class of vehicle have frequently been the cause of bitter complaint. Both these disagreeable features are of course absent from the electric vehicle, and for this reason alone it should assuredly commend itself for universal adoption in large cities and towns. It is noteworthy, in connection with what I have just said, that one of the leading engineering journals, when recently discussing the noise made by motor traffic and the means for preventing it, said: "Electrically-driven vehicles we do not propose to discuss as they are beyond criticism—at any rate, in contrast with other motor vehicles."

The position of the electric vehicle can hardly be considered apart from methods of charging its battery. With the batteries at present fitted, the impressed voltage required towards the end of the charge is in the neighbourhood of 110 to 120 volts. Since the supply pressures in use are generally above 200 volts, it follows that in most cases the charging must be done through the medium of some pressure-reducing apparatus. If the use of the electric vehicle is to reach the proportions that we so ardently desire, it is essential that the charging operation should be made as simple as possible; in fact, it should be made—as it can be made—practically automatic. It therefore remains for the central-station authorities and the manufacturers to see that reliable automatic apparatus is provided. It should be so constructed that when the correct terminal voltage for the whole battery (which is a good approximate indication of the battery's condition) has been reached, the motor-generator is automatically shut down. It is of great importance that vehicles should be able to run into any place where charging facilities are provided, and get connected up with ease. This points to the necessity of standard charging receptacles and plugs. The Electric Vehicle Committee, realizing the importance of this, have decided after careful consideration to recommend to the British Engineering Standards Committee the desirability of adopting the 150-ampere plug and receptacle of the Electric Vehicle Association of America as the standard fitting for this country. The American Association has standardized upon two sizes, 50 amperes and 150 amperes, but we came to the conclusion that, as the larger size would be required for most vehicles, it was desirable to keep to that alone.

I propose to conclude these very general remarks by touching upon the work that is necessary in order to bring

the uses and advantages of the electric vehicle before the general public. At the outset I would say that in my opinion we cannot look for much assistance at the present time from existing motor traders and garage proprietors. They are in possession of an established business in connection with the petrol vehicle, at which no doubt they are making good profits. They do not want that business interfered with, and they may have grave doubts as to the utility of the electric vehicle. As to its mechanism, its merits, and its economy, they are profoundly ignorant. They will only wake up to its possibilities when they see a created business around them and find a reduction in the sales of the petrol vehicle. In the meantime, then, the pioneer work has to be done, and it behoves the electricity supply authorities, as those who are going to benefit most by the extension of the use of the electric vehicle, to work hand in hand with the manufacturers and to carry on an active propaganda for advertising the electric vehicle.

We have got to educate the public and also those in charge of garages. We must show them that because the vehicle is electric it is by no means complicated; in fact, it is by far the simplest and most stupidly constructed power-propelled vehicle at present on the road. We must advertise all its other good qualities, its ease of driving, its all-round economy, and its reliability.

I believe that the story of electric vehicle progress in Great Britain, as it will be told a few years hence, will be such as to constitute a complete rebuke to present-day sceptics. I believe it will be a story of splendid progress, a record of fine achievement.

Mr. J. W. BEAUCHAMP: In my district at the present time there are six vehicles which are being regularly charged from the public electricity supply mains, and I have good reason to think that this fleet will be doubled in the course of a few months. So far as I can estimate, the average revenue obtainable where electrical energy is sold at 1d. per unit will be something like £20 per vehicle per annum. In considering the estimates put forward of the cost per mile for running such vehicles, it must be borne in mind that the mileage varies with the requirements of the users of the vehicles, many of whom I find by the nature of their business are unable to obtain the full possible mileage of the vehicles. At the present time we are charging 1d. per unit for energy supplied for this purpose, and there is an alternative tariff by which a small fixed charge, based upon tonnage, is made per vehicle, with an additional rate of 3d. per unit. This tariff was devised in order to meet the case of vehicles brought in for small boosting charges. In these cases the value of the charge to the consumer is considerable, whilst the amount of electrical energy taken may be so small that on the ordinary flat-rate basis it would not pay to receive and connect up the vehicle. The aspect of the electric vehicle business which appeals to me most strongly is that of "selling and general organization." At the present time four or five different types of vehicle are available on the English market, and so far as I can see these different types are for all practical purposes equally satisfactory, the difference between them being so small that one can recommend any type and be certain that the purchaser will obtain satisfactory results. The real diffi-

culty at the present moment consists in introducing a new article the first cost of which is high compared with competing vehicles, and the details and possibilities of which are but little known. I should like to emphasize that the one thing needed to give the electric vehicle industry the success which it deserves in this country is money. Without a considerably more active and costly business campaign than is being provided at present, I think it will be a very long time before the electric vehicle will make any great headway or bring into the central stations that large revenue which I am confident is to be obtained from this business. I think that at the present time there could not be a better speculation for persons interested in the electric vehicle or in the supply of electrical energy than to undertake ordinary haulage work by means of electric vehicles in the same way that it is done to-day by means of petrol and steam lorries. In any of the large centres a considerable business is carried on by contractors who convey goods of any kind by contract; and from information that I have collected there appears to be no doubt that where heavy goods have to be conveyed within limited distances this work could be done by electric vehicles at a much lower rate than is to-day charged for the use of steam and petrol tractors. I believe that the manufacturers of electric vehicles are alive to the possibilities of such business, and I can only conceive that the difficulty in securing funds is the sole reason which has so far prevented anything being done on these lines. I would commend the proposition to the attention of the more prosperous electricity supply companies. At the present time there is also considerable difficulty in getting delivery of vehicles, and the number available for demonstration purposes is very small. After carrying out a considerable amount of costly advertising and canvassing and securing a customer for an electric vehicle, it is very disappointing to find that he may have to wait several months for delivery, during which time he is continually exposed to the propositions of the makers of petrol vehicles who quote considerably lower prices; and he also sees around him the ever-increasing number of mechanically-propelled vehicles of other types, and is, I am afraid, very apt to wonder whether he has made a mistake and embarked upon an expensive experiment. Immediately, however, that the electric vehicle gets into action the position is changed and the case immediately strengthened for further sales. In the comparatively short experience that I have had with these vehicles I have found no cases of dissatisfaction of any kind. I need not here dwell upon the advantages of the electric vehicle, but would say that they are very rapidly appreciated by the purchasers, particularly if the latter have been accustomed to the various forms of petrol-driven vehicles. With regard to the possible magnitude of the vehicle business, I have come to the conclusion that if in West Ham we had for regular charging a fleet of some 1,200 vehicles of mixed sizes—by no means a large number for that district—they would take practically as much electrical energy as is at the present time supplied to the Corporation tramcars, and that without increasing the maximum demand on the generating station in the winter-time. With regard to the cost of electrical energy for charging, it is certainly desirable that this should be kept down, and I think that

Mr.
Beauchamp

such a price as 1½d. per unit—which I understand is quoted in some districts—is distinctly too high; but at any price between ¾d. and 1d. per unit I anticipate no difficulty whatever in getting this business. The cost for energy apparently accounts for only about 20 to 30 per cent of the total cost of running electric vehicles, so that the precise figure is of less importance than it is sometimes stated to be, and at the same time it must be borne in mind that if any considerable number of vehicles were charged regularly on the premises of an electricity supply undertaking there would be incidental costs with regard to receiving and dispatching, protection from weather, attention, etc., which would reduce to some extent the actual price obtained for the electrical energy.

Mr.
Mitchell

Mr. R. J. MITCHELL: I agree with the last speaker in his very appropriate reference to the industry, and particularly with regard to his views on the charge for energy. I have heard of a rate as high as 1½d. per unit, but am convinced that such a tariff would be a very serious mistake indeed; in fact, the ideal should be to make it 0.75d. rather than 1d. I should like to call attention to the fact that there is an idea in some quarters that the electric vehicle is a direct competitor of the petrol car. That view of the question is not really justified. The electric vehicle is more likely to compete with the thousands of horse vehicles which are at present blocking the streets—particularly in large cities like London—and rendering the competition of all mechanically-propelled vehicles practically abortive, in fact curtailing their usefulness to such an extent that I understand only about 15 ton-miles are being obtained per gallon instead of the 35 ton-miles that ought to be obtained. I feel also that there is very great need for a large amount of research in connection with the vehicle problem in general: I refer particularly to the very small amount of knowledge that seems to be available as to the cost of operation. The figures that are quoted, for instance, in connection with petrol vehicles, vary so much, depending upon whether they are quoted by manufacturers trying to sell or by users who have bought, that one cannot help feeling that such figures must certainly not have been calculated in a scientific manner. It seems to me that it would be a very valuable contribution indeed to our knowledge of transport if the University of London were to follow the lead of the Massachusetts Institute of Technology and start a Department of Vehicle Research, in which they would survey impartially the whole field and give us really reliable information covering the three principal methods of city transport. After all, the electric vehicle will mainly be applied, at any rate in the first case, on city highways, and for that reason it would add very much indeed to the confidence of prospective users if they were to have the opinion of a scientific body of men who had independently investigated the question, rather than the assertions of manufacturers and agents trying to sell the vehicles before they have really got a considerable number of them on the road. Referring to the research aspect of the question again, I should like to state how valuable I consider it would be to go on with the research with which I think Mr. Shrapnell-Smith was associated in the very early days of petrol cars; I refer to the accurate measurements of road resistance. I believe Mr. Shrapnell-Smith, with Dr. Hele-Shaw, started such an

investigation about 10 years ago. I also believe that this investigation did not eventually cover the field which it was originally hoped it would cover. Taking into account the very great improvements that have been effected in accelerometers during the past 10 years, and the fact that measurements of road resistance are now very simple indeed, it would seem that quite a small amount of work, in fact only a few thousand hours' work, would cover all the principal types of roads and districts in the United Kingdom. Another point is that the central-station engineer should not be expected at first to spend a great deal of money on providing facilities for charging, but that where it is possible to provide facilities by spending only quite a small sum he should provide those facilities, even though he had to wait several months for the arrival of the first car, because it would have such a very great moral stimulus for a man owning a car—for example, a pleasure car—to know that if he went to Guildford or Hindhead or some other place about 30 miles from London, he could be reasonably sure of obtaining a supply of energy to carry him back. Although the pleasure car is probably an offshoot, it is valuable to the industry on account of its advertising value; and it is perhaps also valuable in the hands of a few enthusiasts who like a car because it is an electric car, because it represents one step towards the ultimate all-electric touring car. That type of purchaser ought to be encouraged because his enthusiasm is a valuable asset. He talks about his electric car, he interests other people, and the result must in the long run be a definite advance in the movement. A small technical point to which reference should be made is the decision that earthing is not necessary in the case of the connections to charging plugs. It is possible for conditions to arise where the potential difference between the frame of the car and the earth can be as high as 230 volts or even more; and taking this into account and the fact that charging may sometimes be done in rather wet yards, I hope the Electric Vehicle Committee will reconsider their decision on that point and in fact alter it, for I am confident that a few years' experience, bearing in mind the type of man who will very frequently handle electric cars—unskilled labour being possible in consequence of their simplicity—will prove that accidents will otherwise occur.

Lieut. S. SLADE, R.N.: It is fairly well known that there has been an increasing number of electric vehicles in use by the London County Council Fire Brigade for the last four years. Members may be interested to hear some particulars of the vehicles that we have found so satisfactory. At the present time we are using lead batteries with 84 cells, with a capacity of about 200 ampere-hours at the 6-hour rate. The current is controlled by a series-parallel controller and led direct to motors in the wheels without the intervention of any gearing. The total weight of each vehicle is about 5½ tons when fully equipped with men, that is, about 5 or 6 cwt. heavier than a similar petrol vehicle. The contract speed on a level road is 25 miles per hour, and that has generally been exceeded. The contract speed on a gradient of 1 in 19 is 15 miles per hour. The circuit-breaker is set at 250 amperes, so that a considerable current may be used in breasting a hill. The results that we have had with these vehicles have been so satisfactory that we have in a measure adopted them

as a standard for life-saving appliances in localities where the gradients are moderate. The fact that they have been adopted for that purpose will show that we have considerable confidence in their reliability. Of course there are limitations to the use of electric vehicles even for fire brigade purposes. There is a limit in mileage and there is the question of uniformity, because it is rather difficult, if not impossible, to have a complete electrically-equipped station, the difficulty being that a prime-mover other than electricity is required for a pumping engine, at any rate for a power-pumping engine which may have to run at full speed for perhaps 12 hours or so. Where electric fire engines have been adopted—there are none in this country, but in Germany, Holland, and other places—there is a battery in front and a steam fire engine and pump on the back, or in some cases a petrol engine and a radiator on the back. That presents rather an odd appearance. As to the cost of maintenance, I am afraid that I cannot give any figures which would be of much use to commercial users of electric vehicles, and I fancy that it will perhaps be a shock to those engineers who think that electric vehicles can be run very cheaply, when I say they have cost us about 1s. per mile to maintain, that figure not including drivers' wages or first cost or depreciation. But perhaps their feelings will be changed when I tell them that for similar petrol vehicles the cost is 1s. 3d. per mile. When one takes into account the first cost and the depreciation, the cost of maintenance of an electric fire-escape van and of a petrol fire-escape van are practically the same, namely, about £150 a year, allowing for interest and depreciation. The annual cost of repairs for an electrical escape van that runs about 800 miles per annum is £40, that is, allowing for renewals of batteries and so forth. We have had no particular troubles with the lead battery, although we are just beginning now to get the renewals that we expected to do, having regard to the experience of German fire brigades where the vans are run for about 3,000 miles before the positive plates require to be renewed, and about 6,000 miles before the whole battery requires renewing. It might be thought that trouble would arise through sulphating, but we seem to have got over that difficulty by arranging to discharge the batteries down to about 19 volts per cell every 2 months, and then to fill them up and give them intermittent overcharges. No trouble has arisen in that connection, although of course the cells lie idle for some time, and they are always topped up directly they get back to the station after a run. In fact I should have said there is a proper set of charging apparatus in every station. As to the difficulty of getting current of suitable voltage, we require for our batteries only about 30 amperes, and a maximum voltage of 240 for finishing the charge, the pressure at the start being about 180; but very few supply undertakings in London let us have current at a pressure less than about 400 volts. Either we have to waste a great deal of energy in charging, or else a generator has to be installed, which is a considerable expense, although on the other hand I quite recognize that from a charging-station engineer's point of view there is very little in it, because the bill at most of the stations comes to only about £2 per quarter, so that it cannot be expected that they will put themselves about for us. Among the advantages of electric vehicles for fire brigade work, we find

that they require repairing less frequently, and that the rapidity of turn-out is absolutely unequalled by any other form of traction: it is not uncommon at an electric-motor fire station under ordinary service conditions for a turn-out to be effected in 7 or 8 seconds, whereas with other forms of motors a good turn-out is perhaps 15 seconds. That is a very great point with us, especially for the life-saving appliances. Another point is that the battery, being at the very top of its potential when there is a call, starts in the very best trim, and the maximum speed is at once attained, whereas with other forms of traction, namely steam and petrol, a little time has to elapse before things become quite normal. As most of our runs for life-saving purposes are for distances of only about half a mile, the advantages certainly lie with electricity. Another very important point is the provision of electric braking as an addition or auxiliary to the ordinary mechanical brakes. When we are exceeding the speed limit we find that a rather useful facility. In conclusion, I should like to say that after four years' experience I agree with Mr. Ayton as to the advantages of the electric over other power-driven vehicles in regard to its simplicity of construction, its low cost of maintenance, its ease of driving, and its general reliability; but I can offer no opinion as to the commercial efficiency of electric as compared with petrol and steam vehicles.

Mr. P. A. MOSSAY: As the agent of an electric vehicle manufacturer and one who has been personally concerned with the design of a particular class of vehicle, I propose to discuss some of the problems connected with the use of electric vehicles and of interest both to the consumer and the manufacturer. With regard to efficiency, the greatest claim of the electric vehicle, and one which is readily admitted by everybody, is its high efficiency, *i.e.* the relatively small amount of power required for propulsion per ton-mile at a given speed. This has been attributed to the simplicity of the electric chassis, which contains a minimum amount of moving parts, and to the high efficiency of the electric motor. This, however, is only one of the factors, as road resistance, tyres, etc., have sometimes a much larger influence than the resistance of the vehicle itself, especially if the vehicle is moving at a low speed so that wind resistance is of little importance. To take an example, let us consider tyres. I had an opportunity some years ago, whilst developing a particular type of vehicle, to test various makes of tyres; and I here propose to refer to three typical ones. The vehicle was a small delivery van weighing 1 ton 8 cwt. In the first test solid tyres, 800 x 75 mm., were used; in the second test the tyres were 606 x 90 mm.; and in the third test 705 x 105 mm. The power consumption at a speed of 14.4 miles per hour was 186, 212, and 260 watts respectively. The tests were made on good paved roads. The conclusions to be drawn from these tests are obvious; in the first case the theoretical mileage which the car would run with a 132 ampere-hour battery would be 54 miles; in the second case 47 miles; and in the third case 38½ miles. The facility with which it is possible to state in concrete figures the performance of an electric vehicle is an element of its reliability, and affords a means of keeping the vehicle in a constant state of high efficiency. The performance of the battery is influenced by the current that is taken by the vehicle, and in connection

Lieutenant
Sladen.

Mr. Mossay.

Mr. Mossay: with lead cells—with which I have had more experience than with alkaline cells—I may say that the maintenance will thus be influenced by the performance of the vehicle. It is a case therefore where the battery manufacturer should work hand in hand with the vehicle manufacturer and adjust maintenance rates to the performance of the vehicle. If we take the two extreme cases just given, where the same vehicle shows a theoretical mileage of either 54 or 38½ miles, it seems to me that a flat maintenance rate per car-mile would penalize the higher efficiency. Electric vehicles are very economical in tyres. In one of the large taxicab undertakings in Germany, which operates 115 Lloyd electric cabs and over 30 petrol cabs of various makes, the records of 5 years' experience show that tyres last 83 per cent longer on electric cabs than on petrol cabs. This, on bad or indifferent roads, points to even better results in this country. To sum up, I wish to say that wherever conditions are suitable and electric vehicles have been given a fair chance, they have come to stay. The Hamburg Taxicab Company started in 1907 with 25 electric vehicles, and has steadily increased the number to 115. The General Post Office in Berlin, which bought 2 Lloyd cars in 1906, has now over 100 electric vehicles and is contemplating further additions. The General Post Office in Copenhagen is now operating 13 vehicles; Leipzig 26, the Taxicab Company in Amsterdam 44, and the Municipality of Altona 23 vehicles. [Mr. Mossay showed a series of slides illustrating the types of vehicles referred to in his remarks.]

Dr. Porter: Dr. C. PORTER: I feel sure that it will be to the advantage of public health to have electric vehicles on our streets. I remember on one occasion hearing the late President of the Local Government Board, Mr. John Burns, state in an address on infantile mortality that there was no doubt that the lives of many children had been saved by the transformation of stables and mews into garages. I absolutely agree with that statement; but I think that against the advantages of getting rid of the horse have to be placed two disadvantages of the petrol-driven motor, namely, the contamination of the air which it produces and the noise which it causes. I feel very strongly that noise, more particularly noise in the night, seriously interferes with health. Even if one is not awakened, I am quite sure that one's nervous system, the brain especially, is injured by being over-stimulated, with the result that it is not properly rested. The noise produced by motor cars is particularly irritating and shattering to the nervous system. I remember some years ago, when I was engaged in school medical work, picking out in a school several little girls—whose parents were in quite good positions—who looked very tired and fagged, and who, I was informed, were not taking advantage of the education provided for them. On making inquiries I found that these children resided in a street along which trams passed; they did not sleep well, their sleep being disturbed by the noise of the cars, and each morning they came to school dull and unrested and unable to concentrate their attention on their work. The case of these girls, and others that I have since met, impressed me very greatly and helped to strengthen the opinion that night noises are objectionable and distinctly detrimental to health. The other objection to the motor, namely, the contamination of the air, is one which it

shares with the horse. The contamination is not exactly of the same type, but there is certainly contamination of the air just as objectionable from vehicles driven by means other than electrical as from the horse. Anybody who on a warm summer's day walks from the Marble Arch towards the City will have no difficulty in finding evidences of contamination of the air from motor-driven vehicles. He will find that his nose, throat, and eyes are assaulted by something given off by the motor cars, and all these irritations of the mucous membrane give rise to considerable discomfort in the shape of headache, smarting eyes, and sore throat. Anything which gives rise to discomfort interferes with health, and all of these are discomforts, if nothing worse. People who have to work hard—and we all have to work hard nowadays, and to work at a great pace—must have comfort; and interference with comfort in any way, even by petrol-driven cars, is to be avoided. If they can get rid of the contamination of the air, and if it is possible to get rid of some of the traffic noises by introducing electrically-driven vehicles, electrical engineers will do a great deal for the public health, and I, at any rate, will support them as a public health man.

Mr. C. BARBER: I have been rather impressed by the hesitancy of borough electrical engineers to look upon electric battery-driven vehicles seriously, and they do not seem to realize that the present-day electric vehicle is a really practical mechanical job. The present-day battery is quite different from those of past years, and there are many makes which are quite satisfactory. The great point to be borne in mind is the relative working cost of electric battery vehicles compared with that of petrol or steam-driven vehicles for similar work. Naturally, in this country very little experience of working costs has been obtained up to the present time, but a great deal has been learnt from Continental and American experience. As far as it is possible to estimate the conditions in this country, I think it will be found that battery-driven vehicles for short-distance work, say 20, 30, or 40 miles per day, compare very favourably indeed with, and work at 20 per cent less cost than, petrol-driven vehicles for the same class of work. I do not doubt that the cost of repairs would be much less in the case of electric vehicles than for steam and petrol-driven vehicles. The adoption of battery-driven vehicles in this country will, I think, be found to rest almost entirely upon the question of working costs. Of course the facility for charging and similar questions are also wrapped up with it. To start with, there is a large field for the use of battery vehicles for corporation and municipal purposes, and if borough electrical engineers could only be induced to put forward the benefits that would be derived by their own department and by the borough from the use of electric vehicles, I think a great step forward would have been taken.

Mr. A. B. PESCATORE: Mr. Aytoun at the end of his opening remarks said that we have got to educate the public. I think we have something more to do than that. We have to satisfy the public that the electric vehicle can be run, at any rate for commercial purposes, more cheaply than a petrol vehicle. Mr. Mossay has omitted an important point about the electric chassis, namely, that its life can be assumed at about double that of a petrol chassis doing the same work. Taking the petrol chassis

as having a useful life under hard working conditions of about 5 years, the electric vehicle certainly has a useful life of 10 years. That being so, to satisfy the public that the total costs will remain within certain limits, which I believe will be 20 or 25 per cent below the cost of similar petrol vehicles, battery makers at any rate will have to guarantee to the users that their costs per mile run for those 10 years will not exceed a certain sum, and they will have to see that such a figure can be obtained. At present the cost of maintenance, taking only the renewal of materials and not the labour for repairs or the handling and charging of the batteries, will vary between 1d. per mile for a 3- or 4-wheel vehicle weighing 5 cwt. to perhaps 2½d. for a 5-ton van, these weights being the useful load in both cases. If instead of merely supplying materials one provides the labour for repairs, superintending the charging of the cells, and in fact attends to everything in connection with the battery except its removal to and from the car, the cost will be for the same two vehicles about 1½d. and 3½d. respectively. Those figures have been obtained on a number of vehicles, perhaps 60 in this country and probably 10 times that number on the Continent, some of which have been working for something like 7 or 8 years. In this country, for instance, a fleet of 15 omnibuses has been working at Brighton for 6 years. Each omnibus weighs nearly the same as a 5-ton van, and they are working under unfavourable conditions, the roads being bad and the gradients in some parts very severe. There the cost has remained below 3d., including all the supervision during charging and the handling of the batteries, but not their removal to and from the vehicles or the supply of current. As regards the energy consumption, the figures that have been obtained vary between 110 and 140 watt-hours per ton-mile. For a vehicle of 2 to 2½ tons useful load and a total weight of 5 tons, the figure will be about 600 watt-hours. For a larger vehicle it will be less in proportion to the weight; for a smaller vehicle a little more. The consumption of energy for charging will then be one-third more, and the efficiency of the battery in practice will be the same, namely, 75 per cent, a figure which applies to all makes of lead batteries. In addition to those omnibuses there are a number of other vehicles, such as fire-engines, where the cost per mile would have no meaning, as the mileage is so very small; but for vans for the carriage of goods and for any vehicles like omnibuses which would run 30 miles or more each day, those are the present figures. They are obtained with batteries which are exactly similar to the batteries that were first used in the same omnibuses before these were transferred to Brighton. Some of them at any rate were used for about two years by the now defunct Electrobuss Company in London, and it was not owing either to the batteries or to mechanical or electrical causes that this Company came to grief; it was entirely financial troubles that killed it.

Mr. M. E. Fox: One of the popular ideas concerning the battery vehicle is its apparently limited radius of action. When we are told by the manufacturer that his vehicle is capable of running 50 miles per charge, we are too apt without a thoughtful analysis of the conditions of normal delivery service, to assume that its free use is thus handicapped. Actually, it is seldom that a greater distance than

50 miles is covered during the hours of the usual working day, owing to the fact that time is lost in loading, unloading, and making house-to-house deliveries. For instance, one London firm which has been using a commercial van of this type during the past year finds that it runs on an average 32 miles per day. In those cases where the delivery limits approximate too closely to the total mileage of which a vehicle is capable, it must be borne in mind that an hour's charge at a high rate, while the driver is taking his midday meal, increases the possible mileage by 30 per cent. Furthermore, there would be no great difficulty in designing a commercial chassis capable of propelling itself 100 miles per battery charge, as there is usually considerable spare space on the ordinary chassis that might be utilized in adding a larger battery; but such a vehicle would find only a small market, in comparison with the present type. The latter has of course been designed with the proportions best suited to ordinary running conditions. One of the items contributing to the low cost of maintenance of this type of haulage is that the driver's attention is quickly called to the fact that adjustments are necessary, and he can attend to them before they become serious. Thus, any increase in the current is at once apparent, so that a hot bearing, a rubbing brake-shoe, etc., may at once be investigated. In the case of the petrol vehicle faults are not so easily detected, no direct-reading instrument being provided to show the consumption of power, and the engine taking up its increased load uses an increased amount of fuel until the breakdown occurs. It therefore requires the constant attention of a careful mechanic to keep the petrol vehicle at its highest efficiency, while, due to the simplicity of the warning given, the neglect of the driver of an electric vehicle to note the condition of his car would be unpardonable. The gain, then, is twofold, for being easily kept at its highest pitch of efficiency, less energy is required for the operation of the electric vehicle, and serious breakdowns, with their resultant interference with normal delivery service, are avoided. By using any of the various types of recording devices now on the market, accurate running costs can easily be ascertained, with the result that the owner is encouraged to analyse the methods of delivery and observe where economies might be effected. How different, however, is the condition of affairs in the case of the usual horse-owner. He is in most cases blissfully ignorant of just what it costs him per ton-mile to move his goods, and when questioned on this point will usually name a figure considerably below the actual cost, merely because he has not the facilities for obtaining accurate data concerning his horse-haulage. He feeds the horse; it carries his goods; and there the matter ends. In attempting to electrify the public's system of transportation, therefore, the advocate of electric vehicles does not find his path easy. It is at this point that the central-station engineer has an opportunity of aiding the cause by assuring his power consumers that the electric vehicle is an admirable vehicle and that he has at a tempting price and in unlimited quantities the energy required to propel such a vehicle. Electric traction in its most economical form can best be realized when the size of the vehicle is correctly proportioned to the work usually required of it. To use a 2-ton van for carrying a 3-ton load habitually would tend to increase the cost of

maintenance considerably, because the best vehicle manufacturers design the motors, frames, and tyres for the rated load, and so look with concern on the user's attempt to gain economy in this manner. It is for this reason, broadly speaking, that the use of trailers with electric vehicles is not encouraged. In the popularizing of the electric vehicle, the manufacturer of electrical apparatus, other than storage batteries, should not lose sight of the fact that he is interested in the outcome. Usually each purchaser of a van is a prospective buyer of at least a motor-generator, switchboard, and accessories. Manufacturers, therefore, should be among the first to regard favourably the adoption of electric transportation. It is strange to find that most electrical engineers are poorly informed upon the possibilities of the battery vehicle. In justification of this it might be advanced that electric propulsion has never been utilized on a large scale in this country. Although it has been used for slightly over a decade in America, the subject has taken such a firm hold of the public that it is now seriously proposed to make a course in electric vehicle practice a part of the curriculum of the principal technical schools, to ensure that the coming engineer starts his career with at least no erroneous ideas concerning this form of transportation. This subject can certainly be brought to the attention of the layman most appropriately through the electrical profession, and as the furtherance of this movement can bring only benefits to the profession, we can at least give it our encouragement and protection.

Mr. H. BRAZIL: Through the courtesy of Mr. Turton of the Tudor Accumulator Company, I had the pleasure yesterday afternoon of driving what I am informed is the largest commercial electrical vehicle either in this country or on the Continent, and it may be of interest if I give some particulars of its capacity and equipment. The weight empty with a 250-ampere-hour battery is $4\frac{1}{2}$ tons, and it will carry a load of 5 tons, making a total weight of $9\frac{1}{2}$ tons. The maximum speed on the level when loaded is $9\frac{1}{2}$ miles per hour. The consumption is about 1 unit per mile loaded; that is, allowing for the 75 per cent which Mr. Pescatore gave as the efficiency of the battery, about 1.3 units are used per mile in this lorry with its full load of 5 tons. The standard battery consists of 80 cells, divided into 2 units of 40 cells each, with a capacity of 250 ampere-hours, and with that battery a range of 35 miles on the level is obtainable with full load. A larger battery, such as that on the vehicle which I drove, has a capacity of 300 ampere-hours and gives a range of 45 miles with one charge. The driving is very easy; I had never driven an electric vehicle myself before, but found no difficulty in driving this one. The only point to notice is that being 20 ft. long it is necessary to be very careful when going round corners, especially with such a heavy weight as $9\frac{1}{2}$ tons. One other point in connection with the lorry is rather interesting, namely, the method of control. This may be familiar to many members, but was new to me, and I think it brings out a very important point in connection with electric vehicles, that is to say, the reduction of the maximum current taken from the battery, thus making the battery load factor as high as possible. That is done in this vehicle by not only putting the two motors in series, but also arranging the two halves of the battery in parallel. On the first notch the batteries are connected

in parallel and the motors in series, with a resistance in circuit. On the second notch the motors are still connected in series and the batteries are still in parallel, but the resistance is cut out. On the third notch the batteries are in series, the motors still being left in series and the resistance cut out. On the fourth notch the motors are connected in parallel, but the field coils are left in series, so that a lower speed is obtained owing to the whole of the current having to go through each field coil although it is divided between the two armatures. Finally, at the highest speed, $9\frac{1}{2}$ miles per hour, the two batteries are in series, the two motors in parallel, and the field coils also in parallel. Passing beyond the zero point one gets on to the electric brake, which is the ordinary arrangement where the whole resistance is first in series with the motors, then half of it, and thirdly the whole of the resistance is cut out. That gives a very good braking effect; in fact, in the case of a novice it is rather dangerous, because if the lever is pulled right over, one is apt to be thrown off the front of the car, since the latter pulls up within half its own length. The point that I particularly wish to impress on the meeting is the advantage of keeping the load factor on the battery as high as possible. This is important, not only because of the buckling of the plates caused by heavy discharges, but also because it very largely affects the total number of miles that one can go with a single charge. I think that it is not generally appreciated to what extent the capacity of a storage battery, of the lead type at any rate, is affected by the discharge rate. To enable me to illustrate my remarks I would emphasize two figures. We can obtain from a lead storage battery, when it is discharged at the 10-hour rate, twice the capacity that is available when the whole discharge takes place in one hour. That is a very considerable difference and one which, if the discharge rates are heavy, will materially reduce the distance that the vehicle can travel. This brings up the very real difficulty in connection with electric vehicles of determining at any moment to what extent the battery has been discharged. How are we to know how much of the charge is left? It may be said that if we know how much has been discharged then we know how much is left; but that is quite wrong, owing to the fact that the capacity varies so enormously with the discharge rate. We do not therefore want to know so much what is taken out of the battery, as how much is left in and available for work. The difficulty in the past has been to get an instrument that will give us this information with reasonable accuracy, the ordinary ampere-hour meter being useless as it does not take into consideration the variation of capacity with discharge rate. I thought therefore it would be of interest if I were to describe a meter which Mr. F. Lydall and I devised some time ago, and which I think solves this particular difficulty. A meter is required which not only takes into consideration the number of ampere-hours which are passing through it, but also the rate at which those ampere-hours are being discharged. I venture to suggest that the meter I am about to describe fulfils this requirement. As will be seen from Fig. 1, there are two discs, the top one of aluminium and the bottom one of celluloid, mounted on one common spindle, each having a winding, these windings being connected in series and taken to one commutator. The top

Mr. Brazil.

Mr. Brazil.

disc is embraced by the ordinary permanent magnets, and the disc being of aluminium, this provides the braking power necessary. The bottom celluloid disc is embraced by two electromagnets, excited by the main current coming from the battery or by a current proportional thereto. In an ordinary instrument of this type the speed of the disc is proportional to the current in the main circuit, but as there is no braking on the bottom disc it will be seen that the speed of rotation of this meter is not proportional to the current as in the ordinary instrument, but to the current multiplied by a factor, this factor increasing as the current increases. The meter is provided with one large dial divided up into 100 divisions, and the pointer works backwards through 90, 80, etc., to zero; when the zero point is reached it indicates that the battery is empty. The windings and mechanism are so proportioned that when the battery is completely discharged the pointer will move

discharge, the pointer comes very nearly to zero when the battery is empty, that is to say, when the curve crosses the zero line. The question might be raised as to whether the meter would indicate correctly with a varying rate of

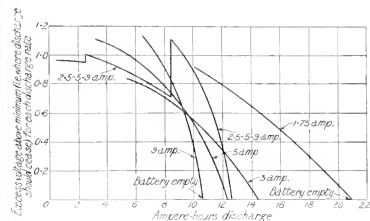

FIG. 2.

discharge, and in order to demonstrate this I took a curve which is shown in Fig. 3. In this case the first part of the discharge was at 2.5 amperes, the second part at 5 amperes, and the third part at 9 amperes, and yet the curve crosses

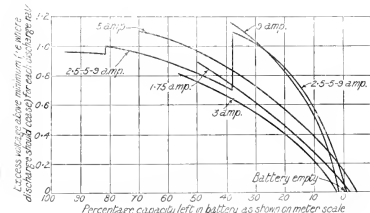

FIG. 3.

the axis at practically the same point as the other curves. It must be clearly understood that, for this meter to register correctly, at the commencement of the discharge the battery must be fully charged and the pointer at 100. An automatic device for setting the pointer at 100 when the battery is fully charged has been introduced in the design.

Mr. A. J. MAKOWER: With reference to Mr. Mitchell's suggestion that the London University might assist in carrying out some tests on electric vehicles, I am Secretary of the Board of Studies of Electrical Engineering and I am sure that there are a number of people on the electrical side of the University who would be only too pleased to carry out any tests that are required. The electric vehicle enables problems to be investigated which cannot be undertaken by any other means, because of the possibility of avoiding the very complicated measurements that are necessary in other cases. The following figures will be of interest in that connection:—

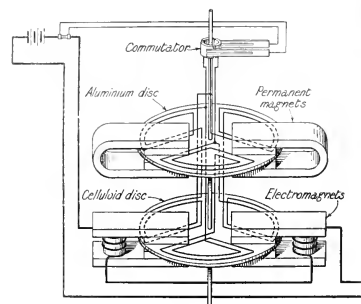

FIG. 1.

from 100 to 0 whatever the discharge rate, and in spite of the fact that the number of ampere-hours may be twice as great in one case as in another. The meter, of course, does not register ampere-hours, but only gives an indication at any moment of the proportion of the total capacity of the battery that is still available for use.

Tests were taken with this meter in circuit with a small Tudor accumulator, and the results are embodied in the curves shown in Figs. 2 and 3. The voltage at which the discharge must cease in order to prevent injury to the battery varies with the discharge rate, being 1.7 volts for the one-hour rate, and 1.83 volts for the 10-hour rate. The values of the ordinates in the two curves are obtained by subtracting this minimum in each case from the actual voltage observed, so that when the curve crosses the zero line the battery is discharged. In Fig. 2 the abscissae are ampere-hours, and it will be seen that with a discharge current of 9 amperes, i.e. just below the one-hour rate, the battery is empty after giving out 10.5 ampere-hours, whereas when the discharge takes over to hours (1.75 amperes) the number of ampere-hours is 21. In Fig. 3 the abscissae are the divisions on the dial of the instrument and it will be at once noticed that whatever the rate of

TABLE I.

	Total Weight Tons	Useful Weight, Tons	Speed Miles per Hour	Watts	Watt-hours per Car-mile	Watt-hours per Ton-mile
5-cwt. lorry ...	1.43	0.25	15	2,850	190	133
Taxi-cab ...	2.1	0.25	16.5	4,245	257	122
1½-ton lorry...	3.6	1.5	12	3,460	288	80
2½-ton lorry...	4.9	2.3	12	4,250	354	72.4
Fire-engine ...	60	—	15	4,830	322	53.6

The figures are not for any particular car, but are averaged over a number of vehicles, some of the vehicles being cabs and some fire-engines. They show how the number of watt-hours per car-mile and per ton-mile depend on the weight carried.

TABLE II.

Battery upkeep	0.90d. per car-mile

		7.00d. "

Table II shows some figures relating to an electric cab company that has been running its vehicles for about six years in Germany. At present 100 cabs are running, and evidence of their reliability is the fact that the cabs average 350 days' work in the year, the average figure for cabs out of service not exceeding 4 per cent. The battery figure is considerably lower than the one that Mr. Pescatore mentioned. The batteries are not run under the manufacturer's guarantee, and they can be run more cheaply by users who employ a staff of sufficient experience to carry out their own battery repairs. The cost of the energy is about 1.1d. per unit. The figure for the tyres, 1.87d., is higher than it would be at the present time, because the figures relate to two years ago when the price of tyres was higher than it now is. The figures for drivers' wages may appear to be very high, but it must be borne in mind that these cabs are running a day and night service, and the figure of 1.56d. per mile includes the wages of two drivers. The total cost—about 7d. per mile—is a good result. I think that the figure for the energy consumed points a moral for the central-station engineer: 0.90d. per mile may not look very much, but on the present basis of 31,000 miles per cab per year it means that about 2½ million units are sold to this company per annum, representing £11,500. On the basis of a 24-hour charge—these batteries are being charged day and night, and there are more batteries than vehicles—that is equivalent to a steady load of 300 kw. When this cab company started with a few cabs, the electrical engineer of the town might

not have considered it a very important undertaking, but when he has to supply energy to the amount of £11,500 per annum to one consumer, and for the best kind of load that it is possible to get, he would probably be willing to reduce the price, but by that time the consumer will have found it to be advantageous to erect his own generating station. This goes to show that central-station engineers should be more accommodating in the initial stages of the introduction of electric vehicles than they are in many cases at present. Some are taking this matter up very heartily, but I have met others who treat those who are proposing to use electricity for charging electric vehicles as though they were only installing a few lamps.

Mr. W. A. A. BURGESS: In the first place I should like to suggest that batteries for vehicles should be assembled in a removable truck on rollers running on suitable rails on the underframe, so that the complete truck can at once be withdrawn on to a charging wharf and if required a new fully charged one substituted. If these trucks are standardized for various duties, and maximum and minimum weights of trucks complete with batteries per h.p.-hour are published, the vehicle makers will then be in a position to provide standard chassis to take batteries by any maker. With the use of removable trucks there would be no need to rank the vehicles up for charging, and the batteries could be grouped much more effectively for charging and overhauling and could thus receive the full attention required to keep them up to maximum efficiency. The vehicles with batteries removed would be manoeuvred in the yard by plug connections through flexibles for cleaning and general overhauling. It would still be possible when necessary to boost the batteries during fairly long halts. Given closer co-operation between battery manufacturers and supply authorities, it might be found advantageous in London and other towns to hire out, against a deposit, batteries fully charged, the charging and maintenance being always in the hands of the joint authority. By the provision of a slightly larger number of spare batteries the charging could be controlled by the supply authorities to suit the load factor of the system, and for this reason I suggest that a vehicle voltage should be chosen approximately half that of the average continuous-current supply voltage, where it is possible to average this, and twin cells used so that they could be charged in series and discharged in parallel, with a considerable saving in resistance losses. A system such as this could easily be arranged so that the batch of batteries in reserve could form some sort of stand-by to the local lighting network in the case of the smaller undertakings and localized distribution systems. With regard to the control of battery vehicles, a considerable saving of energy could probably be effected by the use of tapings off the battery in the place of resistances, a suitable change-over switch or switches being provided to enable the starting current to be taken from any required group of cells and interlocked with the controller so that the act of cutting off current ensures that a different group of cells shall be used to provide the starting current next time, thus discharging the whole of the battery equally. The suspension of the motor is an important matter to which attention should be given, because on it depends the total unsprung weight that is taken on the axles, which very largely affects the upkeep of tyres. I should like to see figures published by the

battery makers for the approximate maximum and minimum cost of batteries per h.p.-hour, as this seems a more workable figure for those whose knowledge of electric vehicles is necessarily entirely non-technical.

Mr. W. E. BURNARD: In the first place I regret that I cannot disagree with those speakers who said that the electric vehicle is not a competitor of the petrol vehicle. I would say, however, that the petrol vehicle cannot compare, and is not a competitor for certain services, with the electric vehicle, also that with improved design and greater knowledge the first statement will not long hold good. In my own case I require deliveries at infrequent and very irregular intervals, and I have both petrol and electric cars available, but it is the electric car that is always taken out to do the work. The determining factor is not the third decimal place in the cost of running the cars, but that the electric vehicle can be driven by anybody, whilst the petrol car cannot. Any man that happens to be available in the shop can go out with the electric vehicle, and he gets the work done in about the same time that it takes to find a man who can drive the petrol car. Apart from the variation of the capacity with the rate of discharge, the mileage obtained by different drivers varies greatly, especially where there is much traffic, as one man will keep using the brake to slow down, and taking it off again to speed up, without moving the controller handle, whilst another man practically never uses the brake but varies the speed merely by working the controller properly and coasting as much as possible. The variation possible in this respect is as much as 50 per cent. For short runs, however, this is not very serious, as the increased cost of the energy used in a run is seldom more than 1d., whilst the time saved and the driver's time is probably worth about 2s. For hilly districts it seems to me important that the change of speed on different gradients should be greater than that obtained with a simple series motor; also that this variation should be out of the control of the driver, as an excessively high rate of discharge greatly shortens the life of the battery in addition to decreasing its efficiency. It seems to me that the question of mileage is merely a matter of decreasing the friction and resistance losses, since it is obvious that in a round trip no energy is actually used apart from these items, and it is the possibility of keeping these losses exceedingly low that renders the electric vehicle a serious potential competitor of the petrol vehicle. Mileage seems to me to be merely a question of design, and it is by no means impossible to double or more than double the present range. Rapid deterioration of the batteries is mainly a question of the better education of the users. There is one other point that I want to mention, namely, regeneration. It has been tried with usually very indifferent results, but I am quite certain it can be made practical, and of great use for hilly districts—for level districts it does not promise much gain. I made an experiment last night on a short run, two miles out and two miles back. The first mile was on a very slight incline, and the second mile on a fairly steep incline. Going out we used 109 units, and on the return journey 0.122 unit, that is, not much more than 1/10th of the amount used on the outward journey. The weight of the vehicle and the load would be about 38 cwt. On making the same journey later on, first charging the battery up to the same condition as before, we used the

same amount of energy on the outward journey, but Mr. Burnard, returning down the hill we regenerated about 0.336 unit, or over the whole journey something like 30 per cent. That is quite worth having, not only on account of the 30 per cent saving, but because it keeps the battery in a better condition. There is, as a previous speaker said, a large reduction in the capacity of a battery on a heavy discharge. I have not seen a definite explanation of that fact, but it seems to me that what happens is that the surface layers get exhausted, and as the electrolyte cannot circulate readily in the pores of the plate there is a certain amount of local action between the charged part and the discharged surface. The result of regeneration is to charge the surface up again, and to save a very considerable loss in addition to the amount regenerated. One unit regenerated is worth about 1½ units at the garage. If the approximately level part of the road were neglected and a test were taken on the steep hill mentioned above, the amount of energy regenerated would represent no less than 45 per cent.

Mr. E. S. SHRAPNELL-SMITH: I was associated for many years with the progress of the steam road vehicle, and then with the petrol vehicle, and it seems to me that the electric vehicle will very probably in the next few years go through some of the early stages of—I will not say trouble, but perhaps I might say lack of commercial appreciation through which the steam and the petrol vehicles successively passed in this country. I entirely endorse the remark that the electric vehicle will mark out its own place, perhaps not for its exclusive use but where it will predominate. It seems to me that those who are seeking to popularize the electric vehicle will have their best field of action primarily in cities. I was much impressed by the reference to the noise of taxi-cabs. One point, which I think is not fully appreciated, about the petrol vehicle is that the silence which has been developed with the help of the police and the designers of the motor omnibus in London is chiefly silence on the top gear. I have suffered, in common with everybody who lives in London who has a certain amount of mental work to do, from the difficulty of sleeping, not only while the taxicab driver's fare looks for his money, but much more so while the man is jerking his change-speed from the bottom gear upwards and reversing, generally with his tyres cutting a hole in the road. One of the great claims of the electric vehicle, to speak of the matter seriously, is that the electric vehicle is silent in all "gears," at all times, and at all speeds, whereas the petrol vehicle, however quiet it may be on the top gear, is not so quiet when it comes to work on some of the lower gears. With regard to the question of current, I think the point to be remembered is not a question of detail, such as the differences in consumption between different kinds of tyres on the same road, mentioned by Mr. Mossay, but that if one goes into the country and runs on various surfaces, including water-bound and sometimes water-logged macadam, the increase in consumption is often not 10 or 15 per cent but nearer 100 per cent. When one comes to country services that is one of the factors that will upset to a great extent the estimated mileage as determined by the amount of energy in the battery, and that will bring one back again to the superior claims of such a vehicle for short mileages in town work as a starting-off point—where in my opinion it will be welcome. I was much impressed

by the reference to the fact that money is wanted. I have often heard that expression used, and have used it myself: "The paralyzing want of money" was a remark that fell recently from the lips of Sir George Gibb in connection with roads. There is not the slightest doubt that the steam and petrol vehicle industries established themselves in this country only by an accumulated charge during the first two or three years on what is termed the "suspense account," which sometimes has to be written off altogether. I think probably the problem is simpler for the electric vehicle industry; but I think it is rather too optimistic for the supply companies or the manufacturers to think that they will make money from the start. They will have to be prepared like the petrol industry and the steam industry had to be to fight against very considerable odds, whatever encouragement they may get for the first few years. There is only one other point. Costs are probably the most elusive factor in the whole of this problem; yet in the sale of commercial vehicles nobody can deny that the working cost is the factor to which every other consideration is subsidiary. It is only by producing convincing figures as to working cost and showing to the satisfaction of the man who wants to buy a vehicle, and who is not influenced by the quietness or the beauty of the suspension so much as by the reduction of id. per mile in the running costs, that it will save him money—it is only by bringing that fact home that the electric vehicle industry of this country will secure a large share of the road transport business. The difficulty that I am in is this. I have never yet, however much I have tried, through correspondence with various American people and in the pages of the many American journals which I see every week, been convinced as to what the cost of electric vehicle operation really is. I am sure that there must be many people in this country who are preserving a perfectly open mind, and they are merely waiting to be convinced by Mr. Ayton and others interested in this matter.

Mr. P. P. WHEELWRIGHT (*communicated*): In the early part of last year the Blackburn Electricity Committee decided that a motor car was necessary to keep up the efficient working of the department. Prices for petrol cars were at once obtained, and a guaranteed number of miles per gallon of spirit for each vehicle was asked for. On looking into these I was very much surprised to find that very few makers would give any figures, in fact it seemed to be considered an altogether unnecessary query. Personally, I think that the question of the cost per mile ought to be the main one when purchasing a car, especially in these days of high-priced fuel. Therefore, as an alternative, the purchase of an electric vehicle was considered. I obtained particulars and went into the matter fully, and found that although the capital cost would be high, the cost per mile, which was obtainable from most makers or agents, would be very much lower than any figure given by a user of a petrol car. After the question of low running costs, the following were the points that helped my Committee to decide upon the purchase of a battery car:—
(a) Driving is practically a matter of steering alone, consequently no specially trained attendant is required, and no work in starting the engine, etc., is necessary; therefore no time is lost in getting the car away. When driven in congested traffic, where rapid acceleration is of great value, the car can be controlled with ease and precision.

(b) The simplicity and reliability of the motors and the control arrangements, and consequently the low maintenance and repair costs. (c) The running of the car is perfectly smooth and silent, resulting in a longer life of the tyres. (d) The cost of housing the car is low, as no special provision for the storage of petrol and inflammable materials is necessary. (e) No emission of smoke or smell or vibration when the car is running or standing. (f) For an Electricity Department the car is the best advertisement possible, as its use keeps in view of the public the variety of purposes to which electricity can be applied. The insurance premium covering all risks that was paid last year by the Blackburn Corporation on their electric car was very high; and at the time I was not able to obtain any reduction, but I am glad to hear that as a result of the good work of the Electric Vehicle Committee there is every probability that the insurance premiums on this class of vehicle are to be reduced in future. This is very necessary, as the premiums, which are based on the schedules for an ordinary petrol car, are unfair when applied to a battery car, as the risks cannot be compared. The argument which I find is most frequently brought against this class of car is the comparatively short distance that it can be taken without recharging. This is most certainly a serious disadvantage, but I think there is every reason to hope that in the near future this difficulty will be overcome, and one must acknowledge the undoubted truth that at the present time there is a very large field for this class of vehicle for town use and local work, i.e. within 40 to 50 miles' radius. As far as the large capital outlay is concerned, in the purchase of these electric cars I think that an electricity department can very rightly allocate a proportion of the cost to the general advertisement and publicity account that all progressive undertakings find a necessity. The value of this class of car for breakdowns is without question, as it can be on the road and away in a few seconds after notification has been received, and should the trouble be in an underground manhole or sub-station, where light is required, portable lamps with long lengths of flexible can be plugged on to the battery, and neither wind, rain, nor carelessness can delay the work of repair. On looking up the figures as to the consumption of energy during the last nine months, I find that the average is 3 miles per unit, which in such a hilly town as Blackburn I consider a most satisfactory figure, and one that in many towns could easily be improved upon. To advance the adoption of electric cars by the public should be the aim of every electricity department and electricity supply company. To do this they must set an example themselves by employing these vehicles for the variety of uses to which they can be applied. The experience thus gained will be of value when considering the question of charging for this class of demand, and when specifying what will be necessary in the charging stations, which undoubtedly will be required in various parts of our towns. Another point is that the manufacturers should aid the electricity department and supply company as much as possible by giving demonstrations of the practical applications of the electric battery vehicle. In conclusion, my own experience of the use of an electric car has been highly satisfactory in every way, and financially there is no doubt that no other form of propulsion can at present compare with it. I trust that steps

Mr. Wheelwright.

will be taken to enlighten and educate the public to the fact that the electrically-propelled vehicle is a sound financial investment which has come to stay.

Mr. E. N. RUDDOCK (*communicated*): In discussing the pros and cons of electric battery vehicles the question seems to resolve itself into two distinct parts, namely, the chassis, and the battery. With regard to the first, in these days of high efficiency motors and gearing, and ball and roller bearings, the very long life of all the component parts of the chassis due to the absence of vibration and reciprocating effects, also the extreme ease of manipulation and simplicity of control, make the electric chassis for many purposes much more satisfactory than either the steam or petrol chassis, and a life of 15 years is not too much to expect, as I know from personal experience. The real crux of the matter is the battery, which may be subdivided into (1) battery plates, and (2) current. The first is a matter for the accumulator manufacturers; and looking back over the past 15 years or more, very little real improvement in plates can be recorded. As regards weight and capacity we stand very much where we were then. Improved methods of manufacture and purity of material have probably increased the life of the plates to some extent, but compared with other branches of electrical engineering the lead battery for road vehicles has been practically marking time. The very nature of the material means a weak job mechanically, and therefore a limited life. The Edison battery is a distinct and notable breaking away from old traditions, and if the price can be reduced very considerably and the watt-hour efficiently raised, it will go a very long way towards solving this very difficult and important problem. The second point, viz. the question of current, is one for central-station engineers, who really seem at last to be awakening to the possibilities of the subject. Owing to the fact that the current will usually be required at a time when the ordinary lighting load is very light, this hitherto-despised load will very materially help to fill up the valley in the load curve between midnight and 6 a.m., and it would surely be possible to supply it at 1d., or even less, per unit. At this price the electric vehicle has a very great advantage over the petrol car; the price of petrol is still increasing and is likely to remain at a high figure until some other agent giving the same results can be produced. There is another point that the central-station engineer will be called upon to consider, and that is the question of having charging pillars erected at various convenient places where a boosting charge can be obtained through a 6d., or even 1d.-in-the-slot meter; these pillars would of course be only used for short emergency charges. When charging plugs and battery voltages are standardized, any type of vehicle will be able to charge from these pillars, and the distressing sight of a "run-out" vehicle being towed home would then be avoided. The question of the cost of running is not an easy one to determine, depending as it does on many points unconnected with the actual car. The two heaviest items are the wages of the drivers and the cost of battery renewals; but both can be considerably reduced by using a battery of much greater mechanical strength than the lead battery, in other words, one that can be abused and is practically fool-proof, since renewals would then be kept very low and a cheaper class of driver, for commercial vehicles

at any rate, could be employed. With these two items reduced, with solid or semi-solid tyres employed, with a cheap and simple garage, and with labour reduced to a minimum, the total cost per mile should certainly not exceed 8d., and could possibly be brought lower than that. Referring to the very small advance made in the batteries for road vehicles, a company with which I was associated ran in 1897 a 4-seated car to Brighton on one charge; the battery was filled up during the night and the car ran back to London on the one charge next day. This was a performance which would not be bad at the present day, and was certainly very good then. I had the privilege a year or two later of taking this same car to New York, where the car was run for 76 miles on one charge, the battery still having some energy left in it. This battery had previously run hundreds of miles in England, was sent over to America dry, and was charged up again in New York. Both batteries mentioned above were of the Leitner type. Certainly the history of the electric battery vehicle in England is not a very happy one, but what can be done in America should be possible, under proper organization, here, although in all probability the pleasure vehicles will not attain the same degree of popularity. For light delivery vans, however, there is an immense field. Mr. Ayton is very enthusiastic on this subject, the Edison Battery Company, of course, is equally so, and several central-station engineers are showing a practical and valuable example in running electric vehicles in connection with their business. It seems therefore that the electric vehicle may even yet have a good time coming, but events must move quickly, as the petrol vehicle has been allowed to get so well established that it will be very uphill work ousting it from positions for which the electric vehicle is in every way better adapted.

Mr. W. E. WARRILOW (*communicated*): When it is considered that the electric vehicle industry has made several false starts in this country, it is not surprising that considerable prejudice and suspicion have arisen around electric battery transport. One of the first tasks of those who are at present engaged in the business must be to remove the causes of this feeling of uneasiness before they can set about placing the movement upon a permanent footing in the world of practical automobilism. The early failures with the electric battery vehicle undoubtedly scared capital away from this class of manufacturing enterprise, and mechanical road traction became identified with the internal-combustion engine. I think it is safe to assume that the rise of the petrol vehicle industry will serve to strengthen the hopes of present-day commercial and industrial vehicle users that a more simple, reliable, and efficient machine will soon be at their disposal. Petrol-car engineering has also rendered a distinct service to the simple electric vehicle by introducing gears and gear-cutting machines of the highest accuracy; such accessories contribute largely to the efficient running of an electric battery vehicle. In order that financial interest may again be aroused in the battery vehicle in this country, practical evidence must be given of its efficiency and reliability. We may then expect that the necessary capital will be forthcoming, and that manufacturing concerns will be established. At the present time I think it is desirable that those interested should consider and act

upon the facts as they find them. There are at present some half-dozen agents for Continental and American vehicles offering their machines for the British market. Assuming that the demand is a large one the supply is unlikely to be equal to it for some time to come. In these circumstances it seems to me that the principal thing to do is to follow Mr. Ayton's recommendation to make known as widely as possible the many advantages of the electric vehicle. A number of central-station engineers are withholding their support from every phase of the movement because they believe that they can do no good without actual demonstrations or a car of their own in service. This policy may have something to recommend it, but at the present rate of progress it seems likely that engineers will have to take their turn in a waiting list both for demonstrations and the delivery of the actual vehicles. It is, however, satisfactory to note that for the first time electric-battery-vehicle makers and central-station engineers have come together upon this important proposition. But it seems to me desirable that the station engineer should avoid a policy of waiting upon the vehicle maker to arouse interest within his area of supply. Quite aside from the fact that, as I have already said, there is a difficulty in obtaining vehicles for demonstration purposes, the makers argue that after they have sold a vehicle it is the central-station engineer who becomes permanently and financially interested in it. For this reason, then, it is not unreasonable that the vehicle maker should expect a full measure of co-operation from the central-station engineer. Another matter I should like to refer to is the possibility of the municipal central-station engineer using his direct influence with the heads of those departments that are interested in the electric vehicle from a public service point of view. The borough surveyor, the sanitary inspector, and also the tramways manager, are likely to act upon his recommendation in a matter of this kind. I refer specifically to this because it sometimes happens that the relations between the electricity department and the other branches of the municipality are somewhat strained. The electric vehicle should therefore provide an excellent excuse for breaking down these barriers where they exist. Again, it would be advantageous if one or other of the makers who have dust-carts and similar public service vehicles at their disposal would place one at the disposal of a corporate body having a fleet of steam or petrol wagons; the electric vehicle could then be run side by side with its rivals for a period of, say, 12 months and a practical comparison made between them. It is not sufficient for the vehicle maker to show photos and data of the performance of his machines on the Continent or in America. Many municipal engineers in this country have a penchant for the steam or petrol wagon, and until they have data from British experience they are likely to be slow to move in this matter. In conclusion, I should like to enter an appeal to vehicle makers and central-station engineers to avoid sensational or exaggerated statements regarding the battery vehicle. The movement was undoubtedly checked by this policy in the early days.

Mr. F. J. HARDING (*communicated*): During the past seven years I have had charge of the steam and petrol delivery vans of a well-known London firm, and during the last nine months also of a 10-cwt. Edison-battery van, which is now doing the round of a petrol car. The

principal points raised in the discussion refer to lead batteries, and unless one has actually used the Edison battery it is impossible to form any idea of its simplicity and reliability, and the small amount of attention that it requires as compared with the lead battery. Lead batteries must not be charged too fast or too slowly, or allowed to run down and be left standing, or to be overcharged; a short circuit would ruin them, and there is also sulphating, acid-creeping, and the renewal of plates every 3,000 miles. These troubles seem to have been overcome by the Edison battery. All the attention necessary is the addition of a small amount of pure water once a month. The great advantage of this type of battery is the short time that is required for charging, since it does not suffer if charged at 70 amperes or more. It can at any time be plugged direct on to a 110-volt circuit without any resistance, whether it is half charged, one-quarter charged, or empty. The repair and upkeep are very small compared with that of steam- or petrol-driven vans, as the modern electric motor is so constructed as to take almost any load and to run without attention for six months, then only requiring a little grease in the bearings; there is thus a great saving of oil. This van has been doing for the last nine months two deliveries a day, each delivery including 30 to 40 calls, and it has not once been out of commission. During that period it has covered 7,500 miles, and has taken from the mains 3,000 units, which represents 3 d. per mile, as against a petrol consumption of 1/10th gallon per mile, i.e. a cost of 13 d. per mile, in the case of a petrol van doing the same delivery. I hope that the engineers in charge of generating stations will encourage prospective buyers by keeping the tariff as low as possible. I am sure that in the near future they will reap a good harvest, since a charge would be taken first thing in the morning and at midday, when there is very little other demand for electrical energy.

Mr. R. RANKIN (*communicated*): In his introductory remarks Mr. Ayton says that we must educate the public. The principal point on which the public will need educating is the care and treatment of the batteries. This is indeed a most important matter if the electric battery vehicle is to be a success. Central-station authorities themselves are frequently not perfect in this respect, and it is scarcely surprising that storage batteries that have to be attended to by chauffeurs sometimes do not come up to expectations. I propose to deal with the case of lead cells, the limitations of which, as regards capacity, must be realized if such cells are to be a success for this class of work. Mr. Brazil has referred to this point and, as he says, any instrument that can be devised to indicate reasonably approximately the state of a battery which is working on varying rates will be a boon in the battery-car equipment. Such an instrument would of course be very valuable in station working, but in car work it would have to be smaller than in the former case, and as compact and easily readable as it is possible to make it. The following are a few details of an instrument that I have devised for this class of work and which is in satisfactory everyday use. Its visible moving members are two pointers which move over the same scale—a scale graduated in volts per cell. One pointer indicates the final permissible potential difference corresponding to whatever current is flowing at any time. The other points to the actual potential differ-

Mr. Harding.

Rankin. ence at that particular time. When the two pointers coincide the battery has reached the limit of its capacity for the particular current then prevailing. If this is a low current the battery is empty; if a high one, more capacity can be obtained from the cells if they are allowed to recuperate. The main value of the instrument lies in the fact that the driver of a car has always before him a true picture of the actual state of the cells at any moment and can, by the exercise of a little common sense, prevent over-discharging and consequent damage to the cells. When

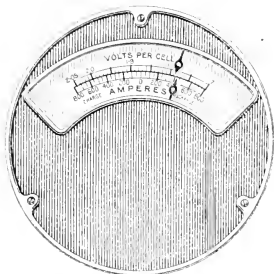

FIG. 4.

this case being a uniformly graduated one, in fact, the Mr. Rankin. ordinary moving-coil instrument scale. The instrument can be provided with alarm or recorder features, but in the case of car batteries those would hardly be required. Fig. 4 represents an instrument which is in use in an electric supply station and is provided with an alarm. In this form it is practically an ordinary 8-in. dial moving-coil instrument, but somewhat deeper. The final potential differences were arranged to be directly proportional to the currents, and hence the currents were marked on the inside of the volt scale. The upper pointer indicates actual and the lower permissible final potential differences. It should be observed that to the left hand of the zero point in the current scale the voltages are not final values. As has been mentioned, the inclusion of the current values was a side issue, and the volt scale was made to cover the full range from open circuit to the final potential difference at the 1-hour rate. The part of the volt scale to the left of the zero-current point is not so valuable as the remainder when working, although of course the instrument can be made to act on charge as well as on discharge. It should be observed that in ordinary car work the ampere scale would be a valuable feature on the long scale of an 8-in. dial instrument, the calibration being made to suit the actual values obtained in running, and that both the volts per cell and the total voltage of the battery can be indicated on one scale. The driver can therefore have before him in one instrument:—(1) Total battery voltage; (2) actual voltage per cell; (3) permissible final voltage per cell; (4) actual value of the current. For car working, the instrument without its alarm and recording features is smaller than that illustrated and takes up less room than the ordinary combined voltmeter and ammeter. It is, in my opinion, in the direction of improved methods of handling batteries that we must look, for the lead battery when properly treated is really a most valuable and reliable piece of apparatus. Were such an instrument as I have described installed with every battery, whether in a power station or sub-station, or in a battery vehicle, and due regard were paid to its indications, I do not hesitate to say that in many cases the length of life of a battery would be increased by 100 per cent, to the lasting benefit of both battery users and battery makers.

BIRMINGHAM LOCAL SECTION, 18TH MARCH, 1914.

Mr. R. A. CHATTOCK: The importance to the electrical industry of the introduction of electric battery vehicles into this country cannot be over-estimated. The Incorporated Municipal Electrical Association has formed a Committee with the idea of standardizing as far as possible the apparatus required and the conditions under which vehicles will operate. It is proposed to deal with such points as the following:—Overall dimensions of batteries and number of cells; charging outfits and plugs; voltages; sizes of motors; methods of control, etc. The proposed charges for current are also under consideration by this Committee and it is hoped to standardize them in all parts of the United Kingdom. Ideas vary very much on this point, prices from $\frac{1}{2}$ d. to 2d. per unit and over being suggested. My opinion is that 1d. per unit should be satisfactory to all parties, with a possible reduction at night-time. From information available as to what has been

done in America and on the Continent, it is known that a Mr. Chattock. big demand for these vehicles can be created if they are properly brought to the notice of the public. They will be specially serviceable for carriers of heavy goods, such as railway companies, for the delivery vans of large shopkeepers, for public services such as street cleansing, watering, and dust collecting, and for motor omnibuses. A service of the latter has been running for some years at Brighton and is apparently giving great satisfaction, whilst the Southend-on-Sea Corporation have now, I understand, purchased one or two vehicles for experimental purposes. Delivery vans and lorries of from $\frac{1}{2}$ to 5 tons' capacity seem to be at the present time the most suitable vehicles for adaptation to electric driving. A 5-ton lorry should produce a revenue of about £80 per annum, with energy at 1d. per unit. It may be concluded, therefore, that a large revenue may be expected by the electricity supply depart-

Mr. Chattock.

ment if these vehicles come into general use. There is no doubt, however, that the public must be educated in this connection before it will recognize the usefulness of such vehicles, and this process will cost money. Manufacturers must be prepared to demonstrate the use of the vehicles in all large towns and to state figures as to the cost of operation which will be convincing to the prospective buyer. The existing garage proprietors, whose interests are at present bound up with petrol-driven vehicles, will not go out of their way to incur expense in dealing with this new branch of the industry unless they are satisfied that by doing so they will eventually be repaid. They are not therefore likely in the first place to provide facilities for charging the vehicles. I suggest that electricity supply stations can give initial help by arranging charging facilities for these vehicles at the stations and sub-stations, although I consider that they should not provide garages permanently for this purpose. Assistance so given in the early stages of the movement will undoubtedly have a very stimulating effect on the use of the vehicles. There will apparently be great competition between the lead and the nickel batteries. Experience can only show which will prove to be the best for the purpose. Meanwhile both are being largely used in America. The battery is that part of the vehicle about which the greatest doubt appears to exist in the mind of the user, and in order to circumvent this I suggest that the makers should be prepared to give reasonable maintenance guarantees over as long a period as possible. It is only by reducing the guarantee charges to a minimum that battery makers can assist in the pioneering work that will have to be done in this country before the public can be convinced of the great utility of the electric battery vehicle. In reply to certain points that have been raised, I may say that the charge of 1d. per unit that I suggest is for current at the standard supply voltage of the undertaking. Motor-generators will undoubtedly have to be used to transform this voltage down to pressures suitable for the batteries. I consider it is very necessary to go into the question of standardization at once. Especially is this the case as regards the standard charging plug and receptacle. It would be a great mistake to allow numerous forms of plugs to be put on the market and to come into general use if this can possibly be avoided.

Mr. Allen.

Mr. S. T. ALLEN: I have been most interested to hear of the work of the Electric Vehicle Committee, from which I received some little time ago a list of questions asking me, amongst other things, what I proposed to charge in Wolverhampton for electricity supply for battery-charging purposes in private garages (1) during peak time, (2) at off-peak times. I should like to ask Mr. Chattock what the committee meant exactly by "peak time" in this case. This appears to me to be important, as what might be considered to be the peak time when supplying direct at the works would not necessarily be the peak time for the purposes of charging at private-house garages. For instance, if a lower charge were made for off-peak supply, and the central-station peak times, say from 3 p.m. until 6 p.m., were taken to determine this, it would hardly be right to allow private householders to commence taking a supply for charging purposes at, say, 7.30 p.m. at the lower rate for off-peak time supply. The peak time in an ordinary residential street, where cooking and heating operations are carried on, is about 7.30 p.m., when the maximum load

on the mains on such a street is experienced. The addition of a load of 250 amperes, due to the charging of half a dozen or a dozen car batteries at such a time would probably entail increasing the size of the mains and services in that street by 100 per cent, and it is therefore obvious that the off-peak time at the generating station should not always be the time at which current could be supplied to private garages at a lower rate.

Mr. Allen.

Mr. W. FENNEL: I note that a committee has been formed by the Incorporated Municipal Electrical Association to promote the adoption of electric vehicles; but if the Institution had taken up this matter it would have been possible to have formed a strong committee of its members which would be representative of all branches of the industry. There is, however, still one field open for the Institution, and it is to be hoped that full advantage will be taken of it. I believe that for about 10 years no important papers have been read on electric accumulators as applied to traction or on the construction or performances of electric battery vehicles. Signal service can be rendered to this branch of electrical engineering by arranging for a series of papers dealing with the details of the construction and rating of electric battery vehicles, so that every electrical engineer will be in a position to speak with certainty whenever the occasion offers, and thereby to inspire confidence in the minds of prospective users. With regard to the question of a standard price, I agree with Mr. Chattock that this is desirable, but I think it would be more advisable to make this standard price the one to be charged to the user for the energy at the standard continuous-current voltage which will be fixed for electric vehicle charging. Simplicity is the great thing to be aimed at in dealing with the non-technical public, who know nothing about peak-load times and will be attracted by a certain reasonable price which they can check against their mileage rather than by a doubtful and varying cost which may be lower on the average. If a charge is made to the user based on the amount of energy supplied at the supply authority's terminals, the user will require information as to the efficiency of the transforming apparatus, and this will vary in different cases, so that the object of standardization will be lost so far as it concerns the vehicle owner. If I were asked to suggest a price I would say 1½d. per unit for all energy supplied to the battery, this price to cover all the costs of providing the supply at the standard continuous-current voltage. The supply authorities could then bargain with the owners of the charging machinery to provide the supply at such a price that the authorities could profitably sell at the standard rate. I agree that the charging business will rapidly pass out of the hands of the supply authorities, and if my suggestion is adopted it will allow a very large margin at the outset to those authorities who do the pioneer work, as they will secure both profits.

Mr. R. J. MITCHELL: Mr. Chattock's remarks on the tariff appear exactly to sum up the situation from the station engineer's standpoint. Whilst the cost of energy bears a small ratio to the other costs involved in operating an electric vehicle, it is nevertheless greatly to be desired that a charge as reasonable and as uniformly low as is commercially possible should become the rule. I would suggest that 1d. per unit should be the standard maximum charge, and that wherever possible this should be reduced. An

Mr. Mitchell.

analysis of the prices charged for energy in 91 cities of America gives an average figure of 3 cents per kilowatt-hour at the station garages. Taking into account the different values of English and American money, this figure would correspond to less than 1d. per unit in this country. Fuel economy affords such an excellent proposition, is such a valuable advertising feature, and, moreover, will be the means of such a large proportion of probable users taking advantage of this feature of the electric vehicle—the fuel aspect being the only one that the uninitiated can understand without explanation—that there seems even more justification for extending the lowest rates to the electric vehicle user than are held out to the domestic user of electrical energy. Yet this latter type of consumer is now supplied at rates cheaper than consumers of electrical energy 10 years ago would have imagined to be possible. A speaker has declared that the battery makers are liable to criticism in that they do not place at the disposal of engineers exact information as to the rating of their products, nor did it seem possible, this speaker declared, to gauge whether any real improvements had taken place in accumulators during the last 10 years. Speaking in support of the Edison accumulator—and leaving the lead type of cell out of the question for the moment—I should like to point out that these strictures apply by no means in this instance. In 1903 Mr. Hibbert read a paper on the so-called E-type Edison accumulator. This type was really a great disappointment to Mr. Edison, who had hoped for far better results than the E-type cell gave in actual service. Nevertheless, the E-type cell was used on quite an extensive scale in the United States, and gave, on an average, 3½ years' service in vehicle operation before depreciating to 65 per cent of its original rated capacity. Many users of this cell refused to sell their batteries back to Mr. Edison, who wished to repurchase as many accumulators as possible in order to keep them in stock for experimental work. The Adams Express Company, a very large transport company in the States, had in operation 200 trucks thus equipped, and obtained an average life of over three years from each of them. The present-day type of cell was introduced in 1909, and in 1912 the same company equipped 88 trucks with it. As an example of the great superiority of the modern (A-type) Edison cell, it is interesting to refer to an endurance test that was conducted in order to compare the two products. When subjected to a process of charging and discharging at very high rates, conducted at a very high temperature of the electrolyte—a combination of conditions well known to be very destructive—the E-type cell depreciated to 65 per cent of its rated capacity after 200 cycles of treatment, whereas the A-type, when treated similarly indicated 4 per cent above its rated capacity after 1,100 cycles; hence it may be inferred that the A-type cell will very far outlive its guarantee period of four years, during which time it is warranted to give 100 per cent of its rated output. As to its electrical characteristics, these are available to any engineer who asks for them. It is, however, useful to remember that on an average the Edison cell may be relied upon to give 12 watt-hours per pound of complete assembled battery at the discharge rates ordinarily met with in vehicle service. I should like to touch on the matter of road resistance. It will be apparent to any

engineer that the rating of an electric vehicle in point of distance and speed is entirely dependent on average tractive resistance, occasioned by the particular condition of the road surface over which the vehicle will generally run. Some years ago investigations bearing on this subject were commenced in a systematic manner, but were for certain reasons abandoned. The advent of the electric vehicle induces in itself a very strong plea for the continuation of this research, and I would suggest that our colleges should assign to some of their research students the duty of making reasonably complete accelerometer measurements of tractive resistance per ton over various road-surfaces in the immediate neighbourhood of each college. A relatively small amount of such field-work, which could be done in a few weeks by co-ordinated effort, would result in our having very much more accurate notions of tractive resistance than have hitherto been available.

Mr. A. C. SOUTTER: Mr. Fennell has raised the question as to what improvements have been made in accumulators for use in road vehicles in recent years, and I presume that he refers to the lead accumulator. The lead cell now used for this class of work is an entirely different article from that used for the purpose several years ago, and as a proof of its reliability to-day I think I can do no better than to refer to its successful use on the Brighton omnibuses during the past six or seven years.

Mr. S. H. BILL: I should like to say a few words from the vehicle user's point of view. My firm runs a fleet of about 20 petrol vehicles, and as electricity is generated as a by-product at less than 1d. per unit, I am under the impression that so far as electrical vehicles are concerned my firm should be in a much more favourable position than the majority of users, but my difficulty has always been in getting any reliable data that would be guaranteed by the battery manufacturers. Our petrol costs are from 3'88d. to 5'33d. per ton-mile with 4-ton lorries, this including the wages of one driver and two draymen, garage costs, renewals, insurances, licences, and stores, together with 20 per cent depreciation and 5 per cent interest on the capital. Even at these low figures it is found to be impossible to compete with horse-drawn vehicles on journeys of less than five miles, so that I cannot agree with Mr. Ayton that this form of traffic is likely to be removed from our streets for some considerable time. One of the disadvantages of electric vehicles is their very great weight, necessitating very heavy tyres and springs. I would suggest that the Electric Vehicle Committee consider the advisability of including a vehicle user on the Committee. Although I believe that the battery vehicle will eventually become common, I think it will not be in the immediate future.

Mr. E. STUBBS: In my opinion one of the greatest difficulties in the way of introducing electric vehicles is their first cost, something over £600 being given as the cost of a small delivery van. Few firms can be expected to face such an expenditure. The battery makers are likely to gain quite as much as the supply authorities by the introduction of this system of transport, and I therefore think they should be prepared to supply vehicles and maintain the batteries either for a fixed charge per annum or for a fixed charge per mile. In many towns one or other of the battery makers have contracts for maintaining central-station batteries and have therefore the staff already available to undertake this work. The actual cost of the supply for charging purposes

Mr. Mitchell.

Mr. Soutter.

Mr. Bill.

Mr. Stubbs.

Mr. Stubbs. is relatively unimportant, as from the figures given for the cost of energy this is a very small proportion of the total cost of running these vehicles.

Mr. A. M. TAYLOR: The points on which we are all desirous of information are the capital cost and the cost of maintenance of the storage battery as applied to electric traction. In order to fix ideas, I have taken records of a certain pleasure car suitable for seating two people and capable of carrying about one ton of luggage. This car is equipped with 50 cells, giving a discharge capacity of approximately 225 ampere-hours at 60 volts. In order to ascertain the cost of a battery, I have assumed that cells as catalogued by an English maker are installed on the car and of such a size that they can give any equivalent discharge to the existing cells. The cost of such a battery, allowing for the usual discount off the maker's list, would be approximately £44; but in order to make the comparison in the case of the more expensive batteries on the market, which would probably have a longer life, let us assume that this cost is increased by 50 per cent, to £66. The question then arises as to what mileage may be obtained with such a battery before it has to be renewed. From numerous records in the United States it would appear that 15,000 miles is a moderately safe estimate. In fact, a certain battery that had been used for two years on a heavy truck which had during that period run a distance of 17,000 miles, was stated to be actually in better condition than at first, and was probably good for another 17,000 miles. Taking, then, this figure for the battery considered above, and the capital outlay at £66, the cost of battery renewals represents only 1d. per mile. This, of course, is a battery for a very light vehicle weighing only 1 ton; and on a vehicle of which the gross weight was, say, 5 tons, it would presumably be reasonable to assume that the cost of battery renewals would be five times this amount, or 5d. per mile. It would seem from this that if the life of a battery can be assumed to be 15,000 miles, the cost of repairs is not at all exceptional, even for a battery costing initially 50 per cent more than a leading English maker's cells. On the other hand I believe it is generally known that the life of a well-known Continental cell has been mentioned as only about 3,500 miles, and that even then its capacity decreased about 60 per cent before renewal. Next, as to the cost of the energy required for the above car, careful records show that 542 miles were covered at an expenditure of energy of 108 kilowatt-hours put into the battery. This, therefore, includes all battery losses, etc., and represents 0.2 kilowatt-hour per mile; and since the car weighs approximately one ton, it is equivalent to approximately 0.2 kilowatt-hour per ton-mile. Now a rough calculation of the amount of energy required for a car on which the tractive resistance averaged 80 lb. per ton and the speed averaged 12 miles per hour, comes to approximately 0.2 kilowatt-hour per ton-mile; adding 50 per cent for the loss in the battery, this would mean 0.3 kilowatt-hour per ton-mile. Now since the car considered above averaged

only 0.2 kilowatt-hour and weighed approximately one ton, it would appear as though the average tractive resistance were only, in this particular case, about 53 lb. per ton. This is only a very approximate figure, but it is interesting as so many estimates of tractive resistance have been made, varying from 20 up to 100 lb. per ton. Of course the average figure is materially altered if any important inclines have to be taken into account. It is also interesting to note that at the above figure, viz. 0.2 kilowatt-hour per mile, the cost of energy at 1d. per unit is only $\frac{1}{3}$ d. This again would increase approximately in proportion to the weight of the car, and therefore on a car with a gross weight of five tons it would be roughly 1d. per mile. This, however, would be quite a reasonable figure. It would appear from numerous records taken in Indianapolis, where there have been a large number of one-ton lorries (i.e. lorries capable of carrying a load of one ton), that these take on an average about $\frac{2}{3}$ kilowatt-hour per mile run, and run some 11,000 to 15,000 miles under all sorts of conditions, in some cases through 14 in. of snow and mud, before the battery requires renewing. Some speakers have complained that the battery companies do not publish any tests or records, but I must say that at least one battery company has published very elaborate tests of the performances of its cells under all sorts of conditions, and tests which have in most cases been verified many times. One of these tests showed that on allowing a fully charged battery to stand idle for 10 days the charge had only decreased by about 10 per cent. In another test a cell was allowed to stand for six months completely discharged, its performance at the end of that time, after recharging, being practically the same as at the beginning of the test. In another case a cell was heated to 130° F. and then short-circuited until completely empty. This process was repeated about 500 times, and it was found that even after such treatment the cell had as great a capacity as at the commencement of the test, and that after the first 150 or 200 such discharges its capacity had actually increased. It was also found that even after 1,000 such discharges the cell had only lost 20 per cent of its original capacity. If we allow 30 miles per charge, 500 charges would represent 15,000 miles, and 1,000 charges 30,000 miles run; and as the above treatment is far worse than any that is likely to occur in practice, it would seem quite safe to assume that the figure which I took for the life of a battery, viz. 15,000 miles, is a reasonable estimate for this class of cell. Reference has already been made to tests in which three cells, after having been used for 17,000 miles on a one-ton delivery van, were found to give a 34 per cent better performance than when originally installed. These three cells were selected at random out of a group of cells. In view of tests such as these it seems incorrect to say that the battery makers have not published the results of tests on their cells.

CURRENT-LIMITING REACTANCES ON LARGE POWER SYSTEMS.

By K. M. FAYE-HANSEN, Associate Member, and J. S. PECK, Member.

(Paper received 20th February, 1914; read before THE INSTITUTION 26th March, before the BIRMINGHAM LOCAL SECTION 1st April, and before the MANCHESTER LOCAL SECTION 7th April, 1914.)

One of the most striking developments in connection with the supply of electrical energy is the rapid rate at which generating stations and generating units are increasing in size. This increase is due not only to the more general use of electricity for lighting and for domestic purposes, but to the fact that large manufacturing firms, tramways, railways, and other large employers of labour, are finding it cheaper to purchase electrical energy than to generate it in their own power stations. Thus an ever-increasing proportion of the community is becoming dependent upon the continuity of supply from these stations and the time is fast approaching when a serious disaster to a large supply station may pass from a mere inconvenience to a civic calamity. On account of their size, however, these large stations have a power of causing internal and external damage quite beyond that possessed by a station of small or moderate size; it is therefore incumbent upon their designers not only to use every means to prevent accidents, but to make such provision that, if accidents do occur, the amount of damage shall be reduced to a minimum and the trouble confined to the particular section of the plant where it occurs. To accomplish these results current-limiting reactances are being extensively adopted, and it is proposed in the present paper to discuss their operation, to indicate where they may be placed, and the sizes which should be used in the different positions, in order most satisfactorily to accomplish the desired results under various conditions. In the latter part of the paper the design of the reactance coils themselves will be considered, and the relative merits of coils with air cores and with iron cores will be pointed out.

It is well known that a generator which will give but two or three times full-load current on sustained short-circuit may give 20 to 40 times full-load current at the instant of short-circuit. This is due to the fact that the armature reaction requires time to assert itself, so that the first rush is limited only by the reactance of the armature circuit. If the armature of the generator has 5 per cent reactance, 20 times normal current may flow at short-circuit, and if an additional 5 per cent is inserted in the form of choke coils, the instantaneous rush is limited to 10 times normal. These values may, however, be increased owing to the so-called "doubling effect."*

The general effect produced by a series reactance is a drop in voltage in the circuit, provided the power factor is unity or lagging; and the greater the lag the greater is the drop in voltage. The power factor is also decreased on account of the reactive kilovolt-amperes of the choke coil.

* When a pressure is suddenly applied across the terminals of a choke coil or of a transformer, the first rush of current may be far in excess of the normal magnetizing current. The magnitude of this current will depend upon the point of the voltage wave at which the circuit is closed (*Electric Journal*, vol. 5, p. 152, 1908).

It may be stated that the number of kilovolt-amperes at zero power factor is increased by the kilovolt-amperes of the reactance coil. This is but another way of saying that the wattless kilovolt-amperes of the choke coil may be added arithmetically to the other wattless k.v.a. components of the circuit in order to give the total wattless kilovolt-amperes. Thus it is evident that the introduction of reactance affects the regulation and power factor of the system; and these are two of the factors which determine the sizes that should be placed in generator leads or feeders.

LOCATION OF REACTANCE COILS.

In general, reactance coils may be placed in any one or more of the following positions:—

1. In the generator leads.
2. In the feeders.
3. Between sections of the busbars.

In the various positions their effect upon the following should be considered:—

- (a) Generators.
- (b) Circuit-breakers.
- (c) Voltage of supply.
- (d) Continuity of service.

The different conditions of operation to be considered are:—

- (a) Normal operation.
- (b) Short-circuit on feeder.
- (c) Short-circuit on busbars.
- (d) Short-circuit on generator.

1. REACTANCE IN GENERATOR LEADS.

Fig. 1 is a one-line diagram showing six generators connected through reactance coils and circuit-breakers to a common busbar. In normal operation the reactances will produce a drop in voltage between the generators and the busbars; but this can readily be compensated for by varying the excitation of the generator. Thus the voltage on all the feeders will be the same, and may be kept constant or may be varied in accordance with the load. The power factor of the load on the generators will be decreased by the reactances, the extent of the reduction depending on the size of the reactances and the load on the busbars.

In the event of a short-circuit upon a feeder as at X, the busbar voltage will drop to zero (provided the impedance of the fault and of the feeder between the fault and the busbars is negligible), and all generators and other synchronous apparatus on the system will feed into the short-circuit. If the system is a very large one, this

current may be enormous and may damage or destroy the circuit-breaker in the defective feeder. It may also cause serious damage at the fault. It should be noted, however, that even on the largest system the current in the event of a fault will be less than it would be without these reactances. The generators should not suffer, because the output of each is limited by the reactance in series with it; and for the same reason the generator circuit-breakers should not be damaged. The worst feature of this arrangement is that, the whole of the busbar being affected, all synchronous apparatus throughout the system may fall out of step and a complete shut-down is likely to occur.

It might be argued that the feeder circuit-breaker should clear the fault before the synchronous apparatus falls out of step, but this is improbable, as the circuit-breaker requires an appreciable time to operate even when set for instantaneous tripping, and it is general practice to set circuit-breakers with a time lag to relieve them from the

in operation the busbar voltage may decrease very little.

The advantages and disadvantages of placing reactances in the generator leads only may be summarized as follows:—

Advantages of reactance in generator leads:—

1. The busbar voltage may be kept constant, giving the same voltage on all feeders.
2. No damage to the generators in the case of a short-circuit on a feeder or busbar.
3. No damage to the generator circuit-breakers in any case.
4. Synchronous apparatus will not fall out of step in the case of a short-circuit on the generator.

Disadvantages:—

1. Enormous current-rush into a short-circuit on a feeder.
2. Excessive load on the feeder circuit-breaker in the case of a fault on a feeder.
3. Synchronous apparatus may fall out of step, and a complete shut-down may follow a short-circuit on a feeder or busbar.

From what has been said it will be evident that reactances in generator leads alone are of little value except for protecting generator windings and circuit-breakers, as they offer no guarantee of continuity of service except in the case of the breakdown of a generator. Their size will therefore be determined by the robustness of the generators and the circuit-breakers. Assuming that the average generator has a reactance of 6 per cent, and 6 per cent is added in an external coil, the maximum current that can flow equals $8\frac{1}{3}$ times the normal current, or somewhat more than this due to the doubling effect. Any generator should be able to stand a current rush of this magnitude. If the generator has 8 per cent reactance, then 4 per cent in the external coil will limit the current to the same value.

Where a step-up transformer is connected between the generators and busbars, it may be designed with high internal reactance, thus giving the effect of a reactance coil without any appreciable additional cost.

2. REACTANCE IN FEEDERS.

Fig. 2 shows an arrangement of six generators connected to a common busbar from which several feeders are supplied, each feeder having a reactance coil in series with it. In normal operation each coil will produce a drop in voltage on its feeder, and if some feeders are more heavily loaded than others, the voltage drop on the feeders will vary and cannot be compensated for by varying the busbar voltage. Under certain conditions this may prove troublesome, but when the supply is to synchronous apparatus this voltage difference can be compensated for by varying the power factors of the synchronous machines. These reactances will also reduce the power factor of the load on the generators, though they will not affect the power factor of the feeders beyond the reactances.

In the event of a short-circuit upon a feeder, as at X, the current supplied to the fault will be limited by the re-

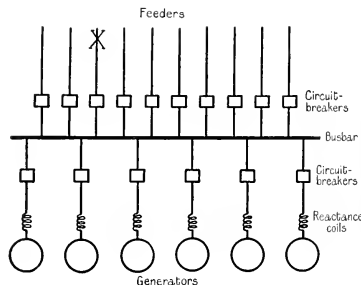

FIG. 1.

duty of breaking the enormous instantaneous rush of current that occurs on short-circuit. However, if the fault occurs at any considerable distance from the generating station, the impedance of the feeder will greatly reduce the current, so that the busbar voltage will drop comparatively little and synchronous apparatus will not fall out of step.

With properly insulated busbars the chances of a short-circuit on them would be almost negligible, but in the event of such a short-circuit occurring, the action will be precisely the same as with a short-circuit on the feeder, except that the feeder circuit-breaker will not suffer.

In the event of a short-circuit on a generator, the armature winding will be distorted if not properly braced; but the current which can flow from the busbars to the defective generator will be limited by the reactance, and the circuit-breaker should be able to disconnect the generator from the busbars without difficulty. Also the voltage of the busbars will not fall to zero, and the operation of synchronous apparatus will probably not be affected; in fact if there are a large number of generators

actance and the busbar voltage will be affected to only a small extent. The circuit-breaker should be able to cut out the feeder without difficulty, and only the one feeder will be affected. Since the current is limited by the reactance, the generators will not be heavily overloaded, and none of their circuit-breakers should open.

A short-circuit on the busbars will short-circuit all the generators, and if the windings are not properly braced may cause serious damage. Also the whole system will be thrown out of action and each generator circuit-breaker must open the short-circuit current of one generator.

Should a short-circuit occur in the generator windings, the self-induction of the generator windings will usually be sufficient to limit the current until the circuit-breaker has acted and cut out the faulty machine; but should a short-circuit occur between the generator and the circuit-breaker, all the generators would feed into the short-circuit, and the circuit-breaker on the defective generator would have to open the short-circuit current of all the other generators. In this case the voltage of the busbars will drop to zero and all synchronous apparatus may fall out of step so that a complete shut-down is likely to occur. It should be noted, however, that in the case of trouble on the busbars or generators, the feeder reactance will slightly reduce the amount of current that the synchronous apparatus on the system can feed back into the fault.

If the generator windings are braced to withstand short-circuits, this arrangement of reactances possesses marked advantages over that of placing them in the generator leads, for the great majority of faults occur on the feeders or on apparatus connected directly to them; and with feeder reactances such faults can do no serious damage to the system. Furthermore, busbars and connecting cables can be so thoroughly insulated that a short-circuit on them is a somewhat remote possibility. But if the generator windings will not withstand a short-circuit, it would be foolhardy to risk the disablement of the whole generating plant through a busbar or generator short-circuit, even though there is little chance of such a short-circuit occurring.

Advantages of reactance in the feeders.

1. A short-circuit on a feeder causes no serious disturbance on the system, and there is no excessive overload on circuit-breakers or generators.
2. The feeder circuit-breakers may be of smaller breaking capacity than those where feeder reactances are not used.
3. The tendency of synchronous apparatus to feed back in the case of a busbar fault is slightly reduced by the feeder reactances.

Disadvantages.

1. The voltage drop on the feeders will vary with the load and cannot be compensated for by varying the busbar voltage.
2. A short-circuit on the busbar or generators is a short-circuit directly on the terminals of all generators. The generator windings and circuit-breakers may be damaged and the complete plant shut down.

3. A short-circuit on any generator or between any generator and its circuit-breaker may throw an excessive load on this circuit-breaker, and if it fails to clear the fault the whole system will be shut down.

The size of the feeder reactances will depend on the capacity of the feeder, as compared with that of the generators, and upon the breaking capacity of the feeder circuit-breaker. Thus if the rating of a feeder is one-quarter that of a generator, a reactance of 3 per cent in the feeder will pass no more current than will a total reactance of 12 per cent in the generator, while if there are several generators in parallel, the effect of the feeder reactances is proportionally increased. Thus unless the total feeder rating is very greatly in excess of that of the generators, the total k.v.a. capacity of the feeder reactances may be

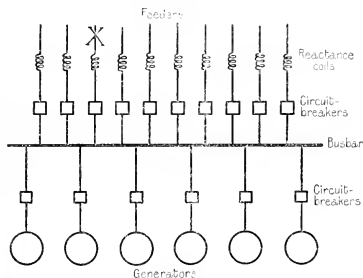

FIG. 2.

less than the k.v.a. capacity of the generator reactances, though the number will in general be much larger. In certain cases it may be desirable to group the feeders and use one set of reactances for the group, thus greatly reducing the number of reactances.

If the feeders are of very great capacity compared with the generators, the feeder reactances must be much larger and their use may not be justified.

Where step-up transformers form part of the feeders, the transformers may be designed with high internal reactance without appreciable increase in cost.

3. REACTANCES IN BUSBARS.

The action of reactances in series with generators or feeders is easily understood and their effect on the system is readily calculated, but when placed between generators or busbar sections their action is more difficult to understand, and it has been thought best to consider this part of the subject more fully.

The only purpose in installing busbar reactances is to limit the amount of current that can flow into a fault on one section of the busbars, and so to confine the disturbance to that part of the system on which the fault occurs. Viewed from this point only, the greater the reactance the better the result; in fact the purpose would be accom-

plished perfectly by isolating the sections entirely. From economical considerations, however, it is highly desirable to operate all the generators of a station in parallel. As a compromise, reactances are chosen of such a value as to permit parallel operation during normal conditions, even with a considerable exchange of energy between the sections; while in the event of a short-circuit occurring on any section, the current rush is limited to such a value as not seriously to interfere with the operation of other sections.*

In order to obtain some idea as to the angular relations of the currents and voltages in two or more generators separated by a reactance, a few cases will be considered.

Fig. 3 shows two generators A and B supplying a busbar which is divided into two sections by a reactance coil. It is assumed that the voltages on A and B are to be kept equal, that the engine governors are set to give equal loads on the two generators, and that the load on feeder D is twice that on feeder E. It will also be assumed that the loss in the reactance coil can be neglected, so that the pressure across the coil will differ in phase by 90° from the current flowing in the coil.

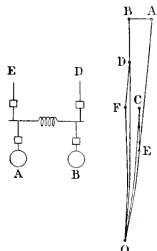

FIG. 3.

FIG. 4.

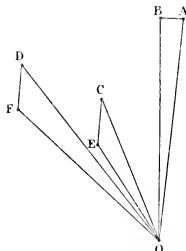

FIG. 5.

Fig. 4 shows the relation between the currents and pressures when the loads on the two busbar sections are at unity power factor.

OA is the voltage on generator A and on its busbar section. OB is the voltage on generator B and on its busbar section. In order that there may be an exchange of energy between the two sections of the busbars, the angular position of the voltages must be different.

AB is the voltage across the reactance coil, and since this differs in phase from the current by 90° , it is obvious that the angular position of the circulating current is midway between the voltages OA and OB.

OD represents the current in feeder D in phase with voltage OB. OE represents the current in feeder E in phase with voltage OA. $OD = OE \times 2$. DF and EC represent the current flowing through the reactance. OC represents the current of generator A. OF represents the current of generator B.

It will be noted that the current through the reactance increases the load on generator A and decreases that on

generator B; the two machines are now equally loaded and the current in both generators lags slightly.

A study of the diagram shows that with a given angular displacement between the generator voltage, the amount of current which can flow between the sections is limited by the voltage drop across the reactance. Thus, having decided upon the maximum allowable displacement for parallel operation and the maximum difference in load, which is likely to occur between the different sections, the value of the reactance may be determined immediately.

Fig. 5 shows the relations between the current and pressures when the loads on the two busbar sections have each a power factor of 0.8. The generator voltages are equal in value, and the current in feeder D is twice that in feeder E. OA and OB represent the generator voltages as before. OE and OD represent the currents in the two feeders lagging approximately 37° behind the busbar voltages. EC and DF represent the current through the reactance. OC is the current in generator A. OF is the current in generator B.

The projection of OF on OB equals the projection of OC on OA, showing that the energy delivered by the two generators is equal. It will be noted that while the current

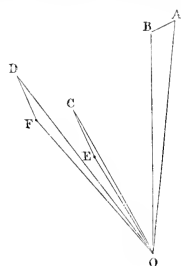

FIG. 6.

flowing through the reactance increases the load on generator A and decreases that on generator B, the power factor of the load on A has been increased and that on generator B decreased.

Fig. 6 shows the same conditions as to loads and power factors as in Fig. 5, but the voltage on generator A is 5 per cent greater than that on generator B. AB is the pressure drop across the reactance, and the vector of the current through the reactance is at right angles to this voltage. This current is shown at EC and DF, giving generator currents of OC and OF. It will be noted that the value of the circulating current is greater than in Fig. 5, and that the power factor of OC is lower, while that of OF is higher than in the preceding case. It is evident that by increasing OA the power factor of the load on generator B could be improved until it becomes higher than that of the load on feeder D and equal to or higher than that of generator A. This is quite what would be expected from the well-known behaviour of alternators operating in parallel. It is, however, seldom possible to operate in this manner, as it will generally be necessary to keep the different busbar sections at the same potential.

* For a brief consideration of the effect of busbar reactances on parallel operation, see Appendix.

Fig. 7 shows the relations that exist where there are two generators working on one busbar section and one on the other section. There is no load on feeder E, and the load on feeder D has a power factor of 0.8. The voltage on the generators is kept equal in value, and the engine governors are set so that the three generators divide the load equally.

O A and O B are the generator voltages, O D is the current in feeder D, O C is the current supplied by generator A, and in phase position is midway between the voltages O A and O B. $D F = O C$. O F is the load on the two generators B and B_n, and the projection of O F upon O B equals twice the projection of O C on O A, i.e. the energy load on generator A is equal to one-half the energy load on the two generators B and B_n. It is evident that the current O F is greater than twice the current O C since its power factor is much lower.

In order to obtain a concrete idea of the values involved in a specific case, an arrangement will be taken such as is shown in Fig. 8. Eight 10,000-kw. 10,000-volt generators are connected to the busbars, which are divided into two sections by reactance coils. Feeders D supply a load of

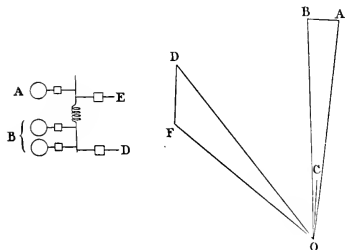

FIG. 7.

60,000 kw. at 0.8 power factor, and feeders E a load of 20,000 kw. at the same power factor. The voltages on D and E are to be kept equal, and all generators are to carry equal kilowatt loads.

It is evident that one group of generators must supply 20,000 kw. to the busbars fed by the other group. Let the reactance coil be of such a size that with the current corresponding to 20,000 kw. flowing through it the voltage across it will be 25 per cent of the normal. The capacity of this reactance = 5,000 k.v.a. 3-phase, or 1,660 k.v.a. for each phase.

Draw OA and OB, making $AB = 25$ per cent of OA. OD and OE represent the feeder currents laid off to the proper scale, each lagging approximately 37° behind its busbar voltage, OD being three times OE. DF and EC represent the currents through the reactance. OC is then the current supplied by generators A, and OF that supplied by generators B.

Since with a current corresponding to the capacity of two generators the drop across the reactance is 25 per cent of the normal, the maximum current that can pass with full voltage across the coil is that corresponding to the normal current of eight generators, though this may

be increased somewhat on account of the doubling effect.

This current is considerably less than a single generator can give at the instant of short-circuit, and is about the same as would be given by one generator after the time interval required for a circuit-breaker to open, so that the effect of the short-circuit would be no more severe than would be the case if there were a total of five generators coupled to one busbar.

In a very large station the busbars would probably be separated into several groups of from 20,000 to 40,000 kw. capacity each. In a case of this kind the amount of energy that it may be necessary to transfer between sections is assumed and the reactances made large enough to limit the current to a reasonable value in case of a short-circuit, but not too large for satisfactory parallel operation. A size that will give 50 per cent of normal voltage with the full-load current of one busbar section is usually a reasonable value to choose.

The use of busbar reactances is carried to the extreme when the busbar is divided by them into as many sections as there are generators. Fig. 9 shows an arrangement of this kind where there are eight generators and eight reactances. It is assumed that each generator is of 10,000 kw. capacity, that the load on the D feeders is 60,000 kw., and that on the E feeders 20,000 kw. Then if all generators are to be equally loaded the A group must supply 20,000 kw. to the D feeders.

Assume that all E feeders are equally loaded and that all the D feeders are equally loaded. Then through R_4 and R_8 must pass 10,000 kw., and through R_6 , R_3 , R_9 , and R_7 5,000 kw. Since the busbar units are small, and it may be necessary to transfer energy through two or more reactances in series, they should be made smaller than where the busbar sections are larger in size but fewer in number.

Assume the voltage across reactances R_4 and R_8 to be 25 per cent of the normal, corresponding to an angular displacement of voltage of approximately 15° . The voltage across reactance R_1 , R_3 , R_5 , and R_7 will be 12.5 per cent, corresponding to an angular displacement of approximately $7\frac{1}{2}^\circ$. Fig. 9 shows the voltage relations that exist between the different generators. It is improbable that the load on any busbar section will greatly exceed the capacity of the generator connected to that section, so that the conditions given above are as severe as are likely to be experienced in actual service; but even with a considerably more unequal distribution of load there should be no trouble in parallel operation.

Arrangements will always be made for short-circuiting any reactance so that in the event of a generator being shut down the feeders connected to its busbar section may be supplied directly from one of the adjacent generators. Arrangements must also be made for opening the busbars between any two generators in order to isolate any section of the busbars that might develop a fault.

With the arrangement shown in Fig. 9 assume that a short-circuit occurs on the busbar section supplied by B_1 . The voltage on this generator would fall to zero, and it would supply maximum current into the fault. If the voltage on A_1 and B_2 kept up to normal for an instant, each of them would feed into the short-circuit four times normal current; but on account of the reactance in each armature circuit, which may be taken at say 5 per cent, the

current would be $100/(25 + 5) = 3.3$ times normal, and would drop quickly to a much lower value. The voltage at the same time would drop to perhaps 50 per cent of the normal.

As soon as the voltage on A_1 and B_3 begins to fall, generators A_2 and B_2 start to supply current through reactances R_1 and R_2 . These currents would reduce to a slight extent the voltages on A_1 and B_3 , but would tend to raise the voltage on A_2 and B_2 . Similarly, A_3 and B_1 would tend to supply current through reactances R_3 and R_4 as soon as the voltages on A_1 and B_3 begin to fall. The effect, however, on the voltage of these generators would be practically negligible.

To determine definitely the voltage on each generator and the current flowing through each reactance is a

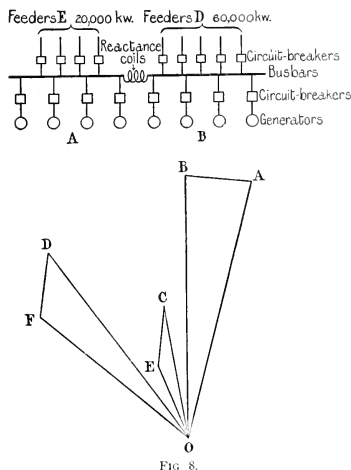

FIG. 8.

somewhat complicated problem, and requires definite data as to the characteristics of each generator, but sufficient has been said to indicate the general effect of the reactances in limiting the rush of current and the damage that can be done.

Another advantage of using reactances between each generator is that it greatly reduces the chances of damaging a generator in the event of a mis-phase, a feature of considerable importance.

Advantages of busbar reactances :—

Trouble is confined to the particular section on which the fault occurs.

The amount of current that can be fed into a fault is reduced.

The danger in the case of bad synchronizing is considerably reduced.

Disadvantages :—

No protection to a generator is given when a short-circuit occurs on or near its busbar section.

The generators coupled to the different busbar sections must be operated with a certain angular displacement in their voltages.

From what has been said it will be clear that reactances between busbar sections may be exceedingly useful for confining any disturbance on the system to that particular section on which the trouble occurs, and thus it is possible to operate a large number of generators or two or more stations in parallel with almost the same factor of safety against a complete shut-down as though they were

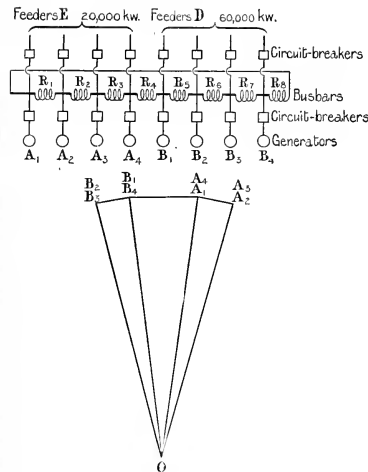

FIG. 9.

operated separately. It is seldom, however, that busbar reactances are used except in conjunction with reactances in generators or feeders, and it is proposed now to discuss very briefly their combined use.

REACTANCES IN GENERATORS AND BUSBARS.

Naturally the size and number of the reactances is the first question to be decided. Since the principal object of the generator reactances is to protect the generator windings, these will naturally be chosen with reference to the characteristics of the generator, and evidently one will be placed in each generator lead. The more completely the busbars are divided up by reactances, the smaller will be the portion of the system affected, and from this point of view reactance is desirable between each generator and the next; but as this may involve

some slight complications in the normal operation of the plant, it may be considered desirable to operate with several generators connected to the same busbar section. The size of the reactances will be determined by the amount of energy that must be transferred from one section to another, and by considerations of successful parallel running.

The advantage of this combination over the use of reactances in generators alone is very great, as it confines the trouble to the particular busbar section affected; it reduces the load on the feeder circuit-breaker, and

circuit, or if the chance of a short-circuit on the busbars is considered negligible, some form of this arrangement probably offers the most complete solution of the problem.

It has been attempted in the foregoing discussion to indicate the advantages and disadvantages resulting from the use of reactance coils placed in different positions in a power station, but when it is attempted to apply this knowledge to a concrete case there are so many factors to be considered that the determination of the best possible combination becomes a difficult problem. For example, if

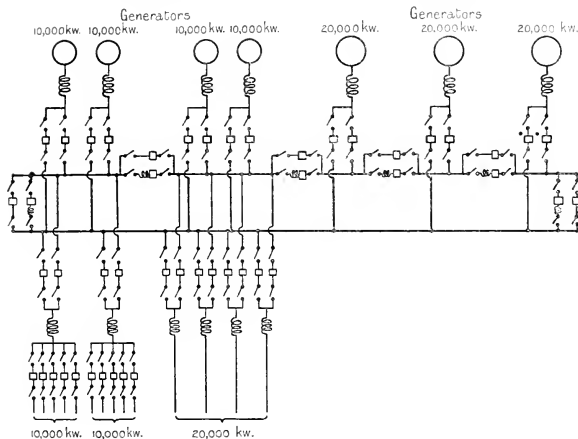

FIG. 10.

reduces the damage at the fault. Perfectly satisfactory operation should be obtained with this arrangement.

REACTANCES IN FEEDERS AND BUSBARS.

Reactances will be placed in all feeders or alternatively in all feeder groups. Their size will be determined by the capacity of the feeder or group, with reference to the capacity of the busbar section and with reference to the breaking capacity of the circuit-breaker. The number and size of the busbar reactances will be determined as previously specified.

This arrangement probably gives the greatest possible freedom from serious operating troubles, for the feeder reactances protect from all troubles outside the station, while the busbar reactances confine any internal trouble to the busbar section on which it occurs.

The objections are that it affords no protection to the generators in case of a short-circuit on the busbars, that it requires a large number of reactance coils unless group feeding is adopted, and that it affects the regulation of the feeders, though this will ordinarily be of minor importance. If the generators can safely withstand a short-

circuit, the busbars are divided into sections by reactance coils, and the different sections feed into the same busbars at one or more sub-stations, the impedance of the cables connecting the different sections may be far less than that of the reactance coils, so that much of the advantage gained by using the reactance coils is lost. Also there is the possibility that when one section is more heavily loaded than another, the cables on one section will be overloaded, due to the angular displacement in voltage between the sections. Thus it is desirable when using busbar reactances to feed one sub-station from one section of the busbars, rather than from several sections, or, failing this, to use fairly large feeder reactances. When the feeders are very long this may not be of importance. When suitable feeder arrangements can be made, there seems no doubt as to the great desirability of using busbar reactances in large stations as an insurance against a complete shut-down.

In the case of feeder reactances, the greatest flexibility is obtained by placing reactances in each feeder; this is quite feasible where the feeders are of large size and comparatively few in number, but where there are many

feeders of small size the number of reactance coils becomes excessive and group feeding must be adopted.

Reactances in generator leads present the simplest problem, once it has been decided to install them. The only difficulty is to determine whether they are necessary in addition to the busbar reactances. The following points should be considered:—

If the generators will stand a short-circuit, reactances serve very little purpose except to protect the system in case of a generator breakdown and to reduce to a small extent the current that flows into a short-circuit. Busbars may be so thoroughly insulated as to reduce the possibility of a short-circuit to almost a negligible amount. It is now becoming fairly common practice to use single-core cable between the generators and busbars. These cables can be so arranged that an "earth" is almost certain to occur before a short-circuit, and a suitable discriminating device will cut off the generator and open its field circuit the instant that an "earth" occurs. Thus the chances of a short-circuit on the generator terminals may be greatly reduced. But there is still the possibility of a mis-phase where more than one generator is connected to the same busbar section; and if the generator will not withstand such an accident it will be advisable to use reactances in its leads.

In order to show a typical lay out for a large station, the following conditions have been assumed:—

Total generator capacity, 100,000 kw.

Seven generators (4 of 10,000 and 3 of 20,000 kw.).

Feeders of 2,000 and 5,000 kw., the 2,000-kw. feeders being arranged in groups of 10,000 kw. each.

A diagram of connections is shown in Fig. 10. In this case, the busbars are divided into five sections of

20,000 kw. each. Each section of the busbar is fed either by one large generator or by two small ones. Between each busbar section is connected a reactance coil, which, with the full-load current of one busbar section, will give a voltage across it equal to 50 per cent of the normal.

Each reactance coil is arranged so that it may be short-circuited by means of an oil circuit-breaker, and an oil circuit-breaker is also placed between sections of the busbars.

A ring busbar system is adopted, which increases considerably the flexibility of the arrangement.

Each group of feeders will have in series with it a reactance coil, which should be of such a size that with the group fully loaded there will be a voltage across it of approximately 5 per cent. Each 5,000-kw. feeder should have in series with it a reactance coil, which will have a full-load voltage across it of approximately $2\frac{1}{2}$ per cent. In series with each generator there should be a reactance of approximately 5 per cent.

It is preferable to have each sub-station fed from one section of the busbars in order that circulating currents may not flow through the cables from one busbar section to another. The ring-main busbars and double set of feeder switches permit any sub-station to be switched over to another section in case of necessity.

Discriminating devices should be provided so that in the event of an "earth" on any feeder it will be cut out. Also each generator should be arranged in a similar manner, so that it will be cut out in the case of an "earth" or other fault developing on it.

In order to give an idea of what will occur in the event of a fault on a system such as that shown in Fig. 10, the values given in the following table have been calculated.

TABLE SHOWING CURRENTS AND VOLTAGES UNDER FAULT CONDITIONS WITH DIFFERENT REACTANCES.

No	Position of Fault	REACTANCE			CURRENT		VOLTAGES	
		Location and Size			Times normal of 1 Section		Percentages of Normal	
		Busbar	Generator	Feeder	Fault	Generator	Faulty Section	Adjacent Sections
1	Feeder	0	5	0	100	20	0	0
2		0	10	0	50	10	0	0
3		0	5	5	16.6	3.3	83.3	83.3
4		0	10	5	14.3	2.86	71.5	71.5
5		0	5	10	9.1	1.82	61.0	61.0
6		0	10	10	8.33	1.67	83.3	83.3
7		50	5	0	23.6	20.0	0	61.6
8		50	10	0	13.4	10.0	0	85.4
9		50	5	5	10.8	9.2	54	66.2
10		50	10	5	8.05	6.0	40.2	61.2
11		50	5	10	7.05	5.05	70.5	97.50
12		50	10	10	5.71	4.20	57.1	93.7
13*		50	10	any	10 + 4.65	10, 2.7 and 0.85	46.5	60.1
14†	Generator	0	10	"	10 + 8.2	10, 1.82	81.8	81.8
15†	"	0	10	"	20 + 13.3	20 and 3.3	66.6	66.6
16†	"	50	10	"	20 + 2.92	20 and 1.25	14.6	88.2
17	"	With 5 per cent total reactance (i.e. no external reactance in generator leads) the results are the same as for a feeder short-circuit given above with zero feeder reactance.						
18	Busbar	The same results as given above when a short-circuit occurs on a feeder with zero reactance.						

* Two generators feeding one section of busbars. First value under fault current is that supplied by faulty generator. Second value is that supplied by other generators. First value under generator current is that in faulty generator. Other values indicate the current in other generators.

† One generator feeding one section of busbars, otherwise the same as 13 and 14.

This table shows the value of the current that will flow into the fault and in the generators, with different values of reactance in different parts of the system. The busbar voltage is also given for the faulty section, and for the adjacent sections.

In each case, the value of the reactance is expressed as a percentage of the normal voltage, with the full load of one section or of one generator flowing through it.

The current is given in terms of normal rated load of one busbar section, and is the maximum at the instant of short-circuit, neglecting the doubling effect and also neglecting any current that may be regenerated by synchronous apparatus operating on the system. The values of current and voltage will, in general, fall off very rapidly as the armature reaction of the generators asserts itself.

THE DESIGN OF CURRENT-LIMITING REACTANCES.

Current-limiting reactance coils have heretofore been designed almost exclusively without iron in the magnetic circuit. The larger coils have usually been cooled by means of an air blast. On account of the great shocks to which these coils are subjected it is necessary to adopt a very strong mechanical construction, and the winding must be so laminated as to reduce the eddy currents caused by the stray fields. The General Electric Com-

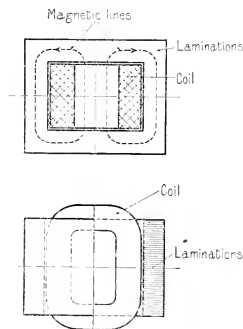

FIG. 11.

pany of America use a winding of stranded cable wound in concentric layers. The core is of concrete, and the different turns and layers of the winding are spaced and held rigidly in position by spacing blocks of porcelain which are bolted together and to the core, thus making an extremely rigid construction. Each coil is usually placed in a cubicle made of bricks or tiles, which acts as a flue for guiding the air blast through the coil and prevents any person from coming in contact with the winding. On account of the heavy stray field outside the coil it is impossible to place it in a metal case, and it is advisable to keep it a considerable distance from any steel structure.

The American Westinghouse Company use a winding of

stranded cable, but wind a number of pancake cores which are placed side by side. There is no central coil, and the turns and layers are held in position by means of fireproof partitions which are bolted together. This gives a very sound mechanical construction, and is easily adaptable for a wide range of capacities.

The air-core construction has been adopted upon the assumption that it would not be possible to use an iron circuit and obtain a straight line relation between the voltage and current without increasing the size, price, and losses in the coils. While this may be true for feeder reactances where the maximum short-circuit current is perhaps 20 to 30 times the normal current that the coils must carry without overheating, it is not true in the case of busbar reactances where the maximum current will as a rule not be more than 4 to 10 times the normal current, and under certain circumstances the coil with a partial magnetic circuit will prove more economical than the air core even for generator reactances.

The larger the capacity of a reactance coil and the lower the frequency, the less will be the advantage obtained by using iron in the magnetic circuit.

Fig. 11 shows diagrammatically the construction of a choke coil having a partial iron circuit. It will be noted that inside the coil there is no iron, and therefore the air-gap is very large, while the coils are enclosed by a complete iron circuit. This construction has the following advantages compared with air choke-coils:—

1. Under normal working conditions there is no external field, so that the whole coil may be placed in a metal tank without fear of eddy currents, as though it were a transformer.
2. The coil may be operated in oil, thus avoiding the necessity for forced cooling, though the air-blast type can be used if preferred.
3. Less room in the station will be required, as it is possible to place the apparatus in the same position as a transformer and to handle it just as though it were a transformer.
4. The metal containing case may be earthed so that there can be no danger from accidental contact with the coil.
5. It is not essential to use a laminated cable winding, as the direction of the flux is such that a solid winding may be arranged by careful designing to avoid any serious loss.
6. The construction being practically the same as that of a transformer, standard transformer parts may be used to a very great extent, thus reducing development costs and the time required for manufacturing.

APPENDIX.

THE EFFECT OF BUSBAR REACTANCES ON THE PARALLEL OPERATION OF ALTERNATORS.

A reactance coil connected between two alternators influences parallel operation in two ways:—

It limits the current that can flow between the two generators.

It necessitates an angular displacement between the voltages of the two generators if there is a transfer of energy through the reactance.

It will be assumed in what follows that the induced voltages of the alternators are equal, that the resistance in circuit between the alternators and in the armatures may be neglected compared with the reactance, and, further, that the alternators are of the non-salient pole type, so that it is allowable to assume the synchronous reactance to be independent of the relative position of the stator and the rotor.

In Fig. 12 O A and O B are the induced voltages of the two alternators which are displaced in position by the angle α , while B A is the vectorial difference between these voltages. This voltage difference will cause a current to flow between the two alternators in a direction O C at right angles to A B. This current is proportional to A B and inversely proportional to the reactance in the circuit, including the synchronous reactance of the alternators. This current produces a torque proportional to

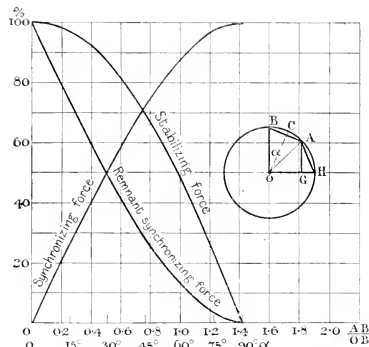

FIG. 12.

$BA \cos \alpha/2 = OA \times 2 \times \cos \alpha/2 \times \sin \alpha/2 = OA \sin \alpha$, which corresponds to O G in the diagram. This is the force tending to pull the two generators into exact synchronism, and will be called the synchronizing force. The force opposing a small alteration of the angle α would be proportional to $\frac{d}{d\alpha} \sin \alpha = \cos \alpha \frac{d\alpha}{d\alpha}$. This is the force tending to prevent any angular displacement from any particular angular position of the voltages, and will be called the stabilizing force. Thus the synchronizing force between the two alternators is a maximum at 90° , being equal to O H in the diagram; but in this position a small alteration in the angle will cause no alteration in the force between the two alternators, so that they cannot be run in parallel with this phase difference between their voltages. In other words, the stabilizing force is zero. On the other hand, when $\alpha = 0^\circ$ the two generators are in exact synchronism and the synchronizing force is zero, while the stabilizing force is a maximum.

Assume that the alternators are running with a constant angle of α between their voltages, and that a torque proportional to O G is acting between them. If now an

additional force proportional to GH is applied in such a direction as to retard the lagging or to accelerate the leading alternator, the angle between the two machines will be increased to 90° and they will drop out of step. $GH = 1 - \sin \alpha$ is therefore a measure of the additional force required to pull the machines out of step when there is an angle α between their voltages. This force may be called the remnant synchronizing force, and is the difference between the synchronizing force at angle α and the maximum synchronizing force at angle 90° .

Thus there are three forces which must be considered:—

1. The synchronizing force, tending to pull the voltage into phase. This is proportional to the sin of the angle of displacement α .
2. The stabilizing force, tending to prevent any displacement from the angular position α . This is proportional to $\cos \alpha$.
3. The remnant synchronizing force, which is the difference between the maximum synchronizing force and that at the angle α , and is proportional to $1 - \sin \alpha$. This force is therefore a measure of the ability of the generator to remain in synchronism when running under conditions corresponding to an angle α between their electromotive forces.

In order to show the relation existing between these three forces at all angles between zero and 90° , the curves shown in Fig. 3 have been plotted, showing $\cos \alpha$, $1 - \sin \alpha$, and $\sin \alpha$, as functions of the ratio B A/O A, which is the vectorial difference of the voltage of the two alternators divided by their voltage. On the horizontal scale is also given the values of α for the different ratios.

In order to obtain a concrete idea of the values involved, it will be assumed that the two generators have each a synchronous reactance of 50 per cent. Then the maximum current that can circulate between them under a 90° displacement is 1.41 times the normal, i.e. $AB = 1.41$ per cent. Since the current is displaced 45° from the voltage of each generator, the torque = $1.41 \times 0.707 = 100$ per cent of normal, i.e. the maximum synchronizing force = 100 per cent of the full-load torque of one machine. If a reactance of 50 per cent is placed between the two generators, the maximum current that can flow under 90° displacement = $1.41/1.50 = 0.94 \times$ full-load current, and the torque = $0.94 \times 0.707 = 66.6$ per cent of the full-load torque. Thus at any angle the synchronizing force = 66 per cent of that which would exist were there no reactance between the generators.

Assume that 50 per cent reactance is to be placed between two generators that are to operate in parallel with 50 per cent of the normal load of one generator passing into the busbar section of the other generator. This transfer of load corresponds to a voltage across the reactance = $0.50 \times 0.50 = 0.25$ per cent of normal, or $B A/O A = 0.25$. In this case the angle $\alpha = 14^\circ 22'$. This reduces the remnant synchronizing force to 75.5 per cent of the maximum value given on the curve. Also the stabilizing force is reduced to 98 per cent of the maximum. These figures are taken from the curves (which are based upon the assumption that there is no external reactance in circuit). The introduction of the synchronous reactance would therefore reduce the above values to 66.6 per cent of those given on the curve. This is equivalent to a remnant synchronizing force of $75.5 \times 66.6 = 50.3$ per cent, and a stabilizing

force of $0.8 \times 66.6 = 65.2$ per cent of the values that would exist with no external reactance in circuit. These values should in most cases be perfectly satisfactory. Where there is a group of generators in parallel on a busbar section which is separated by a reactance from another group, the synchronous reactance of the whole group must be considered in determining the value of the external reactance.

In the manner indicated above it will be possible to calculate the forces existing between any two alternators or groups of alternators provided the synchronous reactance, the size of the busbar reactance, and the transfer of energy from one generator or busbar section to another is known.

In the above example it is assumed that the generators are rated at unity power factor. If the rating is at 80 per cent power factor the forces in the above examples should be multiplied by 1.25. Also it must be noted carefully whether the busbar reactance is rated on unity or on a lower power factor.

It is obvious that the above method of treating the subject would have to be carried much further in order to cover all possible cases, but it is believed that it will serve to indicate in a general way the principal factors that are involved.

Among the papers which have been published recently on this general subject, and in the English language, the following may prove of interest :—

DISCUSSION BEFORE THE INSTITUTION, 26TH MARCH, 1914.

Mr. Woodhouse.

Mr. W. B. WOODHOUSE : There is a natural tendency—I suppose based on past experience—to look with suspicion at all protective devices; so many which were once in use have been discarded. In considering, therefore, any new apparatus I think the first criticism is: What is the necessity of these particular devices? And the next is: What additional disadvantages do they introduce? Reactance coils are introduced broadly for two reasons, which the authors have given. The protection of apparatus is the first; the second is the limitation of disturbances caused by a breakdown on any particular part of a system. Practically all the apparatus that we use on alternating-current supply systems possess reactance as well as resistance, with one important exception, the switchgear; and the question naturally arises whether we can take advantage of the reactance that is inherent to the apparatus that we use. The protection of a generator by an external reactance coil is unnecessary if that generator can be built to withstand being short-circuited; and we all know that the progress of the last few years has been in the direction of constructing alternators and synchronous machinery generally which will withstand being short-circuited. We have been assisted in that by the introduction of automatic pressure regulators, and nowadays the 6 per cent reactance to which the authors refer on page 512 as an average figure for a generator, seems to me to be much too small. I should think that modern practice tends more to the use of 10, 15, or even 20 per cent reactance. If alternators are built with that reactance they can protect themselves; and therefore a reactance coil in a generator circuit is unnecessary for the protection of the generator. There is, of course, the momentary rush of current to consider when a generator is short-circuited, and we hope that it is not beyond the powers of the designers of generators to effect a reduction of that. The same

holds true, I think, as regards static transformers. It is quite easy to build a static transformer with considerable reactance, and it is possible I think to build it to withstand being short-circuited. Feeder protection is the next important matter; but this seems to me rather a question of the limitations of the switchgear that is used. It is a number of years since Mr. Andrews showed us how to protect feeders by introducing reactance; a modern protective device, the split-conductor system, follows on those lines. So far then as the apparatus to be protected is concerned, we are left with only switchgear to consider. The disconnection of a faulty section by switching is equivalent to the gradual introduction of resistance into the circuit. In doing so the switch has to absorb a certain amount of energy—in some cases a very considerable amount of energy—and those of us who have knowledge of the destructive results of switch failures will realize that there is a very real need for some additional protection unless the design of switchgear can be improved by introducing reactance in the switchgear itself. The growth in the amount of energy absorbed by a switch follows a very definite law: it increases to a maximum and then decreases. That maximum is greater the greater the amount of reactance in the system. I do not propose to discuss the theory of the subject, or of the amount of power that has to be absorbed by a switch in opening a circuit; it is quite a simple matter, depending amongst other things on the amount of reactance in the system as a whole. We thus have the curious condition that to protect our switchgear we add reactance, which in itself is destructive owing to the fact that energy is stored in it. For the protection of the switchgear, I think there is no doubt that reactance is not only advisable but essential. In considering the limitation of disturbances it seems to me that the proposal to introduce reactance coils in the generator and feeder

Mr. Woodhouse.

circuits is scarcely necessary except under special conditions, since the diagrams and particulars in this paper show that it is preferable, as covering a much wider range of disturbances, to put those reactance coils in the busbars, *i.e.* to have sectional reactance coils. With a proper use of sectional reactance coils and a correct design of apparatus, both feeder and generator reactance coils seem unnecessary. It is left to the operating engineer to consider the cost of all this. We have first of all the cost of the reactance coils; and secondly there is the cost of using them. The latter, however, is very small compared with the cost of compensating for the reactance that we have introduced. The pressure regulation of the system is made worse by these devices. We must therefore compensate for that by synchronous machines and synchronous condensers, and we have to add the capital cost of those machines and the cost of running them, which is a fairly large sum. The authors have said, and I fully agree with them, that the whole question is one of insurance. The introduction of these coils is in the nature of paying an insurance premium. It is a question of what is the value of the risk. If the apparatus can be improved and the risk reduced it is possible to use smaller reactances; and obviously the smaller the reactance the simpler is the system and the less costly it is to operate. The authors' appendix on parallel running is interesting, and I should like to know what they think are the limits of reactance that may be introduced between machines whilst still retaining satisfactory running. I have for some time been running two generators in power stations about 13 miles apart with a natural sectional reactance in the overhead transmission line connecting the two stations; its reactance is of the order of 10 per cent; the reactance of each generator is about 20 per cent; and under these conditions there has been no difficulty at all in parallel running. It would, however, be interesting to know what is the limit—how much reactance can safely be introduced between the machines while still preserving satisfactory running conditions. The limits to which we can go, such as those that I have mentioned, are obviously made possible by the use of steam turbines, so that although we may have introduced disadvantages by using high-speed generators, we have obtained corresponding advantages owing to the prime-movers that drive those generators.

Mr. G. W. PARTRIDGE: I am very much interested in the use of these reactance coils, and more especially in their use in the case of large turbo-generators. As far as I am aware the London Electric Supply Corporation was the first supply authority in this country to make practical experiments on reactance. These particular reactance coils, I may say, have now been in use for over three years, and have proved in every way of advantage in taking care of short-circuits. It became imperative that some sort of current-limiting device should be used in connection with our power supply to the Brighton Railway, which is a high-tension single-phase railway in which the electrical equipment on the trains is connected direct to the busbars; that is to say, there is no intermediate sub-station or transformer to act as a buffer in the case of a short-circuit. I have seen the large concrete-core reactance coils which are used in America, and, provided there is sufficient room in the generating station, they are very satisfactory. The coils

used by my Company contain a certain amount of iron, and weigh when complete between 13 and 15 tons. They are designed to withstand momentary short-circuits amounting to 20,000 amperes. The advantage of this form of reactance coil appears to me to be that it takes up less room, it can be placed in any position without fear of any stray fields, and, lastly, as the authors have pointed out, it can be made exceedingly strong and able to withstand the stresses that are set up in it during short-circuits. I should like to ask the authors their opinion of the arrangement of reactance coils on busbars which is shown in Fig. A here-

Mr. Partridge.

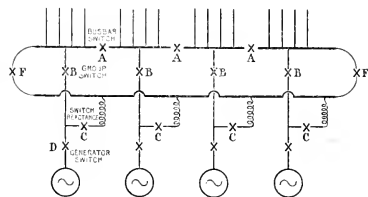

FIG. A.

with, and which is somewhat different from that illustrated in the paper. With this arrangement one can get great flexibility. On top load, for instance, with all four generators running, by opening the switches A and F each generator feeds its own group of circuits, or, if preferred, by opening group switches B and closing F the four generators could supply through the four reactance coils. At times of light load one generator could feed any particular group of circuits direct, and by opening the switch A on either side of the group could feed the rest of the circuits through the reactance, or could feed three groups direct, leaving the fourth group supplied through the reactance coil. The arrangement shown appears to have the following advantages:—(1) Circuits may be supplied at different pressures if required; (2) the danger of bad synchronizing is avoided; (3) short-circuits on sections of busbars or groups are protected against, the switch C opening and cutting off the faulty section; (4) the number and size of the reactance coils is reduced to a minimum.

A few weeks ago I made a large number of experiments on short-circuits, with and without reactance. Altogether 23 short-circuits were made, and by means of an oscillograph we were able to take observations of (1) the momentary short-circuit current with and without reactance coils; (2) the rise in pressure across the terminals of the oil switch when the circuit was opened, and the actual behaviour of the switch itself; (3) the effect on the field when the generator was short-circuited. These experiments were not entirely in connection with the behaviour of the reactance coils, but I should like to show a few of the oscillograph curves which were obtained on this particular occasion, the records being taken by our President, Mr. Daddell. The tests were made on a 7,500-kw. turbo-generator. These generators have a very high internal reactance, being specially built for the rather severe service of the single-phase railway, in which, as I

have previously pointed out, the trains are fed direct from the busbars. Fig. B shows the result of a short-circuit with the reactance coil in series. It will be noticed that the switch breaks the circuit in about $\frac{1}{8}$ second. The current was between 4 and 5 times the full-load current of the generator, that is to say, between 3,500 and 4,000

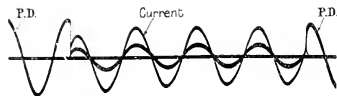

FIG. B.

amperes. The amount of the short-circuit current varied considerably, depending on the particular point on the wave-form at which the short-circuit occurred. Fig. C shows the effect of breaking a short-circuit without the reactance coil in circuit. The effect of this short-circuit was to make the switch arc badly. This arcing of oil switches, which is clearly shown on the oscillograph, is a very serious fault. A great many switches have been blown out and destroyed owing to their not being

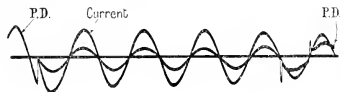

FIG. C.

strong enough to resist the explosion that takes place during the arcing. In other cases the busbars and the terminals have been damaged by the conducting gases escaping and short-circuiting the bare conductors. I always make it a rule now that all bare conductors near oil switches are to be covered up. Last, but not least, there are the very serious rises of pressure and surges that are set up by the arcing in these oil switches. The use of reactance either inside the switch or externally will tend to get over this difficulty of arcing. Fig. D is a record from an oscillograph which

FIG. D.

was connected across the terminals of the oil switch to see what rise of pressure took place; it will be seen that the oil switch arced badly, and from my notes of the test I see that the oil was again thrown out of the oil tank. There was no pressure rise across the terminals of the oil switch. Fig. E shows the effect of a short-circuit on the exciting current of a generator. There was no reactance in series on this particular occasion. It will be noticed that there was alternating current in the field before the short-circuit occurred. As soon as the short-circuit came on, the exciting voltage was reversed, and the field current was increased to about $2\frac{1}{2}$ times the mean exciting current. It will be noticed that the alternating current has twice the

periodicity of the main current. I suggest that it would be a good thing if a reactance coil were placed in the field circuit so as to choke back this alternating current. It certainly would have no effect on the continuous current, and I expect it would tend to reduce the short-circuit current of the main generator itself. As soon as the short-circuit was cleared, it will be seen that the field current gradually fell and became normal, the pressure also becoming normal afterwards. In the other two experiments, of which I have not shown the curves, we were able, by means of reactance coils, to short-circuit the

Mr.
Partridge.

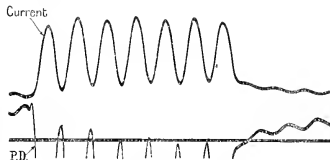

FIG. E.

generators, not opening the switch at all, but allowing the short-circuit to rise and gradually die away as the machine became demagnetized. The last experiment was the effect on the third phase of a three-phase generator when two phases were short-circuited. We disconnected the third phase from the neutral point and connected the oscillograph across it. On short-circuiting the other two phases we found, much to my surprise, that we had no rise of pressure in the idle phase, the phase itself being only slightly distorted.

Mr. J. SHEPHERD: I think that anybody who has had charge of a large alternating-current power station sooner or later comes to the conclusion that reactance is necessary in some form or other. At the same time we must not forget that two years ago reactance coils were practically unknown; but now (in Fig. 10) the authors have introduced them on a large scale. I have made an approximate estimate of the cost of such an arrangement of reactance coils, and I find that it is something like 10 per cent of the cost of the generating plant. If to that is added the cost of the connections, blowers, air filters (that is if they are air blast, or water coolers if they are of the oil type), probably the cost would be something like 12 to 15 per cent of that of the generating plant. I have some doubt as to whether a case has yet been made out for such a wholesale provision of reactance. I should like the authors to give us some idea of the size of the system or station for which the provision of reactance coils to this large extent is really justified. I notice with some surprise that while the authors refer very largely to reactance, which is only one form of protection, nothing is said about relays, which are another form of protection. I think that the provision of a suitable relay is probably a more sensible method of protecting the feeders than by inserting reactance coils in them, because, after all, a short-circuit on a feeder is rarely of an instantaneous nature, and it generally takes some little time to develop, that time being sufficient for a good system of relays to isolate the feeder. I think, however, in the case of generators there is need to introduce reactance, espe-

Mr.
Shepherd.

cially in the older machines that were designed with the view of good regulation, and therefore of low reactance. For instance, a machine purchased about four or five years ago probably had a reactance of something like 3 or 4 per cent, whereas a modern machine would certainly be built with a reactance of 6 or 7 per cent; and if it had to work in a large station under rather adverse conditions the designers would probably introduce something like 10, 15, or even 20 per cent of reactance inside the machine. Reactance must of course be inserted in the machine circuit, whether introduced into the machine itself or in the form of an air coil or transformer shell without the internal iron. Then, again, if the busbar system is fairly extensive there are always risks of short-circuits. The simplest place in which to install reactance coils seems to be wherever the busbar is cut into sections. The provision of reactance coils becomes very expensive. If the air path or concrete type is used the coils cannot be placed in any ordinary building without a risk, I will not say of melting the steelwork, but certainly of making it very hot. If they are of the iron type they become very heavy, and it is very difficult to find room for them, especially in some of the older power stations, where it might be necessary to construct a special building to house them. There is another form of protection which is not mentioned in the paper and on which I should like to hear the author's opinion, namely, what has become of the large induction generators that were so highly spoken of by Dr. Steinmetz about four years ago when they were introduced into the 59th-street station in New York? Those generators seem admirably suited for running in parallel with synchronous machines, as they give no current when short-circuited.

Mr. E. P. HOLLIS: I think it is quite time that we in this country studied the uses to which reactance can be put in large power schemes. The present paper does not by any means exhaust the uses for reactance coils. There are many other uses, such as for constant-potential transmission and pressure-limiting on extremely long lines. The paper concentrates attention on one particular phase of the question, namely, the protection of the power station. One of the first effects of reactance coils is to remove from the system all danger of complete disablement, and it will be appreciated that the engineer having charge of the operation of a reactance-protected system has a large load removed from his mind. No longer is a system dependent on the idiosyncrasies of an overload relay for its safety, or on the reliability of a current transformer. The advent of reactance coils involves many changes. For instance, it is no longer essential to earth the star point of only one generator. The high reactance offered to triple-frequency currents is sufficient to damp down most third harmonic currents to a negligible value. Again, heavy expenditure on quickly operating switchgear is unnecessary, and the rating of existing switchgear can be increased. It has been feared that the advent of reactance in generators would seriously impair the regulation of the system, but it is necessary to look at the matter from the point of view that since the voltage regulator is now available the worst regulating generator can be made to give a fairly constant pressure, and I know of a number of installations in which generators have been purposely given large reactance in the full knowledge that a voltage regulator was to be used. Objections have been

raised to the use of reactance coils in long feeders, because it is said that they make worse an already bad regulation. But reactances can be used advantageously in these cases with the effect of improving the regulation if one provides synchronous plant at the receiving end. Such reactance coils also act as current limiters. By varying the amount of leading current drawn from the line it is possible by utilizing the phenomenon of the rise in voltage due to the leading current flowing through the reactance, to run the feeder at a constant potential, irrespective of load. Against this it is said that the cost of the synchronous plant would be prohibitive. That is not true in many cases. The provision of the reactance of the synchronous plant improves the rating of the line, as well as its efficiency, and it does not require a very long line in order to make the installation of such plant profitable. This is quite apart from the advantages gained by constant potential at the receiving end. There are very many lines in this country which are working at below 75 per cent of the output at which it would be possible to work them were a constant-potential system adopted; and transmission lines are very costly. For the protection of generators I find that many engineers while accepting the benefits of reactance prefer to use it internally only, and do not see any substantial reason for the use of external reactance coils. Internal reactance, however, does not protect a generator from the great influx of power which occurs when that particular generator breaks down, or against a concentration of potential across the end turns due to high-frequency surges. An external reactance would save the machine windings from that total destruction which would be possible were the reactance internal to the machine. I want to join issue with the authors when on page 512 they assert that "Where a step-up transformer is connected between a generator and busbars, it may be designed with high internal reactance, thus giving the effect of a reactance coil without any appreciable additional cost." That is a view, I know, which is largely held. But no amount of internal reactance in a transformer protects the generator against that likely contingency of the transformer itself breaking down. It may be argued that the same can be said if the reactance coil itself broke down. That, of course, is quite true, but there is no comparison between the factor of safety of an air-core reactance coil and that of a transformer where one has high-pressure conductors in close proximity to metal-work, and where the precautions against breakdown cannot be nearly as effective as in a separate reactance coil. Again, it does not by any means follow that reactance internal to the transformer will protect the generator on a short-circuit at the most favourable position, namely, on that side of the system remote from the generator. High reactance is attained in many transformers by the use of magnetic shunts, and it is well known where reactance is obtained by the use of an iron circuit that such reactance is useless in the face of a heavy short-circuit current, owing to the great reduction of the permeability of the iron path.

Reference has been made to the value of reactance coils in the event of a misphase in the synchronizing of generators, and the "doubling effect" has also been mentioned. There may also be a quadrupling effect in the matter of pressure, for on many oscillograms the pressure wave does not oscillate about the

Mr. Shepherd.

Mr. Hollis.

zero axis, but entirely above it, so that the pressure between the windings and earth may be four times the normal. There is a fashion nowadays to use self-synchronizing machines, motors, and rotary converters. I believe in self-synchronizing generators, the synchron-

ance. A reactance of fixed amount had to be made so high that it would limit to a reasonable value the flow of current on switching in, and also so low that it would permit the generators to run in phase when they had settled down to normal running. The compromise

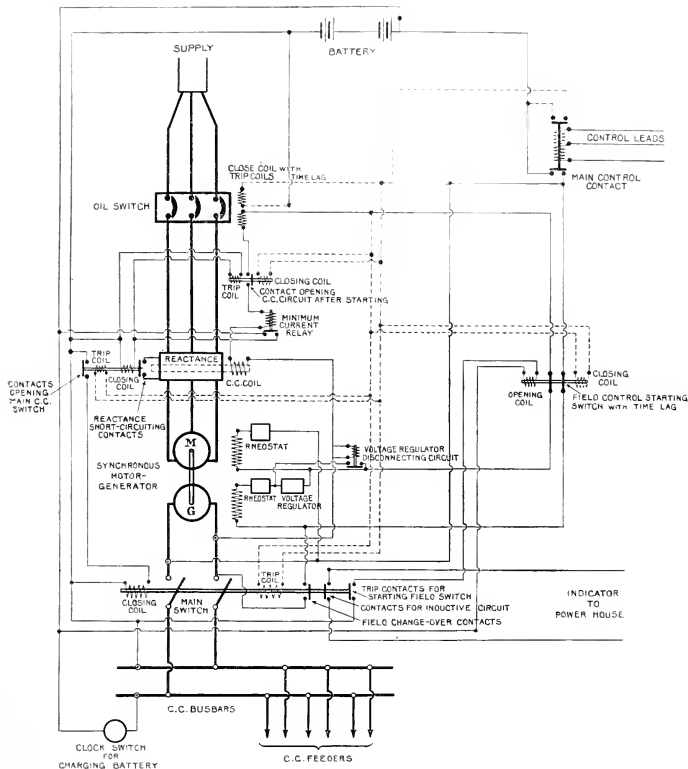

FIG. F.—Starting Connections of an Automatic Sub-station with Adjustable Reactance Coils.

ing current being limited by reactance coils. This is a very old method of synchronizing, for I am told that on the earlier Ferranti boards synchronizing coils were provided. I believe, however, that the system has not come into general application owing to the fact that it was not an easy matter to design an adjustable react-

could not be very effective. If a reactance of adjustable value were employed, I think that generators could be synchronized in this fashion with great ease. I have proposed* to make iron-core reactance coils adjustable

* E. P. Hollis, Reactance and reactance coils in power circuits, *Journal I.E.E.*, vol. 52, p. 254, 1914.

Mr. Hollis. by turning to account the phenomenon that if the core of the coil be fitted with a winding through which continuous current is passed, the iron is given a magnetic bias, with the result that the reactance is increased. The value of the reactance is then dependent upon the strength of the continuous current, and by varying this current the value of the reactance can be adjusted. A generator can therefore be synchronized quite easily without any shock, the reactance being gradually reduced until the machines fall into step. Indeed the generator might be run up as a motor in case of emergency, the synchronizing time being used for warming the engine instead of allowing the usual warming period to elapse before starting up.

One of the developments of the future will be the automatic sub-station. I cannot here attempt to make out a case for such sub-stations, but I merely wish to show how adjustable reactance coils can contribute to their design. There are a number of sub-stations at present in operation abroad in which rotary converters are started up by varying the alternating voltage at the end of the feeder by means of an induction regulator, so bringing the converter up to speed, and relays effect the necessary connections on the continuous-current side; but if the feeder is part of a large system and does not radiate straight from the station, such a method of starting is impossible. Fig. F illustrates without elaboration the principle on which the starting connections of an automatic sub-station would be laid out. The sub-station is controlled through a 3-core pilot cable by the system engineer, or the "load dispatcher" as he is called in America. The operation of a 2-way switch under his control starts up or shuts down the high-tension synchronous motor-generator in the sub-station. Immediately the control switch is closed a solenoid completes the two circuits, one exciting the motor and generator from a battery, and the second energizing the continuous-current coil on the reactance core. In addition, this second circuit contains the oil-switch closing coil, a minimum current relay for short-circuiting the reactance when the machine has fallen into step, and a coil which disconnects the voltage regulator during starting, while the current is also made to pass through the generator armature. On switching on, therefore, the oil switch closes and starts the motor-generator, the reactance then being at a high value. As the generator speeds up, its voltage increases and opposes the battery voltage, in consequence of which the continuous current flowing through its armature is gradually reduced and the reactance of the coil diminished. Thus the motor-generator automatically runs itself up to speed. There comes a time when the motor locks itself into step with the supply and the continuous current flowing through the auxiliary coil on the choking coil has fallen to a low value. The minimum-current relay then trips and short-circuits the reactance. This "reactance short-circuiting" switch carries contacts which cause the main switch on the continuous-current side to close. Prior to this with the current through the auxiliary coil falling to zero the voltage regulator is put into circuit, and on the short-circuiting of the reactance raises the generator voltage to the necessary value. On closing, the main switch completes the contacts which change over the field from separate to self-excitation, and the machine then runs under the same conditions in a similar way to other machines installed in auto-

matic sub-stations. Time lags are put on most of the Mr. Hollis switches in order to give the several relays time to act. When the system engineer reverses the position of his control switch a tripping circuit is energized which opens the switches and sets them for starting up. Arrangements are also made for charging the battery at periodic intervals by means of a clock switch; and in order to facilitate this it is arranged that the battery has a smaller voltage than the generator.

In conclusion, it has been represented to me on several occasions that there is no great necessity for us to apply ourselves to the investigation of these very heavy power problems, and particularly of the use of reactance coils on long transmission lines, on the ground that we have in this country no large power schemes or long transmission lines which require such coils. I do not accept that as true, but even if it were, from the Imperial point of view it is material that we should investigate this question, since in our Colonies and Dominions large power schemes and long transmission lines will shortly have to be installed.

Mr. E. B. WEDMORE: I should like to draw a broad distinction between reactance coils used in series in the system and those employed for paralleling parts of the system. If the reactance coil is in series, the whole of the load current must pass through it, and it introduces all the objectionable features of additional reactance in the circuit. Paralleling reactance coils, however, carry only a small portion of the load current at any time, and thus have relatively little influence on the power factor of the system. Other things being equal, one would therefore prefer the use of paralleling reactance coils to series reactance coils. Fig. 10 shows the use of the different kinds of reactance coils that have been discussed, and I should like to follow in this figure the function of the several different kinds. It is generally agreed that reactance in the generator circuits, whether external or internal, is necessary for the protection of the machines themselves. It is not commercially practicable in the present state of the art to protect the switchgear in a station containing 100,000 kw. of plant by the insertion of reactance coils at this point. There are several stations now in contemplation of a capacity of about 100,000 kw., so that the problem presented by such a case is one of immediate, considerable practicable importance. The diagram illustrates such an installation. In order therefore to protect the numerous switches shown in this diagram connected directly to the busbars, it is necessary to employ some further means, and we choose by preference paralleling rather than series reactance coils. The busbar section reactance coils by cutting up the system into sections and limiting the transfer of current have a limiting effect on the short-circuit current on every switch shown in the diagram. Generator or feeder reactance coils have a similar effect, but do not protect the switches in the case of a fault on the busbar side of the reactances. It might be thought that by careful design one might eliminate the risk of such an accident occurring, but one has to remember the innumerable sources of accident which lie outside the control of the designer, and which exist even in the best-regulated stations. Having regard to the supremely important position in the system occupied by the main station busbars, it is essential that one

should provide means to ensure that the switches connected thereto will not be strained beyond their limit of rupturing capacity. This is the first function of the busbar reactance coils. The second function is to limit the short-circuit current, which can flow out of the station into a section of the distributing switchgear. The use of feeder reactance coils for these purposes has the disadvantages associated with series reactance coils. I take it that there will be very few stations in the immediate future having an output of 100,000 kw. in which we shall not find step-up transformers employed to raise the voltage to, say, 20,000 or 30,000 volts. These transformers are likely to be installed in the feeder circuits, and their inherent reactance will assist in limiting the short-circuit current outside the station itself. The size and therefore the cost of busbar section reactance coils depends upon two features, namely, their ohmic value and their current-carrying capacity. The ohmic value of the reactance is that feature which limits the current transferred from section to section on a short-circuit, and is the feature which we rely on to give protection. The current-carrying capacity determines the amount of load current which can be transferred through the reactance coil. The protection provided by sectionalizing the busbars may be increased in two ways, that is, either by decreasing the size of the section, or by increasing the ohmic value of the reactance. I see that the authors suggest reactance coils with an ohmic value giving a 50 per cent pressure-drop on the rated output of one section. This figure appears to me altogether too high. Supposing that no reactance is used, the short-circuit current in the case illustrated will be 50 times the output of the section. If an infinite reactance is provided, the short-circuit current will be 10 times the rated output of a section. The proposed 50 per cent reactance reduces the short-circuit current to approximately 13 times the output of the section, which nearly approaches the result obtained with an infinite reactance. The first 5 per cent reactance inserted is very much more effective than the last 5 per cent. The addition of, say, 5 per cent reactance will have hardly any effect on the limiting value, whilst it will affect the cost by plus or minus 10 per cent. This indicates that the provision of reactance has been overdone. I find that an ohmic value of 20 or 25 per cent gives a more satisfactory commercial solution in the above case. If 50 per cent is necessary with sections of the size proposed, one should consider whether it is not better to obtain protection by reducing the size of the sections themselves.

There is a second objection to the use of so high an ohmic value, and it is this: In order to operate the plant without excessive differences of voltage between the sections, one cannot transfer from section to section through the reactance coils both heavy energy and magnetizing currents. Say one machine has been shut down and current is being transferred from adjoining sections to help out the remaining machine, this machine must now furnish practically the whole of the magnetizing current where 50 per cent reactance coils are employed, and this seriously limits the output of the machine. In determining the current-carrying capacity of the reactance coil, one should avoid introducing the necessity for constant operation of busbar switches. If the current-carrying capacity is too small it will not be practicable to shut down the machines

without resorting to the operation of the busbar section switches. If there are two machines per section, and if the reactance coils have an ohmic value of about 20 per cent, and a current-carrying capacity of about 30 per cent of the output of the section, this will be found to give a very good compromise between excessive cost and excessive switching operations. Referring, again, to the second function of busbar section reactance coils, namely, that of protecting the distribution switchgear, this function is one of the first importance in the pre-ent stage of the switchgear market. The switchgear shown in Fig. 10 already represents a heavy expenditure, but the number of these switches is but a small fraction of the total number of switches that will be required in the distributing plant. There may be many hundreds of consumers in the area fed by this plant, each of whom will have one or more switches on his premises, and one cannot furnish switches for this purpose capable of dealing with "dead" short-circuits on 100,000 kw. of generating plant, or even 40,000 or 20,000 kw. of plant. It is therefore of the first importance that the size of the sections should be kept down to as low a figure as possible having regard to the size of the generating units which must be employed. Even with this protection some further safeguard is necessary at the present time.

We have in the Newcastle district an example of a plant system of the magnitude under discussion. A large number of transformers are employed in the system; the reactance of these transformers and of the cables carrying the current over this wide area has a very beneficial effect in keeping down the short-circuit current on individual switches, yet one knows that difficulties have been experienced with switches in the neighbourhood of the generating stations. The first safeguard is obtained by isolating the sections of the distributing system fed from different sections of the busbar; but this alone is not sufficient. A mile of 0.1 sq. in. cable has a very useful effect in reducing the short-circuit current on the individual consumer's premises, if that feeder is not in parallel with numerous other feeders. It is necessary at present to utilize this feature for the protection of the distribution switchgear. This is done by subdividing the trunk cables leaving a section of the main station into branches of smaller section, leading to small distribution boards. This arrangement has also the advantage that the individual consumer's switch is supported by several switches in series before the generating station is reached, so that in the rare event of failure of one of the smaller switches, the disturbance is limited by one of the larger switches supporting it, so that only a small area in the distributing system is affected. There is an alternative method of limiting a short-circuit on the individual feeder leaving the main station, in which reactance is employed in such a way as to combine the advantages of the series and paralleling types. I refer to the arrangement described in Hilliard's Patent No. 8571/1095, in which he shows the use of two switches in series so arranged that when a fault occurs one switch cuts in reactance and the other then operates to open the circuit.

I wish to emphasize the point raised by Mr. Everest on the design of busbar reactance coils. Such a coil is really a very long extension of the main busbar and requires to be treated with very great respect. I do not

Mr.
Wedmore.

Mr. Wedmore.

like the idea of unnecessarily bringing a large mass of heavily earthed ironwork into close proximity with the main busbars.

Mr. G. C. Allingham.

Mr. G. C. ALLINGHAM: Reference has been made to the fact that by providing the generators with high internal reactance they are protected against large increases of current. There is also the question of protecting them against pressure rises. Such pressure rises tend to break down the end turns of generators or transformers, and by putting an external reactance in series with it the end turns of a generator or transformer are in effect removed to the reactance, thereby reducing the risk of breaking down the end turns in the case of a surge of potential.

Mr. Everest.

Mr. A. R. EVEREST: The authors have given in this paper a very good review of the factors entering into the selection of current-limiting reactances, but there appears room for some discussion regarding the relative value of reactance in the different locations. It may be stated as a fundamental proposition that the generator windings must always be protected. A generator of good modern construction should readily withstand the shock of 10 times full-load current; 50-cycle machines can be designed without difficulty to contain internally the limiting reactance necessary to keep the short-circuit current within this value. With 25-cycle generators this cannot always be done and it is sometimes necessary to provide additional reactance externally to the generator; when such additional reactance is used it should always be placed so as to form a continuation of the generator windings. This, while taking care of the generator, leaves several other points requiring protection, as pointed out by the authors. We wish to keep within reasonable limits the duty thrown upon feeder and distribution switches in the event of a fault occurring beyond them. It is very undesirable that the entire busbar system shall lose its voltage in the case of a fault. In the event of a fault on one generator it is desirable that the current which can be fed into it from the other generators shall be limited, otherwise the generator switch becomes severely tasked. In considering the relative advantages of reactance coils placed between the sections of the busbars as compared with feeder reactances, we find that feeder reactances protect the feeder and distribution switches, but do not protect the generator switch, nor do they limit the lost voltage to any one section of the system. They produce an objectionable regulation drop in the feeder voltage, and the space and cost involved become very serious if a large number of such devices are contemplated. On the other hand, reactance coils placed between the busbar sections give protection to both feeder switches and generator switches, and limit to the busbar section immediately affected the loss of voltage in the case of a fault. The objectionable effect upon regulation is not present, since normally they are carrying little or none of the load current. As regards the different types of construction available, the iron-clad type is probably best applied when it is necessary to place additional reactance close to the generator, since the space required for the air-core type is usually difficult to spare at this point. It must be admitted that the air-core type should have inherently a higher factor of safety against earthing than is provided by the best insulation on coils of the iron-clad type, and

on this account the air-core type appears preferable for reactance coils placed in the busbar sections.

Mr. K. M. FAYE-HANSEN (*in reply*): I quite agree with Mr. Woodhouse that it is very important not to use protective devices without also considering the risks and the cost of installing them, and throughout the paper we have pointed out the disadvantages which are unavoidable if reactance coils are installed. With regard to the protection of the generator by means of generator reactances, this will probably not be so necessary in the case of new generators, because it is now fully realized that reactance in the generators themselves is very useful, and that it is possible and necessary to brace the windings of the alternators so strongly that they will not be distorted. It must be remembered, however, that the reactance here in question is not the synchronous reactance but the armature reactance. The synchronous reactance of modern generators is perhaps in the neighbourhood of 50 per cent, and often very much higher than that. For large 2-pole, and especially for 25-period generators, however, it is difficult to obtain more than 6 or 10 per cent reactance in the armature of the generator itself, and under these circumstances it may be justifiable in some cases to install external generator reactance coils; but I think these will be used mainly in connection with rather older generators that have been designed so that they cannot withstand short-circuits.

I quite agree with Mr. Woodhouse that it is correct to introduce reactance in step-up transformers for the protection of generators when such transformers are used. It is always possible to put sufficient reactance into transformers to limit the short-circuit current to a reasonable value, without using magnetic shunts. With regard to the breakdown of the transformer itself, the only danger of the generator being damaged is if the breakdown is between the terminals of the transformers. We know from experience that breakdowns in transformers are practically always between the various turns, and the current flowing into the transformers before the protective devices can operate will not in this case be of sufficient amount to endanger the generator.

With regard to the cost of operating these reactances, I do not think it will be appreciable, and it will not be necessary to use any synchronous machines to compensate for busbar reactance. In connection with feeder reactances, if due to other reasons there are no rotary converters or synchronous machines running, the feeder reactance would have to be so small that the regulation would not be affected to any extent. We certainly would not advocate installing reactance to such an extent that synchronous machines would have to be installed merely for the purpose of overcoming it. With regard to the question of the limits of synchronous reactance between the busbar sections, while still retaining satisfactory parallel running, it is impossible to give any definite figures because it depends so much on the conditions, such as the governing gear, sudden loads, etc. We think, however, that the figure for reactance given in the paper is rather the upper limit of what ought to be installed. We do not think it would be advisable to make it higher from the point of view of parallel running. With regard to parallel running, it has also to be considered that the reactance and the displacement of the voltages will influence the periodicity of the natural oscillations of the alternators, and in that way

Mr. Everest.
Mr. Faye-Hansen.

eye-
n.

may cause hunting. In deciding what reactance is to be installed, the hunting question has also to be considered.

We certainly think Mr. Partridge's scheme for installing reactance is a very good one. Generally speaking, it is somewhat like that shown in Fig. 10, because the arrangement amounts to putting reactances in the busbars between each generator and making arrangements so that those reactances can be short-circuited if desired. The method of arranging the switches seems, however, to have advantages compared with the straightforward system described in the paper. It was very interesting to see the oscillograms of the short-circuit tests.

Mr. Shepherd referred to the high cost of installing all sorts of reactances as shown in Fig. 10. In Fig. 10 we have installed reactances in all possible places for the purpose of showing where they eventually should be installed, and what influence they have if installed; but, as pointed out in the paper, we do not really recommend that as a rule all sorts of reactance should be installed at the same time, especially not generator reactances if the generators are designed so that they can withstand short-circuits. It should be pointed out, however, that where there are both generator and feeder reactances, each may be smaller than where only one is used. As previously pointed out, it is rather difficult to design alternators of a 2-pole type with such a high reactance as 15 or 20 per cent without raising the cost of the alternator considerably. In these cases the limit at present seems to be more in the neighbourhood of 10 per cent.

Regarding the use of relays as a protection instead of reactance coils for preventing damage due to short-circuits, I do not think that any relay and commercial switch can be made to cut out the fault before full short-circuit current is reached, if the short-circuit is due to mechanical damage, misphase, or similar cause.

Induction generators are practically obsolete, due to the fact that they cannot supply any magnetizing current themselves, and it is therefore necessary that all the other alternators should be very considerably larger in order that they may supply the magnetizing current, and on account of their larger size they supply more current in case of a short-circuit.

I do not agree with Mr. Everest and Mr. Wedmore that air reactance coils are necessarily safer than reactance coils designed with iron cores. I think it is generally recognized that apparatus which are placed in oil and have

the advantage of oil cooling and oil insulation are safer than apparatus that are air cooled; and I think that advantage is important enough to outweigh the disadvantage of having metal in the neighbourhood of the busbars. It is, of course, possible to insulate the complete iron-clad reactance to earth (including the iron) as is done in case of the air choke coil, using large porcelain insulators.

Mr. Hollis has dealt with reactances for a number of different purposes. The question of current-limiting reactances for the purpose of protection is such a large one that if treated in a reasonable way it gives quite sufficient subject-matter for one paper. To deal with all kinds and uses of reactances is much too large a subject for one paper. I have already pointed out that I am of opinion that the internal reactance in a step-up transformer is a good safeguard for the generator, and in such circumstances it would have to be obtained without reactance iron, or with such a section of reactance iron that saturation would not occur.

I am glad to know that Mr. Wedmore agrees with us that busbar reactance is as a rule the most important and gives the most advantages. Mr. Wedmore states that a busbar reactance giving a 50 per cent pressure-drop with the rated output of one section is altogether too large. I agree that it is about the highest advisable limit, but this depends largely on the size of the busbar sections and the amount of energy which it is intended to pass through the reactance coil. It is true that the first 5 per cent of reactance inserted is much more effective than the last 5 per cent in a 50 per cent reactance coil, but the expense of the last 5 per cent is very much less than that of the first 5 per cent, especially if an iron choke coil is used. The main reason for advocating as large a reactance as possible between the busbar sections is to keep up the voltage on the sections adjacent to a fault, especially if the switches should not clear the fault, before the armature reaction of the alternator has time to play an important part in the voltage drop.

As to Mr. Allingham's remarks, of course it is quite true that the reactance coils also serve the purpose of protecting the end turns of generators against voltage surges. In the case of very large generators, however, this will not, as a rule, be of very great importance, because there will very often be one conductor per slot, and under those circumstances there is practically no danger of breakdown between one turn and another.

Mr. Faye-
Hansen.

DISCUSSION ON

"MOTOR AND CONTROL EQUIPMENTS FOR ELECTRIC LOCOMOTIVES." *

BIRMINGHAM LOCAL SECTION, 25TH FEBRUARY, 1914.

Mr. Carter.

Mr. F. W. CARTER: There is little in this paper to which I can take exception. At the bottom of page 388 the author says that the number of steps in the control system is dependent on the characteristics of the motor, and especially mentions that the lower the internal resistance the greater will be the number of steps. This is followed by a comparison between a 550-h.p. motor and a 100-h.p. motor, and it seems to be implied that the former motor has the greater number of steps because of its lower internal resistance. I do not think, however, that it is the resistance only that enters into the question, but rather the pressure-drop due to resistance, which may be no lower in the large motor than in the small motor, and in fact in some cases may be higher. I do not therefore think that as between one large motor and a number of small motors of the same type there need be any appreciable difference in the number of control steps. However, I agree with the author that the slope of the speed-torque curve affects the number of steps required; but the effect is only appreciable when motors of different types are compared, such as single-phase and continuous-current motors. The real consideration that determines the number of control steps is indicated by Mr. Lydall, and is this: The locomotive must be capable of starting as great a load as possible on the heaviest grade, which determines the minimum tractive effort, whilst the maximum is limited by the adhesion of the driving wheels. In order to get as much as possible out of the locomotive, it is necessary to bring the maximum and minimum tractive efforts as near together as is practicable, and a large number of steps are therefore used in the control; thus, the Butte, Anaconda and Pacific locomotives have 17 steps (10 series and 7 parallel). The Detroit-River Tunnel locomotives have 24 steps (9 with all motors in series, 8 with 2 in series and 2 in parallel, and 7 with all in parallel). Motor cars frequently have only 9 steps (5 series and 4 parallel), for the above considerations do not apply to these, and the limiting feature is simply the amount of jerking that the passengers will put up with when the train starts. On page 389 the author states that the self-induction of the winding does not affect the problem of starting, but he implies that in the case of tramway cars there would be some effect on account of the short time required for starting. I have seen a large number of records from automatic instruments of the amount of current taken by a train, and I have always found the rise of current (when each step of resistance is cut out) to be practically instantaneous: I conclude from this that the effect of self-induction is inappreciable in any case. On page 391 of the paper reference is made to the bridge method of transition from series to parallel. The fact that the accelerating current of a locomotive is varied according to circumstances of load, grade, and condition of rails, makes this method of transition less valuable than in the case of motor cars, where the same accelerating current

can be maintained automatically under all conditions; for unless the transition is taken at the current for which the resistances are designed, a shock will be felt at the transition points very similar in nature to that felt when less perfect systems are used. In other words, for locomotive work the bridge system is not as valuable as in motor-car work. On page 396 the author mentions that where a high-voltage continuous-current supply is taken from an overhead line it is not advisable to break the current violently by means of a strong magnetic blow-out, otherwise surges may be set up in the line. I must say that I have never heard of this before, and believe that the 2,400-volt locomotives used on the Butte, Anaconda and Pacific Railway have contactors and circuit-breaking switches fitted with magnetic blow-outs. The author also says that there is very little automatic control apparatus used in this country. I think he might say that there is not very much used on locomotives at all, and the reason is that the locomotive is sometimes required to give all the tractive effort of which it is capable, whilst at other times it is worked with a lower tractive effort. Resistances could hardly be adjusted to give even peaks under both conditions, and it is felt that in the case of such locomotives the control is best left in the hands of the driver.

Mr. E. C. POULTNEY: As a mechanical engineer most of my remarks must be in the nature of questions, which I hope the author will answer. In the first place I should like to know whether any system of air filtering is used in the case of electric locomotives fitted with fans to cool the motors, as I suppose that dust must be drawn in, and if blown into the machines would be detrimental to their working. I should also like to ask in connection with these large electric locomotives—some of which are of 2,000 h.p.—what is their weight per horse-power, approximate cost per ton, and operating cost per mile (that is to say, maintenance and running costs). A feature of the electric locomotives shown is the large power developed compared with steam locomotives, and it would be difficult to design steam locomotives of such high powers as, say, 2,000 or 2,500 h.p. Steam locomotives working with superheated steam develop about 119 i.h.p. per ton of total weight at speeds of from 55 to 60 miles per hour, or about 220 r.p.m. It will therefore be seen that a steam locomotive fitted with a superheater designed to develop continuously 2,500 i.h.p. would weigh with tender about 200 tons; and as 16 sq. ft. of heating surface (including superheater) are required per i.h.p. at 60 miles per hour, this boiler would have to contain at least 4,000 sq. ft. of heating surface. Looking into this question of cost, I find that £55 per ton is the figure given for a modern express locomotive, and that the operating costs for maintenance are from 2'6d. to 5'7d. per mile, that the running costs vary from 7'8d. to 10'1d. per mile, and that the total costs (i.e. maintenance and running), vary from 11'3d. to 15'2d. per train-mile. In conclusion I should like to show a slide illustrating

* Paper by Mr. F. Lydall (see p. 384).

the latest design of six-coupled bogie superheated locomotive designed for service on the London and North-Western Railway. The engine can maintain 1,400 i.h.p. at about 60 miles per hour, and weighs with tender 117 tons. Another slide which I have shows particulars of the draw-bar pull and indicated horse-power of an engine of this type when working heavy trains between Euston and Carlisle; and a third slide shows how steam locomotives have increased in size during the last 20 years. The small engine shown can develop about 500 i.h.p. and is superimposed on a large six-coupled bogie engine capable of developing continuously about 1,200 i.h.p.

Dr. C. C. GARRARD: The author mentions four alternative electric-traction systems. I should like to refer to a fifth, viz. the series system. Some years ago a paper was read before this Institution by, I believe, Mr. Swinburne, in which this system of electric traction was discussed. The series system has come much to the front recently in connection with transmission schemes and also in industrial work; and I should like to know whether there is any possibility of its being applied to electric traction. I am rather surprised that automatic control has not been used on electric locomotives. The author mentions in connection with non-automatic systems the necessity of the driver watching the ammeter. In view of the recent discussions on the subject of railway work generally, it would appear that automatic acceleration would be very desirable in that it would leave the driver more time to watch the signals, etc. It is interesting to learn that cast-iron grids are satisfactory for the resistances on locomotives. There has been some prejudice against the use of cast-iron grids on account of breakage. Certainly in transit, unless special precautions are taken, such grids get broken. I note that cast-iron resistance grids can be used on the locomotives, whereas they get damaged if placed in a goods wagon. In my opinion it is the rough handling that such consignments receive at the hands of the staff which accounts for the breakage in transit. When they are once installed no further trouble results. I should have thought that liquid controllers could have been used on locomotive work with success. For electric winding machinery, for example, liquid controllers are universal. It seems to me that this is a more difficult problem than the starting and stopping of the locomotive, as the winder has perhaps to be stopped and started once or twice a minute. I cannot see any reason why liquid controllers should not be satisfactorily designed for electric locomotives. Reference has been made in the discussion to the grading of resistances for series motors. A graphical method is given by Arnold in "Die Gleichstrommaschine." In conclusion I should like to know whether any action has yet been taken with a view to standardizing electric traction on the railways in this country. In the past history of the railway service we had the battle of the broad and narrow gauges, but it seems to me that this will be overshadowed in the future when we have to co-ordinate the many different kinds of electric traction now being introduced into this country. It seems to me desirable that an attempt should now be made in this direction.

Dr. T. F. WALL: In Mr. R. T. Smith's paper the conclusion was drawn (pp. 208-9) that for fast passenger service

* R. T. Smith. Some railway conditions governing electrification. *Journal I.E.E.*, vol. 52, p. 293, 1914.

the continuous-current series motor is at a disadvantage compared with the steam locomotive, because the characteristics of the ordinary series motor is such that the torque diminishes too rapidly with the speed—the torque at low speeds being limited by the strength of the draw-gear. It seems to me, however, that by the use of a diverter to the field coils, the torque at the high speeds may be increased at will. If the supply pressure is constant the armature current at any given speed will be greater with, than without a diverter, whilst for a given speed the flux per pole will be practically the same whether a diverter be used or not. Consequently, the use of a diverter will enable the motor to exert a larger torque at a given speed. I should like to ask Mr. Lydall whether the control equipments for electric locomotives provide for the connection of diverters in parallel with the field coils.

Mr. F. LYDALL (in reply): I gather from Mr. Carter's remarks that the question of the number of steps in which it is necessary to switch out the controlling resistances in order to keep the fluctuations of torque within certain fixed limits, is not very clearly understood. Mr. Carter agrees that the number is determined by the slope of the characteristic curve, but considers that the internal resistance does not enter into the question. On the other hand, he attributes the determining cause to the pressure-drop due to resistance. But if the internal resistance does not settle the pressure-drop due to resistance, I fail to understand what does. To a certain extent Mr. Carter is right, if I understand him correctly, when he implies that the degree of saturation has more influence in the matter than the internal resistance. Nevertheless I feel sure he will agree with me, on further consideration, that the deciding factor is the slope of the characteristic curve. But when he states that the determining factor is the permissible fluctuations of tractive effort during the accelerating period, he seems to miss the point altogether. The question is how many steps are necessary to keep the fluctuations of tractive effort within given limits? To say that this depends on the limits is like saying that the distance between two points depends upon how far they are apart. Mr. Carter quite rightly states that the number of steps in the control system on motor-coach trains is determined by altogether different considerations. May I suggest, however, that the principal consideration is not so much what the public will stand in the way of jerks, as what the engineer thinks they will stand.

Reference has been made by one or two speakers to the effect of self-induction in the starting curves. It may be that this effect is inappreciable in any case, even on a tramcar starting up very rapidly, but I doubt if any instrument other than an oscillograph would demonstrate this. My point, however, was not so much that self-induction is important in some cases, as that it produces no useful result in the case of a locomotive starting a heavy train on a steep gradient.

Replying to Mr. Poultney with regard to the use of an air filter on locomotives designed for forced ventilation, I am not aware of any case in which a filter is used. It is not likely that the air in front of a train will contain sufficient dust to make a filter necessary.

Full particulars as to the weights and capacities of the locomotives shown on the screen have been given in the paper published in Volume 51 of the *Journal*, to which

Mr. Lydall. I may refer Mr. Poulitney. The same paper contains some information as to the cost of maintenance.

The question of comparative costs of steam and electric locomotives is not easy to deal with. The cost of an electric locomotive depends on a number of considerations—weight, horse-power, control scheme, electric system, etc. Small electric locomotives of the simplest kind may cost as little as £35 per ton, and the price per ton may be as high as £110 for main-line locomotives. With such a large variation it is practically impossible to deal with this question in a general way.

Dr. Garrard draws attention to the constant-current system and suggests that it might be used for traction purposes. One cannot say that this is impossible, but it would undoubtedly introduce undesirable complications in the way of a double-pole overhead line divided up into insulated sections, and various automatic arrangements for short-circuiting the two poles on any section of the line not occupied by a train. Against these and other disadvantages it is very doubtful whether any substantial advantages can be claimed, and I am not aware that the proposal has ever been seriously taken up. Of course, the use of the constant-current system for power transmission

to traction sub-stations is quite another question, and does not come within the scope of the present discussion.

Dr. Garrard's experience with cast-iron grids agrees with my own. It certainly seems to be the case that the shocks which they have to stand at the hands of the goods department are far worse than those they experience when once they have been installed in the locomotive.

To my mind the difference between the working of a locomotive and of an electric winder is quite sufficient to account for the infrequent use of liquid rheostats for traction work. It may be quite true that a winder has to be started and stopped once or twice a minute, but this represents ideal conditions compared with what a locomotive may have to do. A locomotive may have to start three times in half a minute with any load up to the maximum and with any conditions of track. The one case is distinguished by almost perfect regularity, the other by extreme irregularity. The whole difficulty with locomotive control resistances is not the grading, which is after all merely a question of calculation by one method or another, but the determination of capacity, which is in reality a matter of intelligent anticipation or foresight.

MANCHESTER LOCAL SECTION, 10TH MARCH, 1914.

Alderman Walker.

Alderman W. WALKER: I should like to approach this matter from the point of view of standardization. I am not competent to deal with the technical details in this paper, and few people in Manchester have had an opportunity of seeing an electric locomotive under construction or in operation; whilst opportunities, at any rate my own, of observation on the Continent have not been many. On page 384 a remark is made which points out one advantage of electrification. The author says a moderate speed for an electric locomotive is one of from 60 to 65 miles per hour. If this is only a moderate speed, there is a very good case for the adoption of such a locomotive, as it is believed that the speed of steam locomotives has now reached its limit, and that any increase of the average speed will enable the existing lines to deal with a greater number of trains per mile. On page 386 are two drawings which should to some extent help to indicate the electrical system to be adopted. They are presumably drawn to the same scale, one being that of a 2,000-h.p. and the other that of a 800-h.p. motor, and where space is so limited the advantage can clearly be seen, other factors being equal, of using the motor giving the greatest power for the space occupied. I should like to ask the author if he knows whether there has been any necessity for filtering the air required for the forced cooling of motors owing to the presence of dust, which is so marked a characteristic of our railways. The Chairman referred to standardization, and I know that eminent leaders of the electrical profession take the view that each manufacturer ought to be free to persuade the buyer to adopt his own particular system, as experience will thus be obtained, and should the installation prove to be faulty it can be "scrapped" and another substituted. Taking a short-sighted view, this may appear sound to the manufacturer, but failure on even a small section of railway will do much to prevent, or at least retard, further progress for

some time. I wish to approach this subject from quite a different point of view, namely, that of the general good of the country, and I think that the competition to obtain orders for any and every system, wherein financial arrangements may weigh as much as technical excellence, will not give the best results, or in the end be good for the manufacturer. The idea that a railway company may be willing to spend hundreds of thousands of pounds in order to install an electric service and to be obliged to admit in a comparatively few years that a mistake has been made, and that it must be "scrapped" to be replaced by the system of another manufacturer, is one which cannot for a moment be put forward as a business proposition. Plant will have to be retained in order that it may earn sufficient to defray its cost, or a large proportion of such cost will have to be borne by the plant which supersedes it. I would ask this Local Section to urge upon the Institution the necessity of taking steps to obtain the appointment of a Committee to advise with regard to experimental work, to tabulate and consider the results obtained, and above all to endeavour to secure a national system under which all rolling stock will be able without alteration to run over every railway in the kingdom.

Mr. P. P. WHEELWRIGHT: My regret is that no British manufacturers seem to have had much experience of, or made many motors for use in conjunction with, the electrification of railways, and that the railway companies in this country apparently still refrain from going into the question. The question raised by Alderman Walker is one of great importance, and I agree that until British railways have discovered a system suitable for dealing with the great variety of traffic on all their lines, it will be impossible to standardize. Individual companies cannot afford in these days of increasing expenditure to spend large sums of money in equipping experimental lines, and future practice will no doubt have to be based on the

Mr. Lydall.

Alderman Walker.

Mr. Wheelwright.

collective data obtained, which will eventually be available for standardization on sound principles.

Dr. E. ROSENBERG: The author says that in only one or two cases, principally for three-phase locomotives, liquid resistances have been used, but I would mention that they have been used in the electrification of the Italian State Railways, where there are 140 locomotives either in operation or under construction, with a total capacity of over 300,000 h.p. An interesting application of forced ventilation for rheostats is in use on some rack and pinion railways in Switzerland. In going downhill the motor is used as a generator, and the energy is consumed in the resistances, which are cooled through a large fan mounted in the cab. I should like to make a few remarks with reference to the question of standardization raised by Alderman Walker. At the occasion of a recent dinner he expressed the opinion that no railway company would undertake electrification of a part of its lines unless it were satisfied that the same system was suitable for the electrification of the entire system, and that if different railway companies were to adopt different systems a state of chaos would result which would prevent through-running, and hence that not a single mile of railway should be electrified until a conference of railway men, electrical engineers, and public authorities, has decided on the one system which would be suitable for the electrification of all the British railways and which, therefore, should be adopted by all. I should consider such a step to be disastrous, because I am convinced that such a conference could not agree at the present time, and that it would postpone electrification indefinitely. My opposition is certainly not based on the belief that it is in the interests of a manufacturer to install apparatus which has to be "scrapped" after a few years, giving him the opportunity then to install a new system to replace the old one. There is no manufacturer who likes to see his own apparatus "scrapped," and it is common knowledge that he can ultimately obtain far more business if it is known that his apparatus will do service for 30 years rather than require renewal after 5 years. Nothing would suit the manufacturer better than standardization of a system if he could hope that such standardization could be achieved, and that it would remain in force for a long period of years; but I consider it to be a hopeless task to bring about standardization now. Some railway engineers will consider nothing but single-phase current; there are others who pin their faith to low-tension continuous current, and still others who think high-tension continuous current the only promising system. Certainly as regards high-tension continuous current, matters are in a state of development. When an important firm of consulting engineers in this country reported on the electrification of the Melbourne railways six years ago, it proposed a third rail and continuous current at 800 volts. The electrification was not carried out at that time, but now the same engineers have proposed an overhead line with continuous current at 1,500 volts, and this has been adopted by the Australian Government. The Lancashire & Yorkshire Railway, which electrified successfully several years ago the Liverpool-Southport line with continuous current at 600 volts, thinks now that a high-tension system would be an improvement, and it has

chosen a pressure of 1,200 volts for the electrification of the Manchester-Bury line, and has also experimented on a small scale with a pressure of 3,000 volts. Electrification at 1,500 volts continuous current has proved a complete success in America, and a pressure of 2,400 volts is now used on a few lines. There is no doubt that high-tension continuous-current electrification will prove profitable on certain lines where a 600-volt system would be too expensive. On the other hand, the London & North-Western and London & South-Western Railways, which are now electrifying their suburban lines with frequent traffic, could not do any better than adopt the 600-volt third-rail system. This they are adopting because it enables them to obtain through communication with the Metropolitan and Underground Railways. Nobody will assume that the London & North-Western Railway when choosing a pressure of 600 volts for the Watford line was of the opinion that the same system could ultimately be used for running express trains and goods trains over its entire lines to the north. I see no deplorable chaos in electrifications going on at present, but rather sound commercial undertakings and healthy engineering experiments. There is no better way of experimenting than by letting those who believe in a competitive system show what this system can do. The electrification of the whole of the British railways will not come to pass in the next 10 or 15 years, and all the developments and improvements which will take place must not be foregone by prematurely standardizing, even if such standardization could be agreed upon, of the impossibility of which I am firmly convinced. If electrification be undertaken now, and the equipment has to be "scrapped" after 10 or 15 years, it is not really wasteful. On a suitable line electrification will pay for itself during such a period. I fully believe that standardization will ultimately be effected, but an ideal, unattainable for the moment, should not stand in the way of present progress and healthy activity.

Mr. W. CRAMP: The author has mentioned that the maximum torque desirable is one sufficient to cause the wheels to skid. Is it not unscientific to limit the torque to that which shall be capable of causing the wheels to skid? Does not the point at which the wheel will skid depend on the number of wheels, their diameter, and the weight on the wheels. How then is it possible to determine the question by the use of such an arbitrary rule? Why should the wheels be used as an overload cut-out? The horse-power of the motors quoted seems to me to be excessive. The Löttschberg Railway is stated to possess a locomotive with two 1,250-h.p. motors mounted on it for dealing apparently with passenger traffic. Will the author say what is the rating of these motors, and also how this horse-power compares with that of a steam locomotive for similar work. As to the question of gearing, some few weeks ago I saw some back numbers of the *Auto-Car*, and in them can be seen the horseless vehicle in various stages of its development. To-day the electric locomotive is being developed, and the process appears to me to be very similar. The rotatory motion is being transmitted by reciprocating connecting-rods. No doubt there is a good reason for this, yet one cannot help thinking that it should be avoided. Enormous developments have been made in gearing by motor-car manufacturers, and it is now possible to secure a very high efficiency with a

Mr. Cramp. worm gear giving a very high power. Perhaps the author will be able to explain what has been done in this direction and why worm gearing cannot be used for locomotives. What determines the diameter of the locomotive wheels; and why has there been in the matter of wheel diameters an imitation of steam locomotives? There is nothing to limit this dimension, so far as I can see, except the characteristics of the motors. With regard to Ward-Leonard gear, I should like to mention a locomotive built by the North British Railway Company in which a steam turbine, boiler, condenser, dynamo, and motors are all on one truck. The locomotive has run a number of miles already, and the simplicity of control is very noticeable. Has the author any comparison between such a machine and those which have been illustrated to-night? On page 301 there is a very interesting statement concerning resistance grids. The author points out that in grid resistances a thin coating of aluminium paint, while protecting them from oxidation, seriously impairs their capacity of radiating heat. This fact is new to me and I believe it is not supported by evidence, provided that the paint is properly applied. I should like to ask him if he has any results of tests in support of his statement. It is evident that the centres of gravity of the locomotives shown on the screen are very high. This may be a serious disadvantage, not only in necessitating an alteration to the banking of our railways, but also in rendering it likely that accidents may occur at curves. The motors shown in the slides have an unduly large number of brushes. Cases have been known in ordinary work where the cost of brushes amounts to hundreds of pounds per annum, and it seems to me that the renewal of brushes with these locomotive motors will be an important item. It is very interesting to hear that steam heating is adopted in the trains, and that the method used is that of heating water by electricity. But why put heat units into water when by means of radiators the carriages might be warmed directly? Finally, it seems to me that advantage might be taken of the air movement set up by the train itself to secure proper ventilation of the motors, etc. Is it not possible to arrange the air passages so that air shall be delivered by the movement of the train through those parts which most need cooling? In the diagrams there is no evidence of this being done.

Mr. P. T. MAYBURY: I should like to make one suggestion with regard to gears. One of the advantages always claimed for the electric motor when it is proposed to be installed in any power scheme is its uniform turning moment. I believe this to be quite as important in relation to electric railways as in any other application of the electric drive, and would suggest that such things as cranks and connecting-rods are quite out of place when used for transmitting circular motion to circular motion, and that either direct drive or a drive through spur, worm, chain, or belt gearing is the proper system to adopt. In this connection it would be of interest to know whether steel belts have ever been tried. In a paper read before the Manchester Association of Engineers a few weeks ago figures were given of the results of some tests on steel belts, and it would appear that these have practically an unlimited life and an efficiency of transmission of the order of 99 per cent, as against the 97 or 97½ per cent efficiency of spur gearing. The width of a steel belt is only about one-half

that of a leather belt of the same transmitting power. I should also like to ask the author whether the motors have ever been fitted with their shafts vertical in order to dispense with the gyroscopic effect when rounding curves at high speeds. The motors could be geared through worm gearing, as suggested by Mr. Cramp.

Mr. J. L. MOFFET: A third choice to the two methods given on page 384 of increasing the motor power where space is limited is to increase the motor speed and to use a larger gear ratio. This method is used to increase the capacity of the motor which can be installed on a standard motor car; it will usually be found that where continuous-current motors of greater than 150 h.p. are installed, the extra power is obtained by running the motors at a higher speed at their one-hour rate. In connection with the author's remarks on pages 387 and 388, I should like to ask whether the limiting load that a locomotive can handle is not fixed by the load that it will start, rather than by the load that it can accelerate, since the resistance of a train at starting is considerably higher than when moving. Professor Perry gives the resistance at starting as 20 lb. per ton, compared with 5 lb. per ton at 5 miles per hour, whilst in some tests carried out by Thurston on journals he found that the coefficient of friction at rest was 0.14 as against 0.005 when rotating, with pressures such as occur in railway work. This effect will also have been noticed by anybody who has moved a railway truck by manual labour. I think that the author has not taken this into account in obtaining Fig. 5. Using the curves given in Fig. 6, the following figures can be obtained:—

Starting tractive effort per ton on 1 in 90 gradient
= 20 + 25 lb.

Maximum tractive effort of motor = 4,500 lb.

Maximum weight started on 1 in 90 gradient =
 $4,500/45 = 100$ tons.

Resistance per ton just before going into 3rd notch
= 7 + 25 lb.

Tractive effort of motor just before going into 3rd notch = 3,600 lb.

Accelerating force, $3,600 - 100 \times 32 = 400$ lb.

Acceleration just before going into 3rd notch = 2.5 miles per hour per min.

Acceleration after going into 3rd notch = 8 miles per hour per min.

Average acceleration = 5 miles per hour per min.

Thus, if a locomotive will start a train on a 1 in 90 gradient it will accelerate it at 5 miles per hour per minute even with the moderate number of notches shown in Fig. 6. If the ruling gradient had been less steep, the acceleration would have been still higher. The point mentioned on page 389, namely, that the maximum motor current in a tramway motor during notching is reduced owing to self-induction is interesting. I should not have thought that the increase of speed of a tramcar would have been appreciable during the period that the current is choked back by self-induction. I should like to ask whether the dual control recommended by the author on page 396 arranged either for automatic or hand operation would greatly complicate the control gear.

Mr. F. LYDALL (*in reply*): Dr. Rosenberg has raised the question of the advantages of forced ventilation of motors. The way in which I have looked at it is not so much

lydall. a comparison between motors which have and motors which have not forced ventilation, as between the capacity of the motor on the one-hour rating and on continuous rating. One knows quite well that with most railway motors the ratio between the one-hour rating and continuous rating without forced ventilation is about 2 to 1, but in the case of forced ventilation the ratio is by no means the same. There are a good many figures in the paper which show that the ratio is very much nearer equality. I quite agree that there is a great difficulty in explaining one or two of the figures in the table of motors dealing with this point; the probable explanation is that there are two alternative methods of producing a forced draught, one of which may be called natural ventilation and the other forced ventilation.

With regard to liquid resistances, when I made the remark that these had been used in one or two instances I did not mean on one or two locomotives; I know that there are one or two railway systems which are using a large number of locomotives where these liquid resistances are employed.

Alderman Walker referred to the moderate speed of 60 to 65 miles per hour. It is perhaps not quite understood that the moderate speeds referred to are maximum speeds, that is to say, speeds beyond which the locomotive is not designed to run. It would be correct to say that speeds can be considerably increased by the use of electric locomotives. These can undoubtedly be built for a considerably higher speed than the steam locomotives in use at present on the same lines; whether this increase in speed makes electrification worth while it is impossible to say, as this is really a railway engineering question. He also raised the question whether filtering was necessary in the case of forced ventilation. I am not aware that it has been used. The air in front of a railway train is comparatively good; it is the air following the train that contains a lot of dust and dirt.

Mr. Cramp asked why it is desirable that the motors should be able to skid the wheels. It is desirable because if the motors are built to do this the driver cannot overload the motor beyond the point at which the wheels will slip. If it takes 200 per cent overload to skid the wheels, it would be quite possible to load the motors so that they would burn out. It is of course merely a question of the coefficient of adhesion between the wheels and the rails, but it is practical to say that if the motors are designed so that they are able without injury to skid the wheels with an adhesion of one-third, all that is necessary has been done.

The horse-power of motors on electric locomotives compared with the horse-power of steam locomotives is very high. In the table on page 397, under the heading of geared motors the one-hour output of each motor on the new Löttschberg locomotive with forced ventilation is 1,500 h.p., the continuous output being 1,250 h.p. I think also the various horse-powers mentioned in this discussion are also given in the original paper printed in Volume 51 of the *Journal*.

Coming to the question as to whether worm-cut gearing can be adopted, it is in general the intention of the designer to use a motor in which the peripheral speed is worked up to the maximum, and it is a question as to whether it is necessary to go to worm gearing to arrive

at this result. In a good many cases there is no Mr. Lydall. object to be gained by using such gearing. Single-reduction spur gearing is usually quite sufficient to meet all the requirements of the case.

The reason why certain diameters of wheels are chosen depends entirely on the design of the locomotive. If the locomotive is of the coupling-rod type, the wheel diameter must be chosen such that the number of revolutions is not excessive at the maximum speed. On the steam locomotives the maximum number of revolutions of the driving axles is of the order of 300 revs. per min. If a locomotive has to travel at a certain speed it is a simple matter to calculate the diameter of the wheels to give this number of revolutions. The whole point in the design of the electric locomotive is that the piston velocity of the steam locomotive is eliminated. It has been found that the revolving cranks of electric locomotives can be run at a higher speed; they can be run up to perhaps 500 revs. per min. as a maximum. Having, however, accepted this figure as a result of experiments, if we are given any locomotive speed it is a simple question to ascertain the diameter of the driving wheel.

Reference has been made to the North British Railway Company's system in which a turbo-electric set is installed. This is a very interesting experiment, but I think it is scarcely likely to result in the displacement of the electric locomotive. The great advantage of the electric locomotive is that it is one of a number of units which are worked intermittently and which all take current from a power station at a considerable distance, and in this power station there is the utmost possible economy in generating current. I do not think that any turbo-electric locomotive is likely to enter into serious competition with the electric locomotive.

I have no figures at present available regarding the painting of resistances with aluminium paint.

When Mr. Cramp says that the centre of gravity of an electric locomotive is far higher than that of a steam locomotive I hardly think he is correct. In the Pennsylvania locomotives, where the motors are mounted high up in the cab, the position of the centre of gravity is stated to be within an inch or two of that of the corresponding steam locomotives. The difficulty in many cases is that the centre of gravity is so low. One of the great advantages of placing the motor in the cab instead of on the axles is that this difficulty is removed.

As to the number of brushes on the motors shown on the screen and the question of the cost of renewals of brushes, I do not think that this is a matter which is at all serious. It is one of those things which are obviously a disadvantage, but the importance of which must not be exaggerated. With these large single-phase motors the working of the commutator and the brushes as a whole is very satisfactory.

Steam heating on locomotives is in use in the States just as it is here. In the States the boiler is sometimes fired with oil, while in other cases it is fired by coke or coal, and on some locomotives on the Continent it is heated by electric current.

Mr. Maybury raised the question of steel belts, but I have no experience of these. I do not, however, believe that they would be of much use because of the irregular working of locomotives. The question was also raised

Mr. Lydall. whether it would be possible to use horizontally-mounted motors so as to avoid gyroscopic action. Theoretical calculations made on the Continent show that the gyroscopic effect is scarcely worth taking into account.

Mr. Moffet has criticized the starting curves shown in Fig. 5 because the extra high tractive resistance at starting has not been taken into account. The value that he mentioned, viz. 20 lb. per ton, seems rather high; if I am not mistaken the figure found by experiment on the Lancashire & Yorkshire Railway is about 15. But in practice this high resistance is only experienced when a train has been standing, so that the journals are unlubricated. It is generally possible also to get over this

difficulty when it arises by setting the train back a little so as to lubricate the journals sufficiently to bring the tractive resistance down to about its normal value.

Mr. Moffet also referred to the effect of self-induction in the motors. I called attention to this point more particularly to show that it was not to be taken into consideration in big railway motors when starting up a severe gradient. As a matter of fact it would be difficult to prove whether self-induction does or does not produce any appreciable effect in any case.

The cutting out of automatic acceleration is a simple matter. It is a matter of design of the apparatus, and so far as I know there is no difficulty whatever about it.

Mr. Lydall.

DISCUSSION ON

"SOME RAILWAY CONDITIONS GOVERNING ELECTRIFICATION."*

NEWCASTLE LOCAL SECTION, 23RD AND 27TH FEBRUARY, 1914.

Mr. G. STONEY: There is a point that the author does not refer to, namely, the poor load factor in main-line working. I have long had the impression that until some form of storage is possible other than by means of the ordinary storage battery the electrification of main lines is more or less hopeless. Perhaps the author may be able to give us some information on that point.

Mr. F. O. HUNT: On page 205 the author specially emphasizes the idea that suburban service may be engineered in a totally different manner from that of any other portion of the line to be equipped electrically. This comparative isolation of one section of the traffic from others is certainly a distinct help in the process of bringing about electrical working, but it should nevertheless be kept in mind that ultimately some similarity of method will prove to be an immense advantage when the process of transition is complete. This also has a bearing upon the "new capital" difficulty, which must to some extent be met by the gradual replacement of worn-out steam locomotives by those of the electrically-driven type. I am sorry that the author did not consistently use the term "electric energy" rather than "electricity" when referring to the purchase of electric energy. On page 208 there appears some slight confusion of meaning in the terms "output" and "load." Presumably the former means "horse-power," while the latter refers to "tonnage" hauled. The reason no electrically-operated locomotive suitable for high-speed traffic has been produced is because the whole demand has hitherto been for the rapidly accelerated train travelling at a moderate speed. There appears to be no insuperable difficulty in complying with the conditions laid down. I have been somewhat surprised to notice the tendency in Continental designs to introduce complex gearing of various kinds between the motors and driving wheels. This seems like a repetition of the early history of steam locomotion, from which can be learnt the importance of striving after the simplest form of the transmission of power from the source to the

driving wheels. Mr. Swinburne's lament of 13 years ago "that electrical men were not railway men, and vice versa" is emphasized in this paper. For instance, none but the man with railway experience could fully appreciate the importance of considerations such as the strength of draw-bar gear and the lay-out of sidings in determining the design of goods locomotives. In regard to the shunting locomotive, the author considers that the chief hope lies in the single-phase locomotive, but I would suggest that the possibilities of series-parallel working can hardly be considered to have been exhausted, and also that in making comparisons it must be remembered that even the steam locomotive carries out the very slow movement of wagons under extremely inefficient conditions. A point of considerable importance is alluded to in the last paragraph of the paper, i.e. the possibility of obtaining ample adhesion while concurrently the weight per axle is greatly reduced. This, together with perfection of balance due to the elimination of reciprocating parts should be a source of considerable economy in the upkeep both of track and locomotives.

Mr. S. G. REDMAN: I am somewhat opposed to considering railway electrifications as for distinct and separate classes of traffic as the author does, mainly because so much of the capital cost of installing either could be made common to all. In England our big towns are close together compared with those of America, and the suburban traffic of one such town extends so as almost to become connected with that of another. Hence over large areas the service might easily consist of trains of one general type, operated as stopping and non-stopping trains as the demand requires. The author refers to the possibility of increasing the traffic facilities by electric traction without extending the way or works, and the Tyneside electrification is an instance. Under steam working the traffic demands had not made it worth while increasing what was a comparatively open service; under electric working, on the other hand, the traffic demand has increased beyond the possibility of steam working (without additions to the

Mr. Hunt.

Mr. Redman.

* Paper by Mr. R. T. Smith (see pp. 293, 308, and 405).

permanent way and works), and the rateable value of the seaside towns served has increased by from 60 to 70 per cent since the inauguration of electric working. Although the service has been most popular and the train mileage had been more than doubled compared with what it had been for steam working, it is interesting to note that the actual car mileage has not been appreciably increased. The basis on which the author compared the costs of steam and electric working is of much interest, and generally confirms my opinion that if the cost of electricity for the electric machine could be arranged so as to balance the cost of coal and water for the steam locomotives, the saving in the repairs of the steam locomotives would pay the capital charges on the electric equipment of the railway. The cost of 3d. given by the author for coal and water per steam train-mile is lower than I have generally considered it to be; perhaps the author will state whether this is for any selected services. The continuous-current equipment with series-parallel control certainly labours under disadvantages for heavy shunting work; but where this is occasional duty only, it might still be preferable to tolerate these disadvantages rather than to provide the complication necessary to avoid them.

Mr. C. S. VESEY BROWN: The note of complaint in regard to competition by municipal tramways is one which has been regrettably introduced. The facts have to be faced by the railway authorities. The railway is run for the purpose of conveying the public under certain specified conditions of tenure. As a member of the public I want to get from A to B as quickly and cheaply as possible, and those who undertake to carry me must see that their own arrangements as to remuneration, etc., are in accordance with their ideas of profit, etc. I agree that this may possibly be a "condition governing electrification," but those responsible for the management of the railway know the terms under which they are authorized to carry passengers and goods as well as the competitive terms on which tramways are allowed to carry passengers. They must naturally move accordingly. With regard to the suggestion of a differential tariff, I have often thought that railway companies might adopt such a principle for season-ticket and regular passengers, i.e. a fixed rate per annum between their residence and place of business plus a small sum per journey taken. It may be difficult to fix such a tariff, but it is not impossible to do so. Respecting the credit of British railways, has not the "low point" to which the author refers been induced by the attractions for the employment of capital elsewhere, having regard to greater security of tenure and the use to which the person using the money applies it? Mr. Redman mentioned the classification of passengers into "suburban" and "long distance." I agree with him that in this country there is little to choose between them. The average distance between most large towns is not 25 miles, and this is negligible for a "suburban" service. It is not too much to consider an hourly service to York or London instead of the 2- and 3-hour service with crowded trains that at present exists; and then the 1,100-h.p. locomotive of which the author speaks will be split up into smaller units. With regard to the cost of current, which the author puts at 3d. to 4d. per unit depending on the service required, it is to be hoped that those railway companies who are equipping

their own power stations or who are purchasing electrical energy will some day publish figures showing what is the cost of generating the energy. It is quite an easy matter for a railway company to say that the cost should not exceed x pence per unit otherwise the steam-driven train is the better paying proposition; but the question when buying energy is how to fix a price which will cover fair remuneration to the capital employed as against that at which the railway company can itself generate at its own power station. When figures showing this latter part can be produced, the question of price at which to buy will be easily answerable.

Mr. W. HAWTHORNE: One frequently sees it stated that England is behind-hand in adopting electric traction on railways, but this backwardness ensures the benefits of the experiments in electrical operation made by other countries. Hitherto this country has not been committed to any system of electrification for general use, and it can profit by the experience of those countries which have already selected a system. Italy, for example, has largely adopted the three-phase system. Germany and Switzerland have decided on the single-phase system, whilst the United States seems to be inclining towards the high-tension continuous-current system. In the meantime England has only adopted electric working on urban and suburban lines, and is free either to let these develop naturally into inter-urban working or to select a different system for main-line and freight traffic. In view of the possibility that the latter course may be found desirable, it is important when deciding upon a system of suburban electrification to arrange the track conductors in such a position that they shall not interfere with the conductors of the system ultimately selected for main-line working. Reference has already been made to the close spacing of large towns in this country, and it is this fact which holds out the prospect of a natural development of electric traction on the lines along which a start has already been made. Suburban traffic can roughly be divided into three classes. First, the station-to-station traffic within the city; in London this covers an area within 5 or 6 miles of the centre, and is dealt with by the Tubes. The next zone extends from 6 to 16 miles outwards, and ought to be served by rolling stock more roomy and comfortable than the urban stock. Thirdly, there is the zone extending from 16 miles outwards occupied by people who can afford both the time and the money for a couple of daily journeys lasting up to 45 minutes each. To encourage traffic from this zone the railways must provide a rapid service with few intermediate stops, and coaches approaching in comfort the standard of main-line stock. From an operative point of view the railways will have to solve the problem of running these three services on existing tracks, or will have to build new lines into the centre of the city. The limit of the third zone will often be found in this country to be within the sphere of influence of another large town, and the high-speed suburban service will develop naturally into an inter-urban service. Incidentally it might be permissible to point out that the author on page 205 gives the maximum number of trains per hour on the Tyneside lines as six. This is not quite correct. The closest schedule is five trains dispatched over one track in five minutes; the maximum for one hour is 14 trains. The author lays considerable emphasis on the importance of reducing the

Mr. Vesey Brown.

Mr. Hawthorne.

Mr. Hawthorne.

generating costs in order to keep down the total cost of power; but there are other ways of doing this. The coach designer can help by reducing friction losses and keeping down the weight hauled per passenger-seat. Something may also be done by some form of storage or regeneration whereby a portion of the energy now lost in braking may be available for the next start.

Mr. Hunter.

Mr. P. V. HUNTER: The electrification of railways has now been a matter of interest and discussion among electrical engineers for some years. The subject has only too frequently been discussed from the limited technical aspect as it presents itself to the electrical engineer. No doubt one object in the minds of those writing upon and discussing the matter has been to further the cause of railway electrification; it is, however, greatly to be feared that in this respect the result has been negative. In dealing with the question as a railway problem rather than as an electrical one, and reviewing the conditions from the railway point of view, the author has made a valuable contribution to the subject. He has succeeded to a degree which would hardly have been thought to be possible in making a financial comparison of steam and electrical operation. As was to be expected, such a comparison does not show any very decided advantage in favour of electrical operation. This is, however, a position in which electrical engineers are accustomed to find themselves in the majority of the applications of electricity. It is, I think, quite a frequent experience that electricity does not show a very substantial advantage on paper compared with its competitors. On the other hand, the financial advantage invariably materializes when the conversion has been made, and there is every reason to think that railways will not form an exception to this general rule. The probable explanation of the bad showing of electricity is that the cost of electrical service can be estimated more readily and more accurately than the actual cost of an existing service given in other ways can be ascertained. In other words, when electricity is applied unexpected economies occur. I may cite as an instance the question of painting. It would not, I think, be reasonable to ask anybody to estimate the saving to be expected in the painting of railway stations on account of electrical operations, yet anybody who takes the trouble to examine the conditions of the Newcastle Central Railway Station and to compare that section into which electrical trains run with that into which the steam trains run, will readily agree that a substantial saving should result. I believe, and have no hesitation in saying so, that many unexpected and material savings of this kind would occur under electrical working. Another side of the question is the increased traffic likely to accrue from the flexibility of electrification. It would not be reasonable to expect the traffic department of a railway to form a rigid estimate of the value of a more frequent main-line express service, but since such a service could be given as cheaply as a less frequent one having larger trains it would be adopted, with the result that increased revenue would be obtained. The working of the goods service electrically would relieve congestion which might otherwise occur on account of the greater frequency of express trains. It is unfortunately true that steam and electric service cannot be properly compared, as the natural method is to compare an electric service under steam conditions; whereas the two services would differ in character considerably.

Mr. Hunter.

On the purely engineering aspect of the matter I note that the author limits his attention to tractive equipments, and rightly so, as the remainder of the electrical equipment is a matter of everyday use for purposes other than railway traction. I have not personally worked on this part of the equipment, and it comes somewhat as a surprise to me therefore to find that a motor with a series characteristic falls so far short of what is required for express and goods services. In the case of the express service it is, I gather, at least necessary to develop economically a constant horse-power during starting, this being the ideal which the designers have set themselves to achieve. The straight series motor falls a good deal short of this ideal, but there is not the least doubt that some improvements, such as field control suggested by the author, will enable it to satisfy the requirements. There is, however, no reason why electrical engineers should limit themselves to constant horse-power. It seems to me that if it can be done economically the proper course is to have a constant draw-bar pull up to some speed approaching the maximum. Care should, however, be taken to avoid extremes in this direction, as expense may be incurred without material benefit. Railway engineers will, I think, agree that such a characteristic if obtained would be of value in that it would allow of a high average speed with a low maximum speed. From the point of view of maintenance of the track it is, I understand, important to limit the maximum speed as much as possible. The problem of goods working as described by the author is evidently difficult; it can be met completely by the Ward Leonard system. Such a system would enable the locomotive to meet satisfactorily and with a high efficiency any of the extremes of duty described by the author. Series motors with resistances will no doubt meet the service, and it is, I take it, a question of cost *versus* economy. I think there is no substantial objection to a motor-generator on the locomotive. I feel sure that it would take less attention from the driver than the equipment of the present steam locomotive. If such a system were adopted for goods service it is perhaps questionable whether it would not ultimately be found advantageous to use it for passenger service also (apart from urban and suburban work). Possibly in such a case the same locomotive would meet both services, or in any case, passenger and goods locomotives would be interchangeable for the service of either to a degree at least equal to that now obtainable in steam locomotives. In conclusion, I would plead for an attempt to standardize one expression for "acceleration." It is now most confusing to those who are not constantly dealing with the terms to have continually to be mentally translating "miles per hour per second" into "feet per second per second" and vice versa.

Mr. Prescott.

Mr. C. W. PRESCOTT: Mr. Hawthorne mentioned electric braking from the point of view of regeneration. There is another aspect from which it may be viewed, and that is its usefulness in reducing both the service and emergency stopping distances. With signalling arrangements where train stops are used for the purpose of automatically applying the brakes and cutting off the power should the driver overrun a signal at danger, such as are employed on the underground systems in London, the minimum distance possible for unchecked running between the head of one train and the tail of the one preceding it is twice

the emergency stopping distance plus the service stopping distance; and hence anything which can be done to increase the efficiency of the braking of trains and therefore to reduce these distances will enable either a larger number of trains to be run at a given schedule speed, or the same number of trains to be run at a higher schedule speed for given track conditions. The retarding effect of the mechanical braking is least effective at the higher speeds, but it increases as the speed diminishes. The retarding effect of electrical braking is a maximum at the higher speed and diminishes with the reduction of speed. It would seem, therefore, that if a combination of the two could be used, the present retardations could be improved without increased inconvenience to passengers. It would appear that the question of braking, in the case of electric railways at least, has been largely left by the electrical engineer to other people, but there seems to be a distinct field of usefulness in this direction.

Mr. J. R. BEARD: The author emphasizes the fact that estimates of the effect of electrification on capital and operation charges can be made very exactly. This is an important point since railway estimates in the past have necessarily been more in the nature of approximations, and unless railway managements realize that electrification estimates can be trusted within close limits, there is a possibility that sound electrification schemes may not be adopted. In considering any electrification scheme it always seems to be assumed that it is not a paying proposition unless the additional gross profit is not only sufficient to pay capital charges on the cost of the conversion but also, as the author puts it, to give an immediate return on the old capital. In electrical operation the capital charges constitute a greater percentage and the operation charges a less percentage of the total costs when compared with steam operation; and whereas capital charges when once incurred are fixed, operation charges are, as the author points out, continually on the increase—a fact which is strikingly shown by the reports of the various railway companies for the past year. Consequently if electrification can be shown to increase the gross profit sufficiently to meet the additional fixed capital charges, it would seem justifiable even though there were no immediate net surplus, since, as operation charges in the course of time grow proportionately larger, an increasing net surplus is gradually obtained as compared with the corresponding results which would have been obtained under steam operation with its higher percentage of increasing operation charges. The author's investigation into the financial result of electrification of the complete passenger service on a large railway system is very interesting, but it seems to me to be inconclusive, as he appears to charge the whole capital cost of the track equipment, sub-stations, and distributing cables, against the fast passenger service. Of the three classes into which the author divides railway traffic it is generally agreed that the fast passenger service is that which would show the least favourable return from electrification. Consequently if a large railway system were completely electrified it would not be for the fast passenger traffic only, and a large proportion of the capital cost would be charged against the goods traffic and the suburban traffic. The author may have already taken this point into consideration, but if he has not, it would be interesting to know how it would modify

his figures. In discussing goods and mineral traffic mention is made of the ability of the electric locomotive to haul up to the maximum strength of the draw-gear at more than double the speed possible with a steam locomotive. This is an important point, as owing both to the increased speed and to the greater facility with which goods trains may be interpolated between passenger trains, much greater use can be made of the large capital already sunk in permanent way and rolling stock. It is difficult to place any definite value on this, but in certain cases it may be one of the strongest arguments for electrification.

Mr. J. A. ANDERSON: With regard to the loss of power in brakes and resistances after the plant is installed, most of the capital charges and some of the running charges could be neglected in calculating the cost of the units lost. In that case the cost of power lost is something like 1/10d. per unit, so that the question of the waste in braking, etc., does not appear to me to be very important.

Mr. V. O. I. DAVIS: In Fig. 2 the author gives some curves showing the maximum continuous draw-bar pull for steam locomotives, and he also gives corresponding curves for continuous-current and single-phase electric locomotives. It is very interesting to notice that the shape of the curve for the single-phase locomotive more nearly approaches that for the steam locomotive than that of the continuous-current locomotive.

Mr. J. WRIGHT: On suburban passenger services the advantage of electrical equipment, compared with mechanical equipment, is the ease with which the draw-bar pull can be increased. At the same time it is very interesting to note that the steam locomotive is the main obstacle to the electrification of fast passenger services, in spite of the fact that it is very much handicapped by the distribution of its weight arising from the length of its boiler, and that the electric locomotive has the advantage that the ratio of the adhesive to the total weight is higher than in the case of the steam locomotive, and that the torque is quite uniform. In a paper which Mr. A. H. W. Marshall read before the Cleveland Institution of Engineers in January, 1911, he gave a curve which showed very clearly the uniform draw-bar pull of a steam locomotive as compared with an electric locomotive. He also said that there was as much as 20 per cent difference between the adhesion in the two cases. It seems very difficult to explain why the electric locomotive cannot compete with the steam locomotive for fast passenger traffic. I am surprised to note from Fig. 2 that the ratio of the adhesive weight to the total weight is about the same in the electric locomotive and in the steam locomotive. I should have thought that the electric locomotive would have shown to better advantage, but of course I do not know if the figures are comparable. I notice that in the paper which Mr. Lydall read a few days ago,* he pointed out that the difference in the ratio of the adhesive weight to the total weight in the electric locomotives, as compared with motor cars, has a considerable influence on the control. I should like to know why this is so.

Mr. G. N. WRIGHT: The author refers to the fact that the number of trains per hour can be increased by adopting track signalling. I suppose that means automatic sig-

* F. Lydall. Motoring and control equipments for electric locomotives. *Journal I.E.E.*, vol. 52, p. 384, 1914.

Mr. G. N. Wright.

nalling. I should be glad if he would give the formula, if there is one, for the adhesive weight required in order that a certain draw-bar pull may be obtained. From the figures given in the paper it seems to be about four times that pull. Is that to be taken as a constant ratio? I suppose that with one double-acting cylinder, or two cylinders in parallel, the torque would be of the nature of a sine curve, and the necessary adhesive weight for an electric locomotive for the same draw-bar pull would only need to be $1/\sqrt{2}$ of that required on the steam locomotive. I am surprised that so much extra electrical energy is required where stations are very close together, and it seems a pity that railway companies cannot have the maximum-demand system of charging, so that those passengers who travel longer distances would get a cheaper rate per mile. I wonder if the Ilgner system is applicable to trains running between stations very close together. The author says: "the resistances to train movement increase in proportion to the speed raised to the 5/3 power." Is that figure obtained from tests only, or is it based on theory? It is also suggested that the addition of a shunt characteristic to the motors is worth consideration. Has this ever been done, or have series motors only been used so far? The trouble due to the reduction of the torque at high speeds could apparently be overcome to a certain extent by adding a shunt characteristic. Are there any special difficulties, however, in applying this method? I do not quite understand what the author means by saying that "large weights can be hauled if fitted with continuous brakes." It also seems that although it is not safe to use more than a certain draw-bar pull after starting, a greater draw-bar pull may be applied at starting. The author seems rather despondent as regards the likelihood of large electrifications being carried out in the near future, except perhaps for mineral traffic. I hope that this is not really the case.

Mr. P. S. Thompson.

Mr. P. S. THOMPSON: The author mentions two possible alternatives to the electrification of suburban lines; but as the cost in each case is prohibitive, the only course open to the railway companies is to electrify these lines, for on no other system could they run the 40 or more trains per hour necessary to deal with the traffic. This step should have been taken years ago when they had a monopoly; now they are being compelled to make this move in self-defence in order to retain their traffic in the face of severe competition. I agree with previous speakers that there should not be any serious difficulty in designing an electric locomotive to give a reasonable draw-bar pull up to speeds of 60 miles per hour. This is as high as should be necessary, for although the author says that the schedules call for 70 to 80 miles per hour, I do not know of any instance of steam locomotives running for any length of time at that speed. The average fastest "start to stop" run on 10 of our railways in 1913 was 57.8 miles per hour. The fastest run is that between Darlington and York, a distance of 44½ miles, at an average speed of 61.7 miles per hour. We know of course that in suburban traffic, at any rate near stations, the rapid acceleration and deceleration of trains have a very deleterious effect on the rails. In long-distance traffic, too, there is a certain amount of side wear and "battering" which has been attributed to the unsprung weight of the electric motors. From M. Parodi's paper^{*}

* H. Parodi. Railway electrification problems in the United States. *Journal I.E.E.*, vol. 51, p. 526, 1913.

last year it would appear that the shock to the rails Mr. Thompson in the case of an electric locomotive running at the same speed as those considered above is regular and tends to become resonant. This is rather different from one's preconceived notions of what would occur in the case of a steam locomotive with its pounding action and an electric locomotive with its even turning moment. It has been estimated that about half a million tons of sulphuric acid are given off annually from the coal burnt in the Metropolitan area alone; this should give some idea of the damage caused to ironwork and buildings by the burning of coal. The decreased cost of maintenance of station ironwork, signals, tunnels, etc., should therefore be some inducement to the railway companies to adopt electrification. To my mind, the strongest argument in favour of the steam locomotive is that it is a single unit: a system consisting of a large number of independent units has the advantage of reliability. It is interesting to note that the author is in favour of the purchase by railway companies of electrical energy from those who specialize in the supply of electricity. He emphasizes that particularly in his paper, and we know that this is the only hope for the railways, if they wish to obtain their current at prices that would make electrification profitable. The author says that cheap coal is a factor making against electrification, but as it requires in order to do a certain amount of work twice as much coal when used in a steam locomotive as it does when the coal is burnt in a large power station and the power is transmitted electrically, the time will come when this factor will no longer operate as it does at present. One cannot altogether agree with the author's conclusion that an electric locomotive is unsuitable for shunting work. It has always been my impression that the more intermittent the service the greater is the benefit derived from the use of electricity for haulage and similar purposes.

Mr. A. M. DUKE: The author's suggestion to use a Mr. Duke separately excited field seems to overcome the chief objection, which appears to have been that the torque of a series motor falls off excessively at the higher speeds. A suitable characteristic has been obtained on tramway motors by shunting the field magnets on the last steps of the controller.

Mr. E. EDWARDS: The author points out many difficulties which stand in the way of a general electrification of the railways, and does not present the prospects of its adoption in the immediate future in too glowing colours. I should like to call attention to two of these difficulties. First, he mentions the dearth of money and the demands of labour; I think that since the paper was written the money market has eased considerably and the necessary capital could consequently be more easily raised. On the other hand, it is difficult to see in what way electrification would increase the demand for labour and thus have any influence on labour's demands. Another difficulty to which the author calls attention is the weakness of the draw-gear of the present rolling stock. This trouble does not seem very serious, and if the advantages of electrification are proved, surely it is possible to design draw-gear to take the increased strain and to secure the adoption of such gear on all rolling stock. There is one difficulty which the author has not brought forward, namely, the many different systems of railway electrification at present in use. It

Mr. Edwards.

would seem desirable that electrical engineers should arrive at a consensus of opinion as to which system is most suitable for general adoption, and that this system should be standardized. In conclusion I should like to ask the author to what extent regenerative braking has been adopted in traction work.

Mr. C. O. BRETTELLE: The author has made out a fairly good case technically for electrification, and the chief difficulty seems to be a financial one. The railways being of such great importance to the nation as a whole, I think the Government should help to provide the capital required for electrification. Mr. G. N. Wright adversely criticized Government control. The railway companies are often suspected of bureaucratic methods, and under Government control this unfortunate tendency would no doubt be very largely increased, which we certainly do not want. In Germany a number of electric power schemes have had their appeals for capital supported by the different States, and so have obtained the advantages of co-operative credit and company control, which seems to be a satisfactory arrangement. I notice that the railway companies allow about 6 per cent for interest and amortization of capital. I do not know whether that is due to conditions peculiar to railway accountancy, as it seems to me to be on the low side and thus to make out a more favourable case for electrification than is perhaps justified. I believe that the capital cost per mile of the British railways is $2\frac{1}{2}$ times as much as that of some Continental railways; this burden is partly an inheritance from early days and partly due to our being the pioneers in railway construction and having to buy our experience at a heavy cost. I see that in Berlin, at the average rate of $\frac{3}{4}$ d. per passenger, they are unable to pay capital charges. I do not know whether they work under the same conditions as the electricity supply company, which has to hand over to the civic authorities 10 per cent of the gross profits before any other payment can be made. If so, perhaps this has more to do with the unsatisfactory financial position than the low average fare. In the case of the experimental line of the Lancashire & Yorkshire Railway, two motors are connected permanently in series. Are the field coils connected in series as well, or does the author merely refer to the armatures, a pressure of 100 volts being used for the excitation; i.e. are these motors compound wound, or are they separately excited? If the latter, the characteristic at starting would not be satisfactory. The author gives the cost of coal at 10s. per ton, and arrives at a total of £1,175, inclusive of capital charges, for the annual cost of a steam locomotive. He also mentions a cost per ton-mile, with coal at 12s. 6d. per ton. Is he taking the coal on the higher or the lower basis? I think he must have taken it on the lower basis. Mention is also made of the possibility of using single-phase motors with mercury-arc rectifiers. I think these are not yet in commercial operation.

Mr. R. M. LONGMAN: So far as I know there is no continuous-current railway system working with shunt fields, nor have regenerative systems yet been tried. It seems to be quite possible to use a shunt winding which is cut out at the start and is brought into use when very high speeds are required, that is to say for electric locomotives for high-speed passenger working. The tractive effort curves of electric locomotives will generally be

sufficient for all the ordinary traffic except at the higher speeds, which only come into question in the case of long-distance non-stop runs. There is one point that has not been mentioned, namely, wind resistance. The design of an electric locomotive can be altered much more than that of the ordinary steam locomotive, so that a slight saving can be obtained in that direction. With regard to the track, on many lines considerable trouble has been experienced with hammering, owing to the irregular turning moment. At very high speeds there is a jumping action of the wheels, resulting in powerful blows on the rails. This question is sometimes very serious, but I do not see how it can occur with the even turning moment of the electric drive. The paper referred to by Mr. Thompson stated that the higher centre of gravity of the steam locomotive was an advantage. It is in one way, but not in going round a curve. It would no doubt be possible to support more of the weight on springs, in which case the electric locomotive would not damage the track. With steam locomotives, if more power is required the weight increases very much. It is the weight of these heavy steam locomotives which has such an important effect on the life of the permanent way, so that any economy that might otherwise be obtained is more than offset by the extra cost and maintenance of the permanent way. The specification for draw-gear evidently needs revision, and there is room for improvement in the structure of both passenger coaches and goods wagons. In connection with goods traffic, in America the brakes on all the wagons can be applied from the locomotive, whereas in this country the only brake is on the locomotive, so that the latter has to withstand the whole deceleration of the train. An important point is the necessity for larger power stations; but in any industrial district, by adding the railway load to the municipal lighting, power, and tramway load, the costs could be considerably reduced. Until something more is done on those lines there is not much hope for the electrification of the main lines. Of course London itself is an example of what should not be done, as a number of separate stations have been constructed for railway purposes. The question of the rating of railways is rather an awkward problem. If the rating of the railway is reduced, an additional charge falls on the locality. I should like to know why motor coaches cannot be used for some of the express traffic, and what are their disadvantages. The author refers to the cost of coal, which has increased since 1911. As it is not likely to fall to the level at which it was a few years ago, and as steam locomotives must not be allowed to burn an inferior quality of coal, this is an important factor in favour of electrification. One advantage of electric traction is that tests can easily be made, and that it is possible to know exactly what every part of the equipment is doing, so that the necessary steps can be taken to reduce the energy consumption and cost.

Mr. A. H. W. MARSHALL (replying on behalf of Mr. R. T. Smith): With regard to adhesion, there is no doubt that the coefficient is higher for electric locomotives than for steam locomotives, average values probably being 0.25 and 0.225 respectively. The weight on the driving wheels multiplied by this coefficient gives the tractive effort that can be exerted before slipping of the wheels takes place. In case of the electric locomotive or motor-coach train

Mr.
Longman.

Mr.
Marshall.

Mr.
Marshall.

more wheels can be motor-driven, and thus greater tractive effort can be obtained than in the case of the steam locomotive, the limiting factor for the latter being the permissible weight per driving axle and the length of the coupled wheel-base, either or both of which would have to be increased in order to increase the tractive effort. A further limitation is, as the author points out, the strength of the draw-bar couplings. This also applies where only one electric locomotive is used, as the couplings have to be strong enough to transmit the total tractive effort. In the case of a train hauled by two or more motor coaches the combined tractive effort of the motors is not taken by any one draw-bar, so that a greater horse-power may be used. It is to this, I think, that Mr. J. Wright refers in connection with the influence of adhesion on methods of control. It has been established that a steam locomotive cannot be built to give the high rate of acceleration required for the operation of heavy suburban trains on a fast schedule, having due regard to the track conditions and safety in operation.

Very many attempts have been made to obtain regeneration while still retaining the ordinary series-motor characteristic, but I believe that these have not been attended with any great degree of success. With three-phase traction, however, in which induction motors are mostly used, the deceleration obtained by returning current to the line is an important feature, and is one of the principal reasons why this type of traction has been used on certain mountain railways in Northern Italy and elsewhere. I do not know what success has been obtained with regeneration on lines equipped with single-phase motors, although certain types of motors are said to operate fairly well in this respect.

Formulae dealing with train resistance are all of an empirical character, and are obtained by taking the mean of a number of dynamometer tests carried out under conditions identical as far as possible with those usually obtained in the handling of any particular class of traffic. In connection with Mr. Longman's remarks, I think that there is not much to be gained by altering the shape of the front of the locomotive, as the effect of wind resistance is mainly felt as increased friction at the wheel flanges, caused by wind pressure against the sides of the train. With reference to the increased wear on the rails where electric traction is used, I have always thought that this wear showed up more for the reason that with an electric service the traffic is generally largely increased, and consequently the extra wear cannot be directly attributed to the difference between the methods of driving. It may be, however, that the smaller wheel in the case of the multiple-unit train, and the fact that the wheels are all of the same size, do cause the wear to increase to some extent, especially at points and crossings. I believe that this has been got over by using at these places a rail made of a harder steel.

With regard to the design of fast passenger locomotives, it seems to me that the author's suggestion to use a separate exciting winding might well be resorted to in order to improve the characteristic of the ordinary series motor for the very big range in speed and power required for express traffic. I should not have thought there was any serious difficulty in building a locomotive which would do all that was required of it, and the fact that no such locomotive has yet been built is not, in my opinion, any reason for thinking that the difficulty is in any way serious, seeing

Mr.
Marshall.

that so far there has been no demand for such a locomotive. I think it will be found that manufacturers are quite able and willing to meet any specification that the railway engineer provides.

Reference has also been made to the suitability of electric locomotives for shunting work, and I could point to several instances in this neighbourhood where ordinary shunting operations are carried out quite satisfactorily and with very great economy. In particular, the North-Eastern Railway have had two large electric locomotives at work now for upwards of 10 years, with excellent results. Seeing that shunting operations are an important consideration, more especially from the point of view of an interchange of traffic with large private works which have a number of locomotives of their own, I might refer to some costs relating to the existing methods of handling traffic in a number of large works in this district in 1911. The table given in a paper which I read on this subject before the Cleveland Institution of Engineers² shows that very large savings can be made by spending capital on the electrification of works' sidings, so that in course of time as railway electrification proceeds there is no reason why all goods traffic should not be handled electrically.

I am glad to be able, along with one or two other speakers, to agree with the author that it is to the advantage of railways considering electrification to purchase the power they require from a local power company. It is to the development of the larger power supply systems that I look for future progress in the electrification of railways, beginning with suburban services and ultimately extending farther afield with the express passenger traffic from one power supply district to another. It also seems to me that the question of system will ultimately be settled by the kind of current that power companies are best able to supply; and from this point of view a compromise is most likely to be obtained with the 1,500 and 2,000 volts continuous-current overhead system. I think that the price of current will be low enough to make suburban traffic possible, in spite of the low fares that are now the custom. If this is done, and capital is spent on equipping the tracks in the neighbourhood of towns, the extra capital expenditure required for faster and longer services will not be so serious for this class of traffic and will cause it to become a paying proposition. It should not be forgotten that the price of coal has increased during recent years, and is likely to increase still more, which of course makes the electrical case still better, seeing that less coal is used per track horse-power with electrically-driven than with steam-driven trains, the thermal efficiency of the former being from three to four times higher than that of the latter.

I am inclined to agree with Mr. Thompson that for the conditions which have arisen, under which the railway companies have lost a good deal of their short-distance traffic, they are largely to blame. This has been the principal spur to their doing anything as regards electrification. That this condition should have arisen has always been to my mind a sad reflection on the enterprise of the railway companies. It is scarcely conceivable that capital would have been spent so freely as it was on expensive

² A. H. MARSHALL. The use of electric locomotives for shunting purposes. *Proceedings of the Cleveland Institution of Engineers*, Session 1910-11, Table 2 facing p. 88.

tramway undertakings if at that time the railway companies had appreciated the advantages of a frequent service on their suburban lines, and had begun to use electric cars for these services. One can hardly understand why, until quite recently, steam locomotion was considered the only possible solution for railways, because the possibilities of electric driving were obvious enough as long ago as 1890. By 1895 electric traction was a commercial proposition, and yet we reach 1902 or thereabouts before even one of the larger railway companies makes a move, and then only owing to the pressure brought to bear by tramway competition. One would have expected the large railways, with their vast resources, to have taken part in the development of electric traction and to have produced something to suit their requirements. Had they done so, I believe that the unfortunate question as to which is the best system of electrification would not have retarded progress in the way that it has done during the past 10 or 12 years. I think railway engineers having first-hand experience would have got to know years ago what system best served their purpose. There is, however, one instance of electrification being undertaken not by force of circumstances but by an endeavour on the part of the railway company to avail themselves of the good points which electric driving possesses. I refer to the mineral traffic electrification scheme which the North-Eastern Railway Company is now completing.

Mr. R. T. SMITH (*in reply*) : Mr. Stoney, referring to the poor road factor of such low-density traffic as obtains on main lines, suggests that some other form of energy storage than that provided by the storage battery is required. The author holds that for reasons other than poor road factor main-line electrification for passenger service is not in sight, but Mr. Stoney's point is another argument in favour of the railways purchasing electricity from a supply with such a diversity of load that the coming on and off of an infrequent railway traction load would be unimportant.

Mr. Hunt's criticism of a certain looseness in the use of the terms "output" and "load" is welcomed. The consistent use of the accepted terms is most important. The author is, however, not sure that the use of the single word "electricity," as short for "electrical energy" where the context can leave no doubt as to what is meant, might not with advantage become one of the accepted terms. In common with Messrs. Redman and Vesey Brown, Mr. Hunt criticized the division of passenger traffic into urban and suburban and main line. From the point of view of the electrical engineer there is no doubt that the distinction might very well be considered merely as one of density of train service. But from the economic point of view it is very convenient to distinguish between the suburban type of stopping service and the fast passenger type of non-stopping service. The suburban type may be defined as a service in which, if a reasonably high average speed is to be obtained, the actual speed is continually changing. There is the rush up to the maximum speed, and the rate of acceleration determines the power used. The maximum speed reached is continued for a shorter or longer time as required by the distance between stops, but for the highest schedule speeds used in this country the maximum speed is only reached in time to cut off current and apply the brakes either at once or after a little coasting. This applies to stops up to about 1 mile apart. For stops $\frac{1}{2}$ miles and

over, say up to 2 miles apart, the speed is only constant during such time as the maximum speed is maintained. At all other times during accelerating, coasting, and braking, the speed is constantly changing, and there are very few suburban systems, with a train density justifying electrification, where the average distance between stops is as great as 2 miles. The general character of such a service is a change of speed in which the rate of change is rapid. The main-line non-stopping type of service may be defined as one in which the speed changes during a comparatively small portion of the time between stops. The ideal is to run at the maximum speed for the longest possible time. In any service worked electrically the most wasteful use of power is where the speed changes rapidly, both during acceleration and during deceleration; the most economical use of power is when the speed is kept constantly at its maximum value. Although merely a matter of mechanics, railway men have only learned this through the ease with which electrical measurements can be made, and the author believes it to be of considerable importance that the economic distinction between these two classes of service should not only be made but be insisted on. It must always cost more to carry a passenger in a stopping service than in a non-stopping service.

Mr. Hunt has himself added to the reasons given by the author for claiming that the high-speed electric locomotive suitable for fast passenger service has not yet been produced in pointing out that designers are not yet agreed as how best to transmit the effort of the electric motor to the driving wheels. For low train speeds toothed gearing is quite satisfactory, but as train speeds increase the maximum limit of pitch-line velocity is soon passed, and some other method of transmission, either combined with toothed gearing or without it, becomes imperative. This, and its effect on the most economical peripheral speed of the armature, is very fully treated in Mr. Lydall's paper on Electric Locomotives.⁶ In general, toothed gearing transmission implies a low centre of gravity for the locomotive, which while admissible at low speeds becomes most undesirable at high speeds.

Mr. Redman, in addition to deprecating the dual classification of passenger traffic, considered that the cost of 3d. per passenger train-mile for coal and water was too low. The published accounts do not separate locomotive running costs into passenger and goods traffic, but the cost for the four longest railways in 1913 with the present inflated price of coal varied between 4½d. and 6d. per train-mile for both passenger and goods. The coal per goods train-mile is nearly if not quite double the coal per passenger train-mile, and the author has taken, rightly or wrongly, coal at 12s. 6d. per ton for a calorific value of 15,000 B.Th.U. per lb., which is a lower price than it is at present. Under these conditions the 3d. per passenger train-mile is justified.

Mr. Vesey Brown also referred to the dual classification of passenger traffic already dealt with, and deprecated anything but the frank acceptance by the railways of the tramway and motor omnibus competition. As he himself points out, however, it is a condition governing electrification. If a particular form of competition which the railway, as (in general) the largest ratepayer in any parish,

* F. LYDALL. Electric locomotives. *Journal I.E.E.*, vol. 51, pp. 748-50, 1913.

Mr. Smith.

may be called upon to support through the rates, makes a frequent stopping service unremunerative it may be best for the railway not to cater for it at all.

Mr. Hawthorne has admirably reviewed the various kinds of suburban service, and in general it is only class three, extending from about 16 miles outwards, which is profitable provided the train density is high. With electric traction it is possible to determine the minimum train density which will pay with a given schedule of fares. If fares are, however, continually lowered to meet competition, the margin is so extremely small that an electrification which promised well may turn out a failure. The fares charged are really the governing factor.

Mr. Hawthorne's argument that railway electrification would naturally develop along the present lines of suburban working extended to inter-urban working, supplemented and amplified the remarks on the same lines by Mr. Vesey Brown and Mr. Redman. His argument is supported by his classification of suburban traffic already referred to, and in the busy industrial centres of the Midlands, the North, and the North-East of England, it appears almost self-evident, though the idea is new to the author. The problem of running inter-urban services on the same tracks as a dense suburban traffic is, as Mr. Hawthorne points out, very difficult of solution. The author is glad to be corrected as to the electric train density on the North-Eastern Railway, and entirely agrees with Mr. Hawthorne's insistence that there are many ways besides reducing the cost of electricity in which the total cost of power may be reduced. Regeneration, advocated in the discussions at London and at Birmingham, is a fascinating, if somewhat elusive, problem, and the keeping down of weight is fully treated in Mr. O'Brien's paper on Electric Rolling Stock.³

Mr. Prescott's contribution to the subject of electric braking as apart from regeneration, and his clear statement of the way in which it may be used to improve the headway in very dense urban and suburban traffic, is important, and supplements Mr. Mordey's remarks on the same subject in London.

The author is entirely in sympathy with Mr. Hunter's clear statement of the incidental advantages of electric traction to which no money value can be attached in an estimate, but which may be real railway economies at the same time that they are improvements from the point of view of the public. His instance of the saving in painting of that part of Newcastle Central Station devoted to electric rolling stock is an excellent example. All that he says about the flexibility of the multiple-unit motor-coach train from the traffic point of view, the working of a goods service electrically, and the improvement in the series motor characteristic, especially with the object of reducing the ratio of the maximum to the average speed, is very much to the point. The use of the Ward Leonard system for goods working is dealt with in Mr. Lydall's paper, and needs to be carefully worked out and if possible tried experimentally in England as it has been on the Paris Metropolitan Railway. It is agreed that there should be uniformity in the unit used for acceleration. Miles per hour per second for railway purposes is the most rational, but unfortunately it is not suitable for the many other

applications of the electric motor to electrically-driven machinery used by railways, such as cranes, lifts, traversers, and winding or hauling gear.

Mr. Beard touched on several of the difficulties in presenting an estimate of railway electrification, which should take into account future as well as present conditions, owing to the continual increase in operating charges. The author believes Mr. Beard is quite right in considering that, as time goes on, electrical operating charges will tend to decrease while steam operating charges will tend to increase; but it is not the electrical engineer who takes the risk of an electrification scheme, and only time can convince the management of this tendency. The author has not exactly charged the whole capital cost of track equipment, sub-stations, and distribution against the fast passenger service, but he has shown (assuming his figures are accepted) that a sum would be available to meet these charges which would probably not come within 50 per cent of their cost under present conditions, whatever system is used.

(Communicated): The author wishes to associate himself with all that Mr. Marshall has said on his behalf in reply to the discussion at Middlesbrough. One or two supplementary remarks may, however, be of interest.

With regard to adhesion it is to be remembered that the maximum draw-bar pull of a locomotive is in general required at starting, and especially when starting on a grade. The uniformity of the torque of an electric motor, as compared with that of a reciprocating engine, only holds true when the speed is not being increased by some such device as the controller universally used with the continuous-current motor and generally used with the alternating-current motor. The fluctuations of torque when notching an electric locomotive are fully treated by Mr. Lydall in his recent paper.² In the reciprocating steam locomotive fluctuations have been reduced by design, as they can be in the electric locomotive, but in the latter they only exist during the starting period, and cease after the motor is working with full electrical pressure on its terminals. It is, however, during the period of uniform acceleration that fluctuations in torque are undesirable. Mr. Brettelle refers to the Lancashire & Yorkshire Railway electrification between Bury and Holcombe Brook. The motors are series motors used in pairs across the 3,500-volt continuous-current supply so that there is a pressure of 1,750 volts across each motor. For control, lighting, heating, and brake pump a motor-generator giving 100 volts is necessary, and this necessity led to the suggestion of increasing the size of the motor-generator and using it also for the field current. With regard to this speaker's comment on the price of coal, the figures were based on coal at 12s. 6d. per ton, or 9s. per ton for coal of 10,000 B.Th.U. per lb. There were not two prices.

It is satisfactory that engineers should recognize the inflexibility of the electric locomotive, when equipped with motors having a series characteristic, as compared with the steam locomotive *quai* speed. It is important that all possible means of improvement in this direction, as also in the direction of obtaining controlled regeneration, should be carefully studied by all interested in electric traction.

No. 233.

THE SIGNALLING OF A RAPID-TRANSIT RAILWAY.

A STUDY OF THE RELATION BETWEEN SIGNAL LOCATIONS AND HEADWAY.

By H. G. BROWN, Member.

(Paper received 12th March, and read before THE INSTITUTION 2nd April, 1914.)

The maximum headway which it is possible to obtain is primarily determined by the acceleration and deceleration rates and the maximum speed of the rolling stock, and the length (in time) of the station stops. The result is to a certain extent influenced by the geographical lay-out of the line, and also by the character of the limitations imposed by the signalling system which must necessarily be installed for the purpose of creating safe conditions of operation.

The train characteristics and the geographical lay-out of the line are generally determined before the question of signalling is considered. The length of time required for station stops can be estimated with a certain amount of accuracy, but still remains a variable quantity.

With any of the present systems of signalling it is necessary to divide the line into signal sections, a signal being provided at the entrance of each section for the purpose of indicating the condition of the section, *i.e.* whether occupied or unoccupied.

There are a number of methods of operating and controlling these signals. For instance, they may be controlled manually or automatically. The lock-and-block might be mentioned as a most effective method of manual control, the track-circuit system being the most reliable method of obtaining automatic control.

An automatic system can be arranged to allow of a far greater number of trains being operated than with any system of manual block signalling that affords an equivalent degree of safety.

The apparatus of an automatic system operates practically instantaneously, while with the manually-operated system time is required for the performance of the manual operations, and if the system is designed to obtain a high degree of safety a number of manual operations are usually required to be performed in a definite sequence. The time required for manual operation cannot be reduced when the section is shortened. For example, consider a section having a certain length. The length of this section, expressed in time, is equal to the time re-

quired by the train in running through the section. It is evident that if the section is shortened by subdivision a point is reached when the time required for the manual operation of the block system is nearly equal to that required by the train to run through the section; and should the section be made still shorter it will be found that the train is delayed by the signal system, and that the capacity of the line is being reduced instead of increased.

It has often been claimed that but little time is required for the manual control of a block system; but if these claims are investigated one or more of the following conditions will be found to exist.

Safety has been sacrificed to obtain speed in operation; or a record time has been quoted instead of the average time required by the average man working at a speed that can be maintained without undue strain throughout the time that he is on duty; or the system is practically a form of automatic system requiring a limited amount of manual control. It therefore cannot give the full advantages of the purely automatic system, and is more expensive to operate than either the automatic or the manual considered alone. Under conditions that require a frequent train service it will be found that an automatic system is the cheapest per unit section.

FIG. 1.

On rapid-transit lines that are equipped with an installation of automatic signals it is customary to provide train stops, which are located at the signals. These train stops assume an operative position when the signal is at danger, and should a train run past a danger signal they co-act with the brake mechanism, causing an emergency application of the brakes, the train being stopped thereby.

Fig. 1 illustrates one arrangement of automatic sections. Signal 1 assumes the danger position when the front end

of the train enters section A, and remains at danger until the rear end of the train has passed out of the section. Section A controls signal 1, section B signal 2, section C signal 3, and so on. It will be noted that these sections overlap the signals in advance. This results in signal 1 not assuming the clear position until the rear of the train has passed signal 2 by a pre-determined distance. A train passing a signal at danger at its maximum speed has its brakes applied by the train stop and is thereby brought to a stand before it has travelled far enough to collide with a preceding train. The length of this overlap is influenced by alignment and grade, and is usually nearly double the length required for an emergency deceleration from maximum speed. This extra allowance

required for the stop, the average speed when the train is moving is lower than it is between stations, as the station section includes both a deceleration and an acceleration. When providing signalling arrangements for a short train interval, it will be found that the station sections are the ones most difficult of arrangement.

Fig. 2 is a train diagram showing the maximum headway through an ordinary station, and is based on the following data:—

Maximum speed of trains: 25 miles per hour.

Acceleration: 1 mile per hour per second.

Service deceleration: 1·8 miles per hour per second.

Length of train: 300 ft.

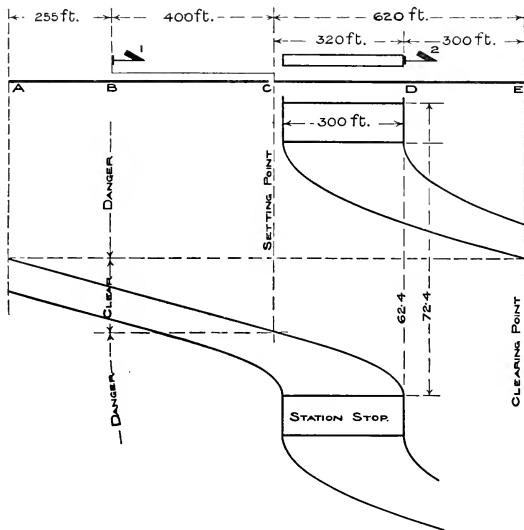

FIG. 2.

is necessary because of the possibility of the deceleration rate being less than is considered normal, due to imperfect brake adjustment or greasy condition of the rails.

The time interval between trains being the important factor, the length of sections is considered in terms of time instead of distance; and it is obvious that the section in which a station is included may, on account of the station stop, be a longer section in time than a section between stations that is many times its length lineally, because between stations it can be assumed that the train is travelling at its maximum speed. The time occupied in a station section is long because, in addition to the time

Signal 1 is controlled by the section CE, and is usually called the home signal. The overlap BC is 400 ft. long. The overlap between D and E is 300 ft. long. The length of this overlap has been reduced by 100 ft. because the section beyond E—being the starting section—is a relatively long one, and it can be assumed that a train stopping in this section would stop at the next signal. The distance AB is what may be termed the sighting distance.

With a deceleration rate of 1·8 miles per hour per second, if a train is travelling at the maximum speed of 25 miles per hour it would be necessary to apply the brakes at a

It will be seen from the above that the interval shown in Fig. 2 as 72.4 seconds is increased to 80.95 seconds, and, provided that each train stops at the station for 10 seconds, the original delay of 11 seconds has the effect of increasing the interval as stated. The tenth train will be nine times 8.45 plus 11 seconds later than its schedule time when passing the station at which the original delay occurred.

It has been assumed that the second and third trains stop at the station for the standard time. It will be evident, however, that this is unlikely. The normal time between

If 10 seconds is the usual station stop, the second train will require more than a proportional additional time, because the time required to load people is not directly proportional to the number to be loaded. This is due to the choking of the means of ingress and the tendency of passengers to move more slowly the moment that they are actually on the train, also to platform congestion. It is fair to assume then that the third train will be much more behind its schedule time than the 27.9 seconds stated.

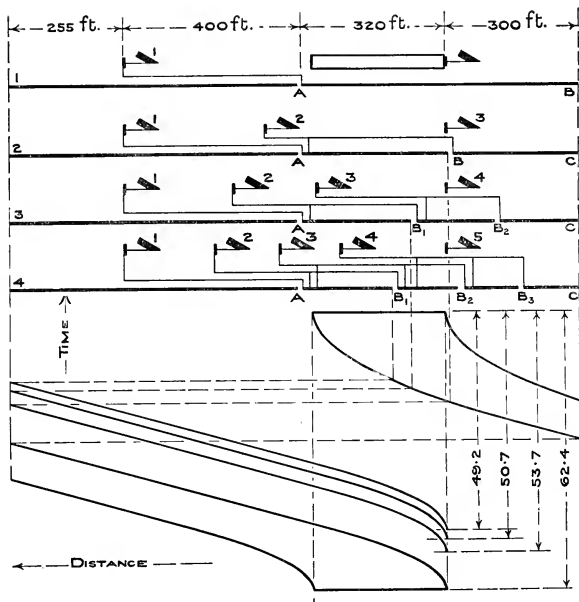

FIG. 5.

the departure and arrival of trains is 62.4 seconds. The second train arrives 71 seconds after the first train has left, and therefore finds more than the usual number of people on the platform. The interval between the starting of the second train and the arrival of the third train is also 71 seconds, and the third train in turn finds a proportionately greater number of people at the station who require accommodation.

Assuming that the volume of the flow of people on to the station platform is continuous, it is evident that each following train must accommodate more than its usual number of passengers.

The foregoing proves that the interval of 72.4 seconds with a 10-second stop is the theoretical minimum, as stated, but this interval cannot be satisfactorily operated, due to the possibility of the station stop exceeding the 10 seconds allotted. The headway which can be practically maintained is therefore equal to 62.4 seconds plus the maximum length of station stop; and any stop longer than what has been, by observation, arbitrarily determined as the maximum, must of necessity result in disorganization of traffic.

The minimum train interval which is practicable with the signalling arrangements illustrated would probably not

be less than double the theoretical minimum interval shown in Fig. 2.

Let us assume that a service is being operated with an interval of double the theoretical minimum. Each minor delay that occurs has a tendency to cause the trains to bunch. Eventually a point is reached when the trains are running as near the real minimum interval as possible, and then any further delay results in accumulative delay with its attendant disorganization, and such disorganization is generally found to continue until the cessation of traffic after midnight.

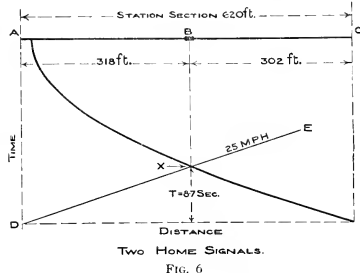

It is evident that the station section is the critical one from the standpoint of time, and if a more frequent service is required the signalling arrangements at the station must be modified. The first step would be to provide one inner home signal, and it is possible that it may be considered advisable to install two or three inner home signals.

Fig. 5 shows the decrease in the train interval obtained by an increase in the number of home signals. Line 1 has the same signal arrangements as illustrated in Fig. 2. Line 2 has an additional home signal, necessitating the subdivision of the station section A C at the point B. No. 1 is controlled by the section A B, and No. 2 by the section A C. In line 3, signal 1 is controlled by the section A B, signal 2 by the section A B, and signal 3 by the section B C, signal 3 being located on the rear end of the station platform. In line 4, signal 4 is located on the platform. This location has the disadvantage that the front car of a train stopping at this signal would be at the platform. In the majority of cases the advantage obtained by the four home signals would hardly justify the cost of the complete extra section, the saving in time being only $1\frac{1}{2}$ seconds. The arrangement shown on line 3 would have a decided advantage over line 1, and the additional saving of 3 seconds to that shown in line 2 is well worth while in the majority of cases. The sighting distance for signals has been assumed as 255 ft. It is evident that the distance between signals 1 and 2 is the same as the distance between the sighting points of these signals. The following train, travelling at 25 miles per hour, should require the same time between these sighting points as is required by the tail of the preceding train to travel between the points B and C, and it is evident that the distance B C must be equal in time to the distance between signals 1 and 2. A 400-ft. overlap is allowed between signal 2 and B. Therefore, the distance from signal 1 to signal 2 is the same as the distance A B, and at 25 miles per hour is equal in time to the latter part of the acceleration occurring between the points B and C. The same time and distance relations exist in lines 2, 3, and 4, of Fig. 5. Take line 4 as an illustration. From 1 to 2 is equal in time to B₁ to B₂, and equal in distance to A to B₁. From 2 to 3 is equal in time to B₁ to B₂, and equal in distance to B₁ to B₂. From 3 to 4 is equal in time to B₂ to C, and equal in distance to B₂ to B₃.

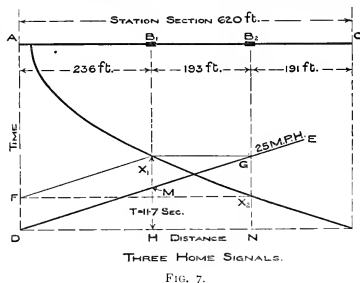

Fig. 6 shows the method of ascertaining the location of the point B. The line D E is drawn at an inclination equal to 25 miles per hour, and the point where it intersects the acceleration curve gives the correct position to subdivide the section A C.

The method of dividing the distance A C into 3 sections is shown in Fig. 7, and differs slightly from that shown in Fig. 6.

The 25-mile-per-hour line D E occurs in Figs. 6, 7, and 8. A trial line X₁ G is drawn first, then the vertical

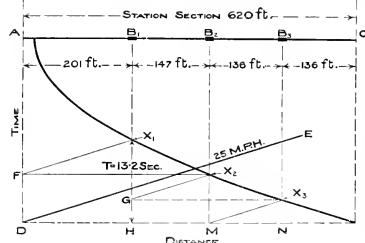

ordinate G N is drawn. This line intersects the acceleration curve at X₂. The point F is found by drawing a line

from X₂ parallel with N D. A line connecting F with X₁ should be parallel to the line D E.

Fig. 8 shows the division of the station section A C into four sub-sections. Select an approximate position for the point X₂ a little more than half-way between A and C. Draw the horizontal line X₁ F, and a line from F parallel to the line D E, to intersect the acceleration curve at X₁. Next, draw the ordinate X₁ H. This ordinate gives the position of the point B₁. Draw the line X₂ G parallel to the line D E, then a horizontal line from G to X₂, also the ordinate from X₂ to M. A line connecting X₁ to F should be parallel to the line D E if the trial position of X₂ was correct. If this result is not obtained, the inclination of the line X₂ M will suggest a new trial position for X₂. It will be evident that three comparisons between the average speed during acceleration in the separate sections and a maximum speed of 25 miles per hour are shown; the first comparison X₁ to F against X₁ to X₂; the second comparison X₂ to G against X₂ to X₂; and the third comparison X₂ to M against X₂ to the ordinate C. It is evident from the construction that the time of the preceding train in one

section is equal to that of the following train travelling at a speed of 25 miles per hour through a distance equal to the length of the preceding section. These points of subdivision can of course be calculated, but the graphic method shown is simpler and requires much less time.

FOUR HOME SIGNALS.

FIG. 8.

Also there is less liability of mistake, as an error is immediately evident. The acceleration and deceleration curves used in these diagrams have been calculated from the rates stated, and it has been assumed that trains would approach the outer home signal at maximum speed. It is most probable in practice that the average acceleration or deceleration would differ from the theoretical curves shown, and it is unlikely that the trains would approach the outer home signal at maximum speed, as in all probability they would be coasting at this point.

In actual practice, it would be found advisable to provide for a signal sighting distance of at least 500 ft.; but as 255 ft. is the deceleration distance from 25 miles per hour at the rate stated, this distance has been assumed as the sighting distance for signals, because any distance additional to the deceleration distance is required by the personal equation of the driver, and if considered herein would introduce a variable factor which would confuse the explanation of the principles involved. When locating a number of inner home signals at any particular station, it is necessary definitely to determine the conditions which exist. Speed curves should be obtained from an average of many tests of accelerations and decelerations at the station concerned; also the average speed in the vicinity of the home signals should be found. These factors are influenced by alignment and grade and other local conditions of service, as well as by the driver's habitual method of acceleration and brake application. When tests of this kind are made at any definite locality it is surprising how near to the average are the majority of the accelerations and decelerations, a small percentage only having any radical variation.

The time required for the station stops is the most important of the various factors which influence the time interval, and while the value of this factor is mainly dependent on the amount of traffic at the station considered, it is greatly influenced by the physical arrangement of the station, and also by the efficiency of the train and platform staff.

If it is wished still further to increase the service, there is another arrangement of station signalling which is considered very satisfactory where it has been installed, and which undoubtedly further reduces the time elapsing between the starting of the first train and the arrival of the next. With the speed-control system the second train is allowed to decelerate to a position very near the rear end of the train standing in the station, while in all the signal arrangements described a 400-ft. overlap has been provided. In the previous arrangements, should the train remain in the station more than the usual time, the following train would be stopped at the outer home signal, and when the signal cleared would accelerate and then decelerate to the stopping-point in the station. With the speed-control system, as the following train would be stopped only a short distance in the rear of the train standing in the station, it has much less distance to travel than in the former case. The important function of the system is its control of the deceleration of the following train. This result is obtained by dividing into a number of signal sections the distance between the outer home signal and the point at which the train is intended to stop, a train stop and signal being provided at each point of subdivision. A timing apparatus is installed in connection with each signal and train stop, and is arranged so that the signal clears a predetermined number of seconds after the entrance of the train into its approach section. The time interval between the entrance of the train into each section and the clearing of the signal at the entrance to the next, is based upon the portion of the deceleration curve which should occur within the section, with the result that a train approaching an occupied station and decelerating properly finds that each signal clears just before it is reached, but if it fails to decelerate at a sufficiently rapid rate the brakes are applied by the next train stop because it has travelled through the approach section in too short a time. The speed-control system as described has the drawback that the deceleration of the train is checked only at certain points. It is possible to enter a section at a speed below normal and then to accelerate, passing the next signal after it had cleared and then being tripped by the following signal, by that time having attained a higher speed than was anticipated at that point. An arrangement of sections and section times which would satisfactorily overcome this liability would partially defeat its own purpose.

A system of this type is a check on a driver who has failed to decelerate sufficiently quickly through error rather than intention, and it cannot provide for extreme negligence or ill-intention.

The advisability of installing speed-control at junctions and on steep inclines has been suggested, but the author would hesitate to make such an application of the system, at least of the form in which it is now in use. To get sufficient control of the train, the sections must be very short, and as the reflex time of the apparatus is not always perfectly constant any variation would quickly assume a larger percentage of the total time allotted to any section.

The advisability of the use of the speed-control system as at present installed is open to argument, and the author is of the opinion that in the majority of instances it is better to maintain at all times a definite minimum distance between trains.

DISCUSSION.

Mr. ROGER T. SMITH: With regard to the general subject of signalling as it affects electric traction, I think there are two types of signalling likely to be rapidly developed: first, track circuiting for signalling purposes, in which the train itself completes the circuit and through a relay can work the signal; and secondly, cab signalling on locomotives. The paper deals only with the results of track signalling in a particular case, no reference being made to principles or methods of application; but I think we ought to remember that as far as electric traction is concerned the signal engineer and the traction engineer have to make use of the same rails, and they do that for their mutual advantage. The maximum number of trains per hour during the times of busiest traffic can only be obtained by the co-operation of the traction engineer and the signal engineer, and both deserve about equal credit for the results achieved. Most track circuiting on large railways is at the present time carried out by continuous current at very low voltages—rarely exceeding 2 volts—and such currents are of course subject to interference by any stray earth current. There comes a time in most busy places, especially where there is any electric traction by continuous current on the railway itself, or where there are electric tramways in the neighbourhood, or even possibly where a power or lighting supply can go to earth, when the risk of interference to track circuits from stray currents is a greater risk than the signalling engineer can afford to take. In such places alternating-current track circuiting may be said to be the complete solution of this dual use of the same rails by the traction engineer and the signal engineer. The alternating current for track circuits can quite easily be superimposed on continuous current in the same rail. It can also be superimposed on other alternating-current traction currents in the same rail, provided the periodicity of the former is two or three times as great as that of the latter. Impedance bonds at the end of the signal section choke back the track-circuiting currents while allowing the traction currents to pass. I think it is important, in the case of any railway which has in contemplation the use of electric traction in any form, that the signalling engineer and the traction engineer should get together and determine from the start the exact terms on which they are both going to make use of the same rails. Fig. 2 in the paper shows a service with a normal time interval of 62½ seconds; that means 57 trains per hour each way. The author, however, on page 548 says that with the type of signalling shown in Fig. 2 double this interval would probably be wanted in practice, that is, it would only be possible to get 29 trains per hour each way as a maximum train service. Now at the present time on the London underground railways 44 trains per hour are, I believe, actually being run, and 50 trains per hour each way as a maximum during the "rush hours" has been stated to be possible. I should like to ask whether lines 2 and 3 on Fig. 5 represent anything like 50 trains per hour each way, not in theory, but in practice, and whether that is the type of signalling that the author would propose for such a number of trains. I think the case may perhaps be stated somewhat differently from the way in which it

has been put in the paper. If 50 trains per hour each way are being run, the time interval is approximately 72 seconds, and from the last home signal into the station will, with the speed and retardation mentioned, probably take 35 seconds. To accelerate out of the station and to leave it will take another 10 seconds, and we have thus accounted for 45 seconds out of the 72. There remain 27 seconds for the station stop and for any margin. Provided the station stop never exceeds 27 seconds it appears as if under those conditions, with the accelerations and decelerations mentioned in the paper, 50 trains per hour could be run each way. I should like to ask the author whether he considers that limit has ever been reached in actual service, or if not, whether it could be reached.

Mr. A. T. BLACKALL: I agree with the author that an automatic system of signalling will allow of a far greater number of trains being operated than any manual system which would be equally safe. The graphic method which has been devised by the author for determining the locations of signals and the dividing points of the sections should prove very useful to engineers and others who have to provide for the signalling of a rapid-transit railway. I take it that the author's experience of rapid-transit railways has mainly been gained on underground lines, and in some respects the conditions underground will probably vary from those on a surface railway. The Great Western Railway Company is considering at the present time the problem of signalling in the case of an electric rapid-transit surface railway. An automatic system has been proposed which differs in certain respects from the usual automatic system of signalling employed on the existing rapid-transit railways in London. In order to provide for the ready sighting of the signals above ground, particularly in snowstorms, fogs, and bad weather generally, it is proposed to have signals of a very distinctive type. It is suggested that these signals should be what is known as "upper quadrant" signals, that is to say the arm of the signal when not in the "stop" position will rise above the horizontal instead of dropping below it, as in the case of the ordinary signals used on most railways. If the proposed signals are adopted they will be known as three-position signals, having what I believe American engineers call three "aspects." The first aspect, or the third—it does not matter much which—is "Stop," and the arm stands out at right angles to the post. A red light is shown at night. The second aspect has the arm raised 45 degrees, which means "Proceed Cautiously" (yellow light at night), and the third aspect has the arm pointing upright, which means "Proceed" (green light at night). These signals will be controlled by alternating-current track circuits. When the "Stop" aspect is exhibited, what is meant is that the section immediately in front of the signal is blocked. When the "Proceed Cautiously" aspect is exhibited, it means that the section next beyond that is blocked. Whilst when the "Proceed" aspect is exhibited it means that neither of those sections is blocked. In addition to those 3-position signals it is suggested that an automatic system of cab signalling should be provided, in conjunction with the usual train stops, the signals in the cab to be given by

Smith.

Mr. Blackall.

means of the passage of shoes upon the trains over ramps fixed between or by the side of the running rails, so as to provide for the contingency of drivers failing to observe the visual signals displayed at the side of the line. It is thought that such an arrangement will be particularly useful, and much facilitate the working of traffic in times of fog and in bad weather. It is probable that the arrangements which I have mentioned will have to be supplemented by the use of treadles for placing the signals to danger and clearing them, since it appears doubtful whether under some conditions an alternating-current track-circuit will take care of light engines of the ordinary locomotive type which may possibly run over the line, and light-weight trains composed of empty goods trucks. It seems probable, particularly after the line may have been closed for a few hours, that the alternating-current track-circuit arrangement might not in such cases do its work properly. This seems to make it necessary, in addition to the apparently complete arrangement which I have just mentioned, to provide treadles. I should like to ask the author whether in fixing the location of signals and the dividing points of sections he actually adopts in practice the diagrammatic method which he has explained.

Mr. Firth.

Mr. H. W. FIRTH: Mr. Blackall has drawn attention to one point which I think is important, namely, that the strict title of the paper should be carefully kept in mind, viz. a system or method of signalling for rapid-transit lines, and it must not be assumed, as Mr. Blackall has pointed out, that this is universally suitable for lines carrying general traffic. I regret that the author has not given us any information whatever upon the subject of signalling at junctions or terminals. He rightly emphasizes the importance of the length of station stop in rapid transit, but the junction and the terminal factors are in some cases of almost equal importance, and apart from the traffic point of view the technical aspect of the signalling problems in junctions and terminals is extremely interesting. I should very much have liked the author to have given us his views on these uses of electric signalling, and as to how far such automatic signalling will decrease the limitations of those junctions and terminals. I think it is all the more important too because my opinion is that these are just the particular cases where automatic track circuiting does score heavily over manual arrangements. On the plain, straight-through runs with the lock and block arrangement manual operation can and does in practice give surprisingly quick and good results. On the other hand, in heavy, quick traffic over junctions, and in traffic such as that on the Metropolitan District Railway or on the Tubes, I think it is quite safe to say that that type of traffic could not be handled except under automatic track-circuit-signalling conditions. The length of station stop, which the author emphasizes, is, as I have said, of great importance. He points out at the bottom of page 550 the various factors which influence the time interval. One point, which I think he has not mentioned, and which in my opinion is very important, is the influence of train design upon the time of the station stop. I have timed several hundred station stops on London railways, both steam and electric, and I am certain from my observations that the type of rolling stock, the arrangement of doors, and so forth, are of great importance in determining the length of the station stop. The author

has to some extent cleared up one point which I was going to mention about the overlap of 300 ft. shown in Fig. 2 from D to E. As he has mentioned, with a train not calling at that station that overlap is certainly not enough, but he seems to have based his time calculations entirely on the assumption that the trains call at all stations. I should like to know how the elimination of a certain number of station stops over a given line will affect the signalling and the total carrying capacity of the line. I was very much interested in the author's remarks as to time-discriminating signals. He does not seem to be very enthusiastic about them. In *Elektrische Kraft, triebwerke und Bahnen** last year there was a paper by Brugsch and Briske in which a very exhaustive account was given of an investigation into the traffic capacity of a rapid-transit line, and in that paper the use of these time-discriminating devices was mentioned as being quite a usual practicable arrangement; in fact, I think it was said that satisfactory methods of carrying this out were numerous and need not therefore be referred to. I believe the method was first suggested by Mr. Bion J. Arnold in his Report on increasing the traffic capacity of the subway in New York, and I believe it has been in operation there. I should be very interested if the author could tell us where this time-discriminating arrangement is in operation, and what success has been obtained with it. Another question that I should like to ask is this: the paper is apparently based on a 300-ft. length of train; assuming that a line is laid out with the signalling as described by the author on a basis of a 300-ft. train, what will be the effect upon a signal lay-out of increasing the train length to say 400 ft. if the necessities of the traffic demand that length of train being used? That is to say, what differences would the author make in the signalling in the first instance when considering a line where 300-ft. trains are required at very short intervals, to allow for the possible increase in the length of trains?

Mr. H. G. BROWN (*in reply*): Mr. Smith has raised the question of the number of trains per hour shown in Fig. 2, and wishes me to state the results in trains per hour with the different arrangements of signalling shown in Fig. 5, lines 2, 3, and 4, and so forth. In replying to that I will answer to a certain extent one of Mr. Firth's questions. I was anxious to explain the principle of cumulative delay, and had therefore made certain definite assumptions, so that in all instances the results would be directly comparable. Referring to Fig. 2, take a railway with a number of stations, some busy, some not busy. It is quite possible that a satisfactory service could be operated with a headway less than double the time shown in the diagram, provided that the critical stations were not too great in number; in fact, it is done on the District Railway at the present moment and on some of the Tubes. Supposing that every station were a critical station, then I doubt very much if a continuous schedule, day in and day out, could be operated if the headway were much less than double the theoretical minimum, but it is quite possible to operate a service with a few critical stations when those stations come within 10 or 15 per cent of the theoretical. Fig. 5, line No. 2, represents practically 55 trains per hour; line No. 1 represents 50 trains per hour; and line No. 3 represents 59 trains per hour, that is, assuming a 10-second stop. It is very difficult to say exactly what schedule

* Vol. 17, p. 553, 1913.

own. could be run with the signalling installation shown, because, as I say, it depends so much on what is occurring in the other parts of the line—how many narrow necks the bottle has. I think they maintain the 44 trains per hour in the "rush hour" with more or less success on the District Railway at the present moment, and I think the maximum number of inner "homes" at any one place is two, which corresponds to line No. 3. A schedule of 44 trains per hour is not readily maintained; it is a strenuous proposition, and every additional train makes the fight infinitely harder, much more so than is apparent.

Mr. Blackall referred to two things, namely, cab signals and whether I myself make use of these diagrams. I am strongly in favour of cab signals for the purposes for which they were meant. I think that on the Great Western Railway they have the proper idea of the use of the cab signal. As to whether I use these diagrams, I may say that I do not always have time. There is some difficulty in finding out the conditions that actually exist at any given place, and a great deal more judgment than mathematics is required.

Mr. Firth referred to the question of junctions and terminals. I intentionally avoided that, because I did not want to make the discussion too long. The junction and terminal proposition from the signalling standpoint is, if I may say so, more interesting, inasmuch as it is more complicated than the simple illustrations given. A terminal gets more complicated when one tries to lay out and demonstrate definitely what occurs, because as soon as a terminal is approached one also encounters a hundred questions which cannot be calculated and which must be assumed arbitrarily—and the correctness of the assumptions depends upon the judgment and the experience of the person making them. I knew that if I referred to a junction, or showed a train diagram of a junction, or tried to justify the location of signals, or the length of track circuits at a junction, it would start a discussion which would take too much time. The physical arrangement of the station has a very great effect on the possible headway. There is one thing that has always surprised me greatly, namely, that so many people know how to arrange a station perfectly, and so few stations are arranged perfectly. The two things do not seem to justify each other. There are some fundamental principles to be borne in mind. One might be said to be the fact that opposing streams of people should be kept separate, so that the progress of people, either going to or leaving trains, will not be impeded. The same principle applies in reference

to car design. I am very strongly of opinion that it is better to have all the people moving in one direction inside a carriage standing in a station, that is, in, at the middle and out at the ends when there are three doors, or vice-versa; or in at one end and out at the other with two doors only, the two ends of the carriages which are together having the people either coming out or going in. That experiment was tried on the District Railway some years ago when the line was first electrified, and for some reason it was given up. I think it was a great mistake, because I have great faith in the capacity of the public for training of that kind.

In reference to the 300-ft. overlap at starting signals, many of the overlaps are short on the District Railway, and on similar railways where all trains stop at all stations. The Board of Trade allows a very short starting-signal overlap here in London, say 15 or 20 ft., but it requires a longer overlap when trains run express through stations. I think one thing has to be borne in mind when considering station overlaps, etc., namely, that it is as necessary to allow the traffic to run as it is to protect it, because it is impossible to do the latter until the former occurs. We find it necessary to obtain dispensations from the authorities in the case of a number of things in railway work, otherwise it would be impossible to operate railways. Certain conditions may justify the modification of general principles.

The speed control, as Mr. Firth points out, was first installed on the Interborough Rapid Transit line in New York. The idea of a system of speed control is excellent, and would be exceedingly useful if the method were satisfactory in detail. In my opinion the system as installed is, however, not sufficiently good to warrant its installation under conditions where it would be of most use.

The effect on the interval, of trains longer than those shown in the diagram, has been referred to. The use of longer trains would undoubtedly increase the time interval, while shorter trains would to a certain extent decrease the interval. The signalling would of course be arranged to accommodate the longest trains in general use. There is greater disadvantage in running trains longer than those that the signalling is planned to accommodate than would result if shorter trains were used; the signalling arrangements would therefore be planned to accommodate the longest trains. With trains shorter than those shown, the following train would find the outer "home" clear, although a train was standing at the starting signal, and it would be able to run up to the first inner "home." This would be perfectly safe, as all the home signal overlaps are full length.

Mr. Brown.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 19TH MARCH, 1914.

Proceedings of the 565th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 19th March, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 12th March, 1914, were taken as read, and confirmed.

The subject of "Electric Battery Vehicles" was discussed (see page 493), and the meeting adjourned at 9.55 p.m.

ORDINARY MEETING OF THE 26TH MARCH, 1914.

Proceedings of the 566th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 26th March, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 19th March, 1914, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Donations to the *Library* were announced as having been received from A. Blok, W. Brew, A. E. Kennelly, and Messrs. Siemens Brothers & Co., Ltd.

A paper by Messrs. K. M. Faye-Hansen, Associate Member, and J. S. Peck, Member, entitled "Current-Limiting Reactances on Large Power Systems" (see page 511), was read and discussed, and the meeting adjourned at 9.50 p.m.

ORDINARY MEETING OF THE 2ND APRIL, 1914.

Proceedings of the 567th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 2nd April, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 26th March, 1914, were taken as read, and confirmed.

Messrs. W. R. Mickelwright and M. G. Tweedie were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

		ELECTIONS.	
		<i>Graduates.</i>	
<i>Members.</i>			Krohn, Vere Ronald.
de Valbrenze, Robert.		Fraser, George Victor Ross.	Lee, James Frederick.
Michôd, Percy Douglas.		Marchinton, William Franklin.	Lovegrove, Clifton George.
Powell, Alfred Everett.		Murphy, Gerald Hope.	McWhinnie, Donald Rolfe.

A paper by Mr. H. G. Brown, Member, entitled "The Signalling of a Rapid-transit Railway: A Study of the Relation between Signal Locations and Headway" (see page 545), was read and discussed, and the meeting adjourned at 9.20 p.m.

SOME METHODS OF IMPROVING THE POWER FACTOR IN ALTERNATING-CURRENT CIRCUITS.

By GEORGE STEVENSON, Member.

(Paper received 20th February, and read before the SCOTTISH LOCAL SECTION 3rd March, 1914.)

The title of the subject under discussion this evening has been chosen so as to cover as wide a range as possible. The author proposes to deal with the matter briefly from the standpoint of the user of electrical plant, and to confine his remarks to industrial installations of a capacity not exceeding 5,000 kw. It will be convenient to classify the consumers according to whether—(A) they obtain a supply from an outside source, or (B) generate their own electrical energy on the premises.

(A) PUBLIC SUPPLY.

Upon application being made for a supply of electrical energy it will be found that there is usually a special clause in the form of an agreement relating to the power factor of individual motors, or of the installation as a whole. Hitherto very little attention has been paid to this clause by engineers engaged in the electrical equipment of factories, and the consumer has been advised that it is no concern of his, and that the matter will be looked after by the supply company.

Is this attitude justified at the present time? The answer evidently depends on the geographical situation of the consumer. The author has examined the rules in respect of power factor in the case of 23 supply authorities in the United Kingdom. A few examples are given below—

1. The power factor of any individual motor on the system must not be less than 0.7 at full load under normal conditions of supply.
2. The power factor of the installation must not fall below 0.85.
3. The power factor in the aggregate shall not be less than 0.8. If it falls below this figure the right is reserved to recalibrate the meters, or otherwise to take such steps as may be deemed necessary to safeguard the system.
4. If the power factor of the installation as a whole is 0.8 or over, the scale of charges is subject to a reduction of 5 per cent. If it falls below this figure, no reduction is allowed.

The first three are obviously "blanket" clauses, and, so far as can be ascertained, no installation has yet been refused a supply on account of low power factor.

The fourth example is on more business-like lines, and it will easily be seen that in the case of a large factory having from 2,000 to 3,000 h.p. installed it is important that the wattless current should be reduced to the minimum value if the owners are to obtain their power at minimum rates. Now it is clear that considerations of price and starting torque limit the choice of motors to the asynchronous or induction type in all industrial installations, hence it is desirable to choose well-designed motors running at as high a speed as possible, and also carefully to study the power requirements of each group of machines in the factory, so that under normal conditions the motors will

be running at or near full load. Fortunately the modern induction motor with its high overload capacity and pull-out torque enables this to be done in most cases, except where a large margin of power is called for on account of future extensions.

To illustrate the above points curves are given in Fig. 1 showing the power factor of a three-phase 50-cycle motor of 200 b.h.p. running at 1,480 revs. per minute, and of a similar machine at 375 revs. per minute, from which the superiority of the higher speed machine is apparent, especially at fractional loads. It will be seen from the foregoing that until the supply authorities take steps to enforce their rules it may be stated in general that it will

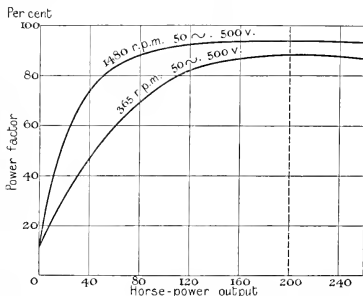

FIG. 1.—Power-factor Characteristics of Induction Motor.

not pay the consumer to take any special precautions other than the above in respect of power-factor improvement. Of course there are extra I²R losses in the feeder cables at low power factor, but this is a point which more immediately concerns the supply engineers, and is therefore outside the scope of these remarks.

(B) PRIVATE SUPPLY.

In a paper* which the present author read before the Glasgow Local Section in April, 1908, it was pointed out that it was usual to assume an overall power factor of 0.8 for general industrial installations and of 0.75 for mines. Some representative examples taken from actual installations may be of interest.

	Plant capacity, kw.	Power factor
(1) Small iron and steel works ...	750	0.65
(2) Textile mill ...	4,000	0.87
(3) " " (special fabric) ...	750	0.7
(4) Group of collieries ...	—	—

* G. STEVENSON. Polyphase induction motors: the choice of type. *Journal I.E.E.*, vol. 41, p. 670, 1908.

Actual experience shows that the harmful effects of low power factor are at once evident on the generating plant, causing a reduction in the rated electrical output and introducing difficulties in maintaining normal voltage, owing to the demagnetizing effect of the lagging currents upon the alternator field magnets. Hence the great overload capacity of the steam turbine and stator of the alternator cannot be utilized because the lagging current begins to overcome the field at heavy loads, and it is necessary to

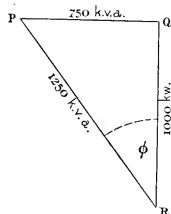

FIG. 2.

start up additional plant. Taking a concrete example and assuming a load of 1,000 kw. at 0.8 power factor, the relations between the various quantities in the circuit are shown by the vector diagram in Fig. 2, where

PR = total output in kilovolt-amperes,

$$= 1,000/0.8 = 1,250 \text{ k.v.a.},$$

QR = 1,000 kw. = true power load,

PQ = wattless component = $\sqrt{PR^2 - QR^2} = 750 \text{ k.v.a.}$,

ϕ = angle of lag; $\cos \phi = QR/PR = 0.8$.

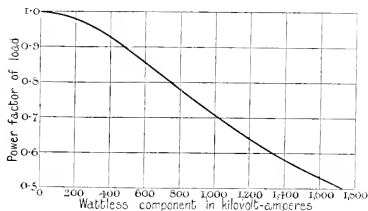

FIG. 3.

It will be seen that the total load in kilovolt-amperes represented by PR is made up of two components QR and PQ , which are at right angles to each other corresponding to a phase difference of 90° . Hence the wattless component at any power factor can be very simply obtained as follows:—

Let A = total number of kilovolt-amperes at the given power factor,

and B = useful load in kilowatts.

Then wattless component = $\sqrt{A^2 - B^2}$.

The curve shown in Fig. 3 has been prepared from a table by Mr. W. M. Mordey. It gives the output in kilovolt-amperes which would be required for the correction to unity or any other power factor of a load of 1,000 kw. at various power factors. The abscissae represent the number of kilovolt-amperes required at leading power factor equal to zero, *i.e.* the wattless component, and the ordinates give the corresponding power factor of the load. For example, if it is desired to raise the power factor from 0.7 to 0.85, the number of kilovolt-amperes necessary will be $1,020 - 620 = 400$; whereas to raise the power factor from 0.85 to unity, 620 k.v.a. are necessary.

MACHINES IN ACTUAL USE FOR POWER-FACTOR CORRECTION.

A number of different devices have been proposed for the purpose, *e.g.* electrostatic condensers, vibrators, etc., but the author is not aware that any of these are in commission in this country, and in any case he proposes in what follows to deal only with plant with which he is personally familiar.

1. SYNCHRONOUS MOTOR RUNNING LIGHT.

This arrangement may be briefly described as an alternator without steam. It has low initial starting torque, and its speed is constant, depending only on the frequency and the number of poles. A supply of continuous current is required for exciting the rotating field-magnets. For a given load there is one particular value of the exciting current which causes the motor to draw minimum current from the line. Under these conditions the current is then in phase with the electromotive force and the power factor is unity. A reduction in the exciting current results in an increase in the amount of alternating current in the stator, and it lags behind the impressed voltage. If the exciting current be increased, there is also a corresponding increase in the main current, but with the important difference that it is now a leading current and consequently can be made to compensate the lagging current, due to self-inductance, of other apparatus on the system.

Methods of starting.—For the smaller machines an auxiliary squirrel-cage winding is embedded in the poles of the field system, and the motor can then be switched on to the line through an auto-transformer starter. In practice a throw-over oil switch is used, which in the first or starting position allows the motor to run up to a speed a little under synchronism, when the switch is then quickly connected straight on to the line. It will be understood that the field winding is short-circuited—usually through a resistance, although this is not really necessary in the smaller sizes when a squirrel-cage winding is added—at the moment of starting up, and that in the final position of the main oil switch the field switch is thrown over to the continuous-current supply. Suitable interlocking devices ensure that the operations are carried out in the correct sequence.

The maximum current drawn from the line with this method is approximately the full-load current if the starting torque required is very small. A diagram of the connections is given in Fig. 4 for a 100-k.v.a. set. In larger sizes a separate induction motor is direct, coupled to the machine at one end, a small continuous-current machine

being attached to the other end and used as an exciter. In view of the fact that the initial cost of this description is about £3 per k.v.a., it is evident that its use

current side. The cost of this type of machine, in so far as power-factor correction is concerned, will naturally depend on the proportion of the total cost debited to the mechanical

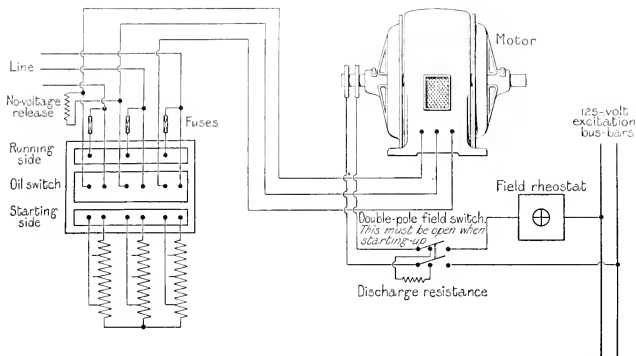

FIG. 4.—Diagram showing Connections of Starting Compensator and Field Circuit for Synchronous Motor.

is restricted to exceptional cases, but the following results obtained in the case of the small works plant referred to on page 555 (example 1) show that the method is justified. Before the installation of the synchronous motor, three steam-driven sets each of 250 kw. were required, the full-load current being 1,150 amperes per phase and the power factor 0.65 lagging. It was found impossible to maintain normal voltage under these conditions. When the synchronous motor was installed the full-load current fell to 850 amperes lagging, and the power factor rose to 0.9 lagging, the leading current given in the system by the motor being 450 amperes. This relieved the situation to such an extent that one 250-kw. set is now shut down entirely.

2. SYNCHRONOUS MOTOR WITH MECHANICAL LOAD.

If a suitable load can be provided, the practice of using synchronous motors for power-factor correction assumes a much more favourable aspect, and can be regarded as quite good under all conditions. For example, if a supply of continuous current is required, the motor and generator can be direct coupled, and thus in addition to compensating for the lagging current the machine can at the same time supply the necessary mechanical power to drive the continuous-current generator. The electrical output available for power-factor correction in addition to the mechanical output of the motor can be ascertained from the curve in Fig. 5. For instance, if 80 per cent of the rated output of the motor is used to drive a generator or other load, then 59 per cent of its rated output is available for improving the power factor of the system. Maximum utility occurs when the electrical output equals the mechanical output, i.e. when each has the value 71 per cent. As regards starting, it is preferable to arrange for starting up from the continuous-

load. Probably £1 to 30s. per k.v.a. would be a reasonable figure to assume.

A set of 300-k.v.a. capacity is at present being installed to

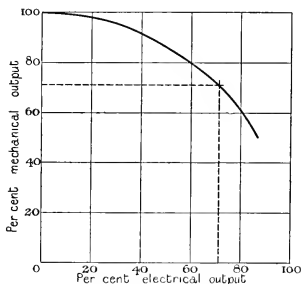

FIG. 5.

deal with case (2), page 555. No figures, however, are yet available, as the machine has not been put into commission.

3. THE PHASE ADJUSTER.

The foregoing methods are quite general in their application, and can be applied either in the main power station or in sub-stations, and they can also be used to compensate for lagging current due to one large induction motor or to a number of small motors. The increasing use

flow in the direction shown by the arrows. If, however, the adjuster were connected at the points P and Q then the wattless current would circulate in the circuit PRSQ. Hence only the generators can be relieved of wattless current when the compensating plant is in the main power

station, and as the saving in long feeder cables in a large network will generally exceed all other economies combined, it is essential that in such cases the adjuster or synchronous motor be installed close to the load which causes the low power factor.

DISCUSSION.

Mr. J. CALDWELL: I should like to draw the author's attention to the use which has been made of static condensers for improving the power factor. The Midland Electric Corporation's installation of condensers was referred to in the discussion on Dr. Kapp's paper,^{*} and in view of the prevailing opinion that condensers are unreliable, it is interesting to learn that no trouble has been experienced in that case. I think there are two points of view in regard to the author's question as to the justification of the present attitude of consumers in omitting to improve the power factor of their installations and incidentally that of the supply company's system also. The consumers' view is that if the power company's system has a low power factor it is the company's concern to improve the power factor by installing condensers or a synchronous motor at suitable positions in the network. On the other hand, if it is desired that consumers should improve the power factor of the supply system they will have to install synchronous motors or fit phase advancers to induction motors larger than 150 h.p. As it is probable that motors of such a size would be supplied at high pressure by a power company, the induction motor would be the most suitable type to use, even though it has a low power factor. The power company might certainly grade their charges for current according to the power factor, although this method would introduce complications in measuring the extent of the improvement in order that credit might be given for it; but as the addition of a phase advancer would do away with the simplicity and reliability of the induction motor, I think it will be extremely difficult to make consumers appreciate the value of power factor improvers and go to the expense of fitting such auxiliary apparatus. If the power companies will not incur the necessary capital outlay involved in fitting phase advancers to customers' machines, although they would be the gainers thereby, I certainly think that they should make some reduction in their tariff where phase advancers are installed. In the case of a private supply the conditions are somewhat simplified as the whole installation is under one control. An instance of the economy that may result from improving the power factor is that it has been found possible to increase the power load at collieries by raising the power factor, difficult and costly additions to the existing cables being thereby saved, while at the same time the capacity of the generators and motors has been increased and better pressure regulation has been obtained.

Mr. J. S. NICHOLSON: I should be glad if the author would explain the use of the stator windings of the phase advancer, as they appear to be unnecessary. As the frequency of the currents in the phase advancer will be very low, there should be no great difficulty with the commutation; it would be interesting, however, to hear how these machines behave in practice. I agree with Mr. Caldwell that the cost of using condensers should not be

very much greater than that of several of the appliances mentioned by the author. I have had considerable experience on a small scale with condensers and have usually found them very reliable if certain precautions are observed; and bulk for bulk I believe they will compare very favourably with phase advancers. There is no reason why condensers should continue to be so expensive, but the present demand is probably too restricted to allow manufacturers to lower the prices. In my opinion engineers have already in the condenser an excellent means of improving the power factor of many alternating-current circuits.

Mr. J. A. ROBERTSON: I have been fortunate in supplying about 90 per cent of the power load in Greenock through rotary converters, and have therefore experienced no trouble with low power factors. In one case where a power load of 600 kw. is taken from transformers, the power factor at the consumer's switchboard is 70 per cent, but by over-exciting the rotary converters in another sub-station the power factor at the supply station is kept at unity. In most cases the low power factor is due to incorrect design or proportioning of the consumer's plant, and the supply authority is quite justified in stipulating a minimum power factor. In the case of winding engines and rolling mills special terms should be made to suit each case. If power factor correctors must be used, the proper place for them is on the consumer's premises, or in an adjoining sub-station, so as to keep down the expenditure on feeder cables. It is usual now to specify that generators shall give full-load output at a lower power factor than unity, and it is probable that the extra cost of a generator designed for the lower power factor would be less than the cost of any type of phase adjuster installed at the station. The figures of relative cost quoted by the author show that the phase adjuster will in most cases be cheaper to install than the synchronous motor. With regard to condensers, I believe there is a difficulty in making them in such large sizes except at great expense.

Mr. W. L. SPENCE (communicated): No reference is made in the paper to the use of rotary converters for improving the general power factor. A rotary converter is neither a synchronous motor running light nor a synchronous motor with mechanical load; it is about halfway between the two—a synchronous motor with an electrical load—and it is capable of being quite effectively used for the purpose in view. I have been connected with two large installations, both steel-rolling mills in the Glasgow district, where rotary converters of 300 kw. and 500 kw. respectively are used to improve the power factor of the supply to three-phase induction motors. There can be no doubt of the advantages of power factor improvement when the supply is from isolated generating plant, but until power supply companies and municipalities make real and substantial concessions for high power factors there is little or no inducement to the consumers on public

* G. KAPP. Phase-advancing. *Journal I.E.E.*, vol. 51, p. 243, 1913.

supply mains to do anything in regard to power-factor improvement.

Mr. W. A. KER (*communicated*): I should like to point out that the power factor improver not only reduces the wattless current, but that it may also effect a reduction in the coal bill. I think that the synchronous motor referred to by the author is one for the introduction of which I was responsible. The load at the works in question necessitated three steam alternators being run continuously at nearly full current, but at a power factor of from 0.6 to 0.65. When the synchronous motor was installed the current was reduced, as the author says, from 1,150 amperes to 850 amperes, and the power factor rose to 0.9, still lagging. This allowed one steam alternator to be shut down and kept as a stand-by. Owing to the fact that the two remaining steam alternators were working at or near full load, their steam consumption was considerably improved, and it was found possible to shut down one of the five boilers, with the result that the fuel bill was reduced. It had originally been intended to install a fourth steam alternator as a stand-by at a cost of about £1,200. In place of this, however, the synchronous motor, costing about £300, effected the same purpose and reduced the fuel bill. Still better results would have been obtained if it had been possible to place the synchronous motor near the load, which consisted of a number of motors running lightly loaded; but owing to the large number of circuit cables of considerable length leading from the main switchboard to the motors it was only feasible to place the synchronous motor in the generating station itself, thus improving the power factor of the alternators but leaving the cable loss as it was before. The machine has given every satisfaction since it was installed.

Mr. F. ANSLOW (*communicated*): The author's summary of the steps that have been taken by various power companies to cope with this question of power factor improvement is interesting, but the first three methods appear to be too academic to have any beneficial results. To specify what the power factor of any installation must be, particularly in the case of ironworks or collieries, is to specify an almost impossible condition. The conditions under which the motors for such installations have to work render their construction such that to attempt to secure a high inherent power factor is diametrically opposed to their satisfactory operation. The matter is purely a commercial proposition, and if the power companies will deal with it as such and on the lines indicated in the fourth example cited by the author, there can be little doubt that the point will be appreciated by the consumers, and that the results will be beneficial both to the supply authorities and to the consumers, notwithstanding the fact that the capital outlay of the latter may be somewhat increased. In dealing with the improvement of the power factor by means of a synchronous motor the author shows in Fig. 5 what proportion of the energy is available for mechanical power after the lagging current has been compensated for, and also that the best results are obtained when the electrical output equals the mechanical output, each having the value 71 per cent. It occurs to me, however, that it would be difficult under actual working conditions to maintain this proportion, especially when the mechanical output from the motor is used, say, for driving a generator for supplying continuous current for motors or other fluctuating loads.

It would appear that unless the mechanical load on the motor is of a constant nature there would be considerable variation in the results obtained; and if a steady load is an essential condition, the use of this arrangement must necessarily be somewhat restricted. My experience of phase adjusters for colliery winding-gear and rolling-mill motors gives me the impression that it is extremely difficult to obtain satisfactory results with them when used for such purposes. In the case of the former, a liquid or similar type of starter is required for starting, and in the case of the latter, automatic or permanent slip resistances are frequently necessary to cause the speed of the motor to drop sufficiently to allow the energy of the flywheel to be utilized. I should be glad if the author would state, first, if it is possible to have continuously in circuit with the starter and regulator the phase adjuster which he describes, and, secondly, what would be the effect of, say, a 15 per cent slip on a plant designed to give unity power factor with normal slip.

Mr. E. SEDDOX (*communicated*): The existing rules with regard to consumers' power factors vary considerably with different authorities, and none of the examples taken appear adequately to meet the case. I think one way of making the consumer take an interest in the power factor of his load would be to have a scale of charges depending on the power factor, the charge being a minimum with unity power factor. So far as the central station is concerned, the correction of power factor is very important. Years ago it was the general practice to install alternators designed for a power factor of about 0.8, which certainly met the case when the industrial load was small compared with the lighting load; but with the present large induction-motor load the power factors have fallen so low that the older machines cannot be economically run unless provision be made to relieve them of their wattless current. As the author shows, there are many ways of correcting for power factor, but where the undertaking has no traction or other converting sub-station, the correcting apparatus must be placed either in the generating station or on consumers' premises. There are cases where a large consumer requires a continuous-current supply for electrolytic or other purposes; this provides an opportunity for the engineer to try and arrange for a synchronous motor-generator set with the motor designed for a large k.v.a. capacity, compared with the requirements of the supply, so as to give a leading current to the line. At a power factor of 0.8 the total current for doing certain work is about 25 per cent greater than would be the case with unity power factor, thus showing how important it is to relieve the feeders as well as the generators of wattless current. With regard to the installation of new generators to meet this low power factor, the tendency is to install machines with a large k.v.a. rating compared with their normal kw. output, and to provide some margin in the capacity of the exciter. The exciter has always been a trouble. The output of a large generator is frequently limited by the output of this accessory, which is often overloaded and causes trouble owing to destructive sparking, this in turn affecting the supply pressure. In the installation mentioned by the author it is very interesting to note the saving effected by the synchronous motor. I know of a case where a 1,500-kw. set could be shut down by raising the power factor from 0.65 to 0.9, but a synchro-

nous motor of about 3,800 k.v.a. capacity would be required. The starting up of a plant of this size presents a difficult problem if money is to be saved, unless arrangements could be made to run the set up to speed with a turbo-alternator and synchronize the two machines together on the bushbars, afterwards switching out the alternator if it is not required. If the above capacity were split up between two or three synchronous motors it would not apparently justify the expenditure. In general, I think it can be said that it does not pay to raise the power factor above 0.9; and in conclusion I would recommend members interested in the subject to read an article by C. T. Mosman in the *General Electric Review** for July, 1912.

Mr. G. STEVENSON (*in reply*): With regard to condensers, I would call Mr. Caldwell's attention to the remarks that I made at the outset, when I said that I only proposed to deal with machines with which I was familiar. I believe that one of the reasons why condensers have not come into more general use is on account of their excessive cost, which, I understand, approaches that of a synchronous motor running light. There is also the question of reliability, and I believe I am correct in stating that in this respect they cannot be compared with the types of machines referred to in the paper.

In reply to Mr. Nicholson, the armature winding of the phase adjuster may be considered as a closed circuit and similar to a delta-connected three-phase winding. The slip-rings of the main motor are connected to the stator coils of the phase adjuster, and the circuit is completed by the delta connection of the armature winding, which is electrically equivalent to a star winding, although it has no actual star point. The currents passing through the phase adjuster are of low frequency, and for this reason the fluxes set up in the machine will travel round the periphery at a low speed determined by the frequency in the same way as in all three-phase windings. It is possible, however, by rotating the armature at a much higher speed to cut the slowly rotating field, and in this way the generated terminal voltage is obtained. The machine exerts no torque because the position of the field in space is such that one-half of it is cut by conductors carrying current in one sense, and the other half by conductors carrying current of opposite sense. Apart from the principles of its operation, the difficulties experienced by designers have mainly been as regards commutation, but I can assure Mr. Nicholson that with the arrangement shown it has been found possible to obtain perfect commutation in actual practice.

Mr. Nicholson also mentioned that it would be much simpler to design the generators in the first instance for a low power factor; of course that is so, but I might point out that it has been the practice for a number of years now to specify a power factor of 0.8. In many instances this has been found to be too high, thus resulting in the electrical end of the set being too small for its duty, and consequently in the steam end being operated at less than its rated load. In most cases the difficulty when laying down a new plant is that one does not know what the power factor is going to be, and it is only when the plant has been set to work that difficulties arise and some method has to be adopted to cure the trouble.

* C. T. MOSMAN. Synchronous condensers. *General Electric Review*, vol. 15, p. 435, 1912.

I was interested in what Mr. Robertson said about the rules drawn up by supply companies in connection with power factors. I stated in the paper that the fourth example (see page 555) appeared to be the most business-like. I am not quite sure about the legal side of the question, but I think that the first three rules set out on page 555 could not be upheld, as it seems only fair that if a consumer is penalized for low power factor he should be given a bonus when the power factor is high. With regard to the cost of the phase adjuster, I would say that the comparisons of cost are not made upon the same basis, for it is mentioned distinctly that the cost of the phase adjuster is based on the k.v.a. correction to the wattless component.

With reference to Mr. Spence's remarks, it is quite true that rotary converters are useful for maintaining or improving the power of an alternating-current supply, and the introduction of the phase adjuster is not intended in any way to supersede them. Each machine has its own special sphere of application, and the phase adjuster merely fills a gap that has previously been neglected. For instance, it is not likely that a consumer taking a bulk supply from an alternating-current system would use induction motors for the greater part of the load and then install a rotary converter and switchgear and utilize continuous-current motors for the rest of the load in order to obtain an improved power factor. This is clearly a case for the phase adjuster, where there is no necessity for transforming apparatus or for more than one type of machine. With regard to the ability of the rotary converter to supply a leading current, these machines may be classified as follows: (1) simple rotary converter without voltage regulation; (2) simple rotary converter with voltage regulation; (3) rotary converter with booster or induction regulator for voltage regulation. It is usual with the first two types to insert reactance in series with the slip-rings on the primary side of the converter. For case (1) this is useful for limiting the current that can flow in case of a short-circuit on the continuous-current side of the converter; and in case (2) additional reactance is inserted in order to obtain voltage regulation on the continuous-current side. As is well known, the continuous-current voltage increases with an increase of the field excitation. This is produced in the following way:—The fundamental property of an increase in the field excitation is the ability to draw a wattless leading current from the alternating-current side, and the voltage across a reactance carrying leading current is added to that of the transformer supplying the rotary converter. The direct result of increasing the excitation is therefore an increase in the impressed voltage on the slip-rings of the converter, which naturally raises the continuous-current voltage in the same proportion because of the fixed relation between the primary and secondary voltages. It is therefore quite true that with simple rotary converters, or with rotary converters with reactance voltage control, an increase in the excitation for the purpose of obtaining leading current changes at the same time the continuous-current voltage. In case (3) the reactance is entirely omitted and a booster is substituted for purposes of voltage control, and in the absence of reactance there is no increase in the slip-ring voltage when the field excitation is increased. Leading currents may therefore be drawn from the supply without in any way affecting the continuous-current voltage. The main purpose of a rotary

Mr. Stevenson.

Mr.
Stevenson.

converter is to convert from alternating current to continuous current, and if power-factor-improving properties are necessary in addition, they will have to be paid for as in any other apparatus, owing to the necessity of modifying the design and increasing the capacity of the converter. The field spools are evidently larger, and the armature heating is very considerably increased, when a leading power factor is required. The armature heating at 90 per cent leading power factor is very nearly double that at unity power factor, and this must of course be provided for by additional copper in the armature of the machine, which again necessitates an increased diameter.

Mr. Anslow raises a point of considerable importance when inquiring if the phase adjuster would work in conjunction with rolling-mill motors which had an additional permanent resistance inserted in the slip-ring circuit for the purposes of producing slip under load so as to utilize the flywheel energy. The use of resistances in the rotor of an induction motor for the production of increased slip is very common, but it would be useless to insert the phase adjuster in the slip-ring circuit at the same time. This will be evident when I mention that the inserted resistances may be about 10 times the value of the rotor resistance, hence for the phase adjuster to produce the same value of wattless circulating current it would be necessary to provide a voltage of 10 times the normal amount. To overcome this difficulty the firm with which I am associated has introduced a machine which in appearance is similar to the phase adjuster, but is differently wound; it is called a "slip regulator." It produces slip in the main induction motor without introducing any resistance, and at the same time it also improves the power factor. The energy which was previously dissipated in the resistance, amounting to some 15 per cent of the output of the main motor, now passes into the "slip regulator" and is converted into useful power available as torque on its shaft. This torque may be utilized

Mr.
Stevenson.

by coupling the "slip regulator" to the main motor, or to some other shaft capable of utilizing its output. The speed may be constant, or variable to a slight extent. By these means the efficiency of the main motor is very considerably improved, and the saving of energy by the "slip regulator" will very soon pay for its introduction in cases where permanent resistance is now employed. The power factor is also improved, which is a considerable advantage in rolling-mill motors, the latter being generally of very low speed.

Mr. Kerr is correct in stating that the synchronous motor running light to which I referred in the paper was the one for the introduction of which he was responsible.

Mr. Seddon's suggestion, that the consumer should be charged in accordance with the power factor of his installation, is on the right lines, and as a matter of fact I understand that several large power companies are now introducing a scale of charges on this principle. With regard to the output of the exciter and field magnets being restricted by low power factors, I would refer Mr. Seddon to a statement made by Professor Miles Walker in a paper* that he read some time ago before the Institution. Referring specially to turbo-alternators, he stated that the output of the field magnets at unity power factor is four times as great as at 0.8 power factor, which I think shows very clearly the effect of low power factors on the generating plant. He also stated that a cable having 4 per cent reactive drop at unity power factor has 18 per cent drop at 0.8 power factor. The case referred to by Mr. Seddon where a synchronous motor of 3,800 k.v.a. would be required is very interesting, and, as he says, the question of the starting up of this plant would be difficult, but I think it could be got over by the use of an induction motor coupled direct to the machine and used for starting purposes only.

EXPERIMENTS ON AIR-BLAST COOLING OF TRANSFORMERS.

By F. J. TEAGO, Associate Member.

(Paper first received 23rd February, and in final form 2nd March, 1914; read before the MANCHESTER LOCAL SECTION 24th March, 1914.)

SYNOPSIS.

1. Transformer design data.
2. Air-blast plant.
3. Apparatus for measuring air flow.
4. Effect of size of Brabbe tube on accuracy of air measurements.
5. Methods of measuring temperature rise.
6. Cooling properties of air as affected by humidity.
7. Relation between surface temperature rise of coil and mean temperature rise.
8. Air and "fogged" atmosphere as cooling media.
9. Rating of transformer as affected by air blast.
10. Appendixes and bibliography.

The following experiments were made on one of a pair of single-phase transformers of the core type designed and built in the Electrical Engineering Department of the University of Liverpool, in order that accurate information

Secondary: 4 coils, 36 turns each, strip 0.944 in. \times 0.02955 in.
Current density 2,200 amperes per sq. in. (R.M.S.).
Net weight of copper, 48 lb.

Estimated amount of air, for mean coil rise of 50° C., with inlet air at 15°–20° C., equals 5 cub. ft. per sec.

AIR-BLAST PLANT.

Fig. 1 shows the arrangement of the air-blast plant. The air enters at the fan inlet, passing through the baffles in the air pipe into the air box, which is divided into two sections, the shutters A controlling the air inlet to the transformers through the openings D.

The air baffles, consisting of perforated metal and wire gauze, are placed at each end of the air pipe in the joints Band B'. The baffles at the inlet end of the air pipe are

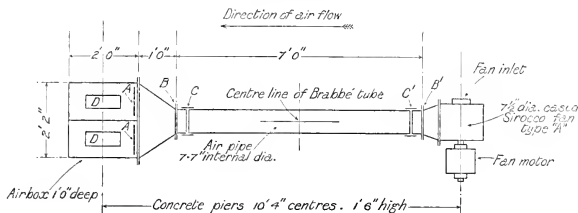

FIG. 1.—General Arrangement of Air-blast Plant.

could be obtained as to the relation between the "heat rating" and the quantity and condition of the air. The two transformers are very similar in design, the most important difference between them being that one has a rectangular core with one ventilating duct, and the other a chamfered core without a ventilating duct. The experiments to be described were made on the transformer having the rectangular core. The chief particulars of the apparatus are as follows:—

TRANSFORMER.

Output.—12 k.v.a., $\cos \phi = 0.8$, 200 volts (ratio 1:1), 50 Ω .

Core.—Rectangular, net cross-sectional area 7.75 sq. in., B_{max} , 80,000 lines per sq. in., plates 0.02 in. Stalloy, one ventilating duct 0.407 in. wide, net weight of iron, 82 lb.

Coils.—Sandwiched, P.S.P.S.P. per limb.

Primary: 6 coils, 24 turns each, strip 0.63 in. \times 0.0472 in.

two sheets of perforated metal having 165 perforations (each of 0.0024 sq. in. area) per sq. in. At the outlet end of the air pipe the baffle is a sheet of wire gauze having 2,500 meshes per sq. in. In arranging the baffles, the object was to get as large a quantity of air as possible through the pipe with a distribution as nearly uniform as possible.

C and C' are leather joints in the air pipe to prevent the transmission of vibrations which would interfere with the Brabbe tube readings.

Each transformer has a sheet-iron case; these cases are connected to an air-shoot which discharges the warm air outside the building. Arrangements are also made so that either transformer can be fitted to the fan inlet.

BRABBE TUBE.

The relative dimensions of the Brabbe tube used (Fig. 2) are those advocated by W. B. Gregory.² This form of

² *Transactions of the American Society of Mechanical Engineers*, vol. 25, p. 184, 1904; and vol. 30, p. 351, 1908.

tube has also been largely used by Dr. Stanton at the National Physical Laboratory, and it is stated that its coefficient can be assumed to be equal to unity when the tube is properly handled.

To measure the pressure due to the velocity head of the

where H is the column of water representing the pressure $P_1 - P_0$. The liquid in the left-hand limb in this case was water, coloured with a minute quantity of methyl orange. The other liquid was either carbon-bisulphide or a mixture of toluol and chloroform. The fraction H/h depends upon

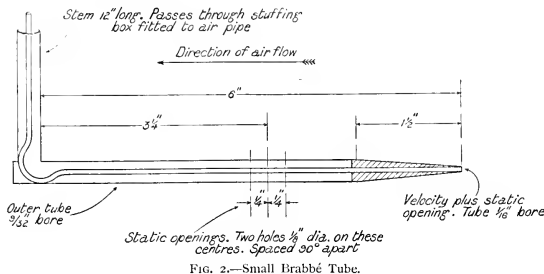

FIG. 2.—Small Brabbe Tube.

air a special multiplying manometer was used, the details of which are shown in Fig. 3.

If P_1 equals the pressure due to velocity + static head, and P_2 equals the pressure due to static head alone, then,

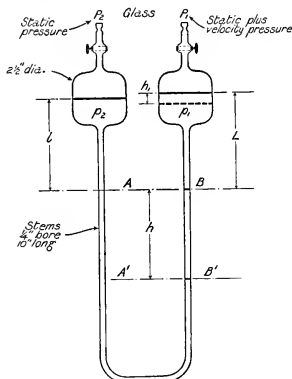

FIG. 3.—Differential Multiplying Manometer, of the type used by Dr. Stanton.

on the assumption of equal cross-sectional areas in the bulbs and a uniform bore for the tube connecting them, we have that $P_1 - P_2$, the velocity head, is given by the formula—

$$H = h_2 \left\{ \left(1 - \frac{l}{L} \right) + \frac{h_1}{h} \left(1 + \frac{l}{L} \right) \right\}^*$$

* See Appendix I.

the ratio of the densities of the liquids in the two limbs; hence the mixture of toluol and chloroform is useful where a particular value is desired lying between the limits of either liquid used alone.

This equation for the velocity head is difficult to use on account of the large number of observations that are necessary. A calibration curve connecting H and h , obtained by placing the differential multiplying manometer in parallel with an ordinary water U-tube, is better, and was used in these experiments. One of these calibration curves

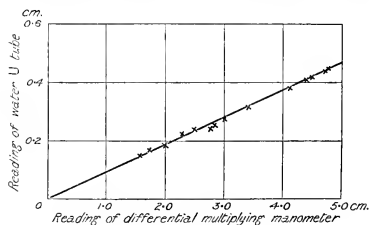

FIG. 4.—Calibration Curve.

is shown in Fig. 4, and from it the ratio is seen to be nearly 10 to 1. This ratio gave excellent results. The readings of the differential manometer are easily obtained to within 0.025 cm., that is to within 0.01 in. With a ratio of 10 to 1, this means that the readings when converted to an equivalent head of water are correct to within 0.001 in., and since the readings average 0.1 in. of water the error is not greater than 1 per cent.

AIR PIPE.

As will be seen from Fig. 1, giving the overall dimensions, the length of the air pipe between the fan and the

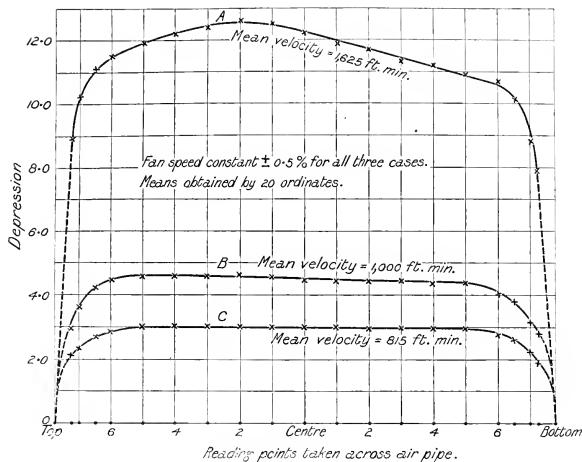

Fig. 5.—Curves showing the Effect of baffling the Air Pipe, using small Brabbé² Tube.

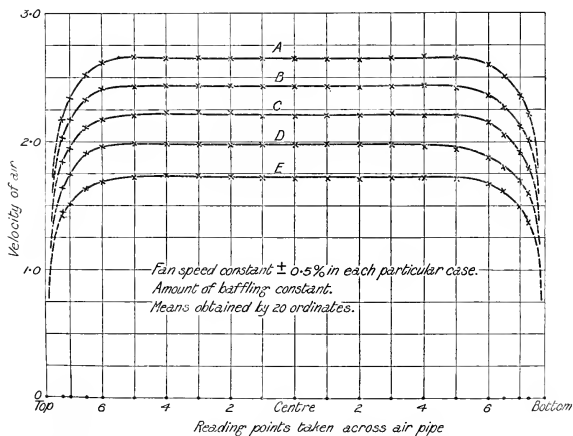

Fig. 6.—Curves showing Variation of Velocity of Air across Pipe Diameter, using small Brabbé Tube.

air box is only 7 ft. It was anticipated that considerable trouble would be experienced in the attempt to make accurate air measurements in such a short length of pipe.

of the curves are proportional to the velocity of the air. Curve A was taken with the air pipe unbaffled; curve B was taken with the air pipe baffled at the fan end; and curve C

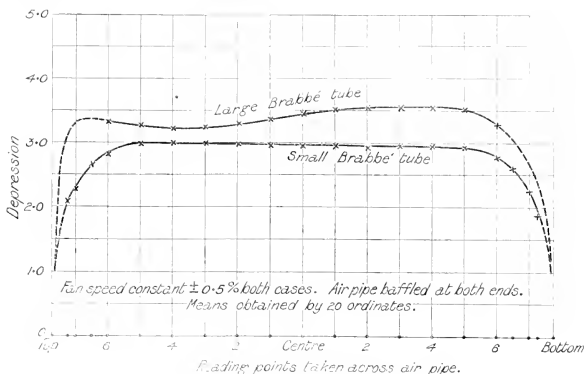

FIG. 7A.—Comparison between two sizes of Brabbe Tubes.

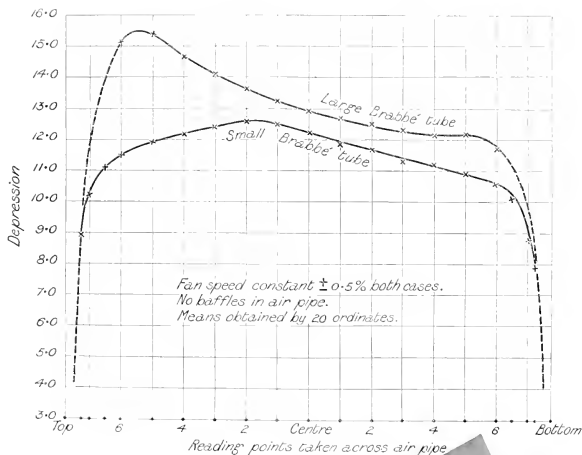

FIG. 7B.—Comparison between two sizes of Brabbe Tubes.

This was achieved by fitting the baffles at each end of the pipe; and the curves in Fig. 5 illustrate the effect of these baffles. In each case the square roots of the ordinates

was taken with the air pipe baffled at both ends. The curves become flatter as the amount of baffling increases, and there is therefore less error in the observation of the

centre depression (in case the Brabbé tube is not always set accurately at the centre) as the baffling increases.

When the pipe is baffled the air flow is very steady, and the common surface of the liquids in the differential manometer is also steady; without the baffling the common surface oscillates and a mean position has to be determined. It follows, therefore, that in a short pipe baffling is necessary if the velocities are measured at the centre and multiplied by a coefficient so as to give mean velocities, and if the common surface is to be steady enough to permit of accurate readings being taken. To be efficient, the baffles must be tightly stretched.

Ratio of mean velocity to actual velocity at centre.—From the above set of curves it is seen that the ratio of the mean velocity to the actual velocity at the centre is not constant; it increases with the amount of baffling, thus showing that the baffles tend to distribute the air uniformly over the cross-sectional area of the pipe. The figures are as follows:—

Curve	Mean velocity Velocity at centre
A	0.922
B	0.94
C	0.942

The next set of curves (Fig. 6) shows the effect of the velocity of the air flow on this ratio when the amount of baffling is kept constant, the ordinates being proportional to the velocities in this case, and the air pipe being baffled at both ends.

Curve	Mean Velocity of Air ft. per min.	Mean velocity Velocity at centre
A	1,200	0.942
B	1,160	0.942
C	1,050	0.942
D	935	0.942
E	815	0.942

This suggests that within the limits of the velocities taken the ratio is constant for the baffled pipe. The value 0.942 was taken as being correct.

ACCURACY OF AIR MEASUREMENTS AND SIZE OF BRABBÉ TUBE.

Preserving the relative dimensions of the Brabbé tube advised by W. B. Gregory, it was decided to ascertain the difference between the reading of a certain velocity given by a tube whose cross-sectional area is only a small proportion of the area of the air pipe and a tube whose cross-sectional area is a larger proportion. For this purpose two tubes were constructed. The smaller one had an area equal to 0.163 per cent of the area of the air pipe, and the larger one an area equal to 3.16 per cent of the air pipe. In the first case, at a velocity of 815 ft. per min., the large tube reading

is 9 per cent high, indicating a velocity of 895 ft. per min. In the second case, at a velocity of 1,625 ft. per min., the large tube reading is 6.5 per cent high, indicating a velocity of 1,740 ft. per min. Now $v = c\sqrt{2gh}$, and if $c=1$ for the smaller tube, as is assumed, then the figures indicate that for small tubes of which the cross-sectional area is about the same percentage of the area of the air pipe as that considered above, there must be considerable latitude in the design without introducing serious error when c is taken as unity.

The curves, from which these comparisons are deduced, are shown in Figs. 7A and 7B. In each case the square roots of the ordinates of the curves are proportional to the velocity of the air. The figures are as follows:—

	Large Tube	Small Tube
Mean velocity	1.782	1.622
Proportional to	3.453	3.233
Mean velocity	0.962	0.942
Velocity at centre	0.958	0.922

COOLING PROPERTIES OF AIR AS AFFECTED BY

The first set of experiments was made in order to find out whether the varying humidity of the air had any effect

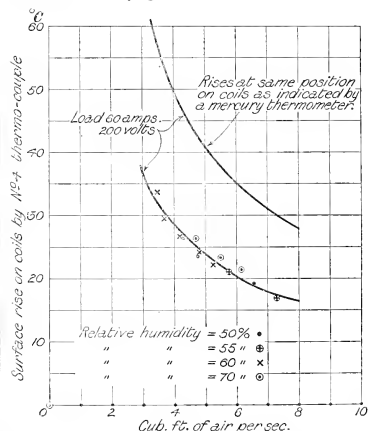

FIG. 8.—Curves showing Temperature Rise as affected by Humidity.

on its cooling properties. It was not anticipated that the effect, if any, would be great since the moisture is already in the form of vapour. The specific heat of water vapour is only about 25 per cent greater, for equal volumes, than that of air, and the amount of water vapour present, even when the air is saturated, is very small. From Fig. 8 it

will be seen that in the ordinary way the differences due to humidity are too small to be detected.

In these experiments on the effects of humidity the average number of grammes of water, in the form of vapour, per cub. cm. of air varied from 0.8×10^{-5} to 1.2×10^{-5} . Expressed in litres of water vapour per cubic metre of air the amount varied from 10 to 15° .

A mercury thermometer and a toluol thermometer were tried in place of No. 4 thermo-couple (Fig. 9). The curve

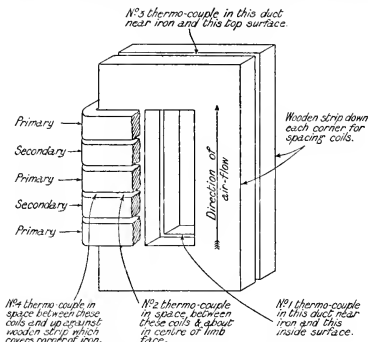

FIG. 9.—Diagram showing Positions of Thermo-couples.

shows the rise as indicated by the mercury thermometer (there were 4 grammes of mercury in the bulb of this particular thermometer). The toluol thermometer showed the same rises as the thermo-couple.

RELATION BETWEEN SURFACE RISE AND MEAN TEMPERATURE RISE OF COIL.

Since No. 4 thermo-couple is largely protected from the cooling effect of the air by reason of the wooden strip, it is likely that the surface rise of temperature of the coils is a maximum at that point. A temperature run was made to obtain the relation between the surface rise as indicated by No. 4 thermo-couple and the mean temperature rise of the coils as determined by their resistance, a continuous-current supply and Siemens precision instruments being used.

The results were as follows:—

Surface Temperature Rise by No. 4 Thermo-couple	Resistance of Coils (Volts \div amperes)	Mean Temperature Rise by Resistance method $t = (250 + t_0) \left(\frac{R - R_0}{R_0} \right)$
Degrees C.	Ohm	Degrees C.
4.6	0.1217	3.75
10	0.1244	9.75
15.8	0.1268	15.10
21	0.1295	21.30
26.8	0.1321	26.80
32.5	0.1346	32.40
37.8	0.1374	38.60
43.8	0.1400	44.30

* Appendix II.

Initial temperature 16.2° C. Resistance at this temperature as determined by readings of volts and amperes $= 0.1105$ ohm, and by Post Office box $= 0.12$ ohm.

From this it is seen that the surface temperature rise of the coils at this particular place is equal to the mean temperature rise. These results may be compared with those recently given by E. H. Rayner in the *Electrician*.³ The coils in this case are double cotton covered and shellac varnished, and the temperature rises were measured on the edge of the strip as is indicated in Fig. 9.

The relation between the surface temperature of the coils, as indicated by No. 2 thermo-couple, and the mean coil temperature, is shown in Fig. 10.

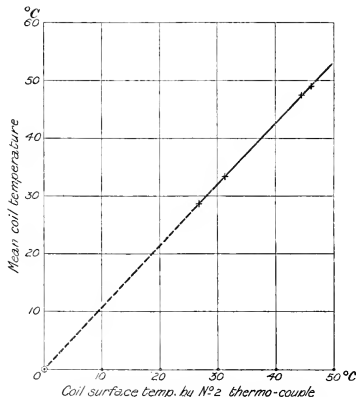

FIG. 10.—Curve showing Relation between Surface Temperature by No. 2 Thermo-couple and Mean Coil Temperature.

Taking the inlet air at 15° C., the mean temperature rise of the coil is 17 per cent greater than the surface rise at the lowest point given, and 10 per cent at the highest point. These figures agree with the general rule that the mean temperature of the coil is higher than the surface temperature.

AIR AND "FOGGED" ATMOSPHERE AS COOLING MEDIA.

A "fogged" atmosphere has been suggested as a cooling medium for electrical machinery on a number of occasions, notably by H. M. Hobart.[†] A number of tests were made with air rendered "fogged" by atomizing water at the inlet to the transformers, and these are compared with similar tests where the air was not "fogged."

In these experiments the average cooling effect of the water equals 300 and 600 watts respectively (see Appendix III), and the heating effect of the losses equals 900 watts. One might therefore expect the tempera-

³ E. H. RAYNER. Investigation of the Temperature of Field Coils. *Electrician*, vol. 72, p. 702, 1914.

[†] *Proceedings of the American Institute of Electrical Engineers*, vol. 32, p. 1835, 1913.

ture rise to decrease by 33 per cent in one case, and by 66 per cent in the other. From Figs. 11, 12, and 13 it is seen that No. 1 thermo-couple shows a greater decrease, No. 2 a less, and No. 3 a decrease approximately equal to that anticipated. These results justify the serious consideration of a "fogged" atmosphere as a cooling medium

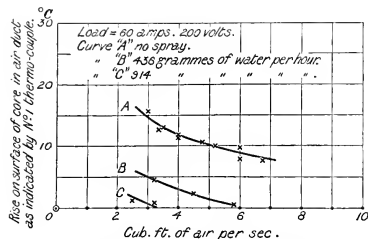

FIG. 11.—Comparison between Air and "Fogged" Atmosphere as Cooling Media. (Bottom of Ventilating Duct.)

for electrical machinery, especially where the electrical pressure is only moderately high. In the ideal case the air would be thoroughly "fogged" so as to obtain a homogeneous mixture, the amount of water used being no greater than was necessary to ensure that the water particles were not deposited on the coils, etc., as the cooling mixture

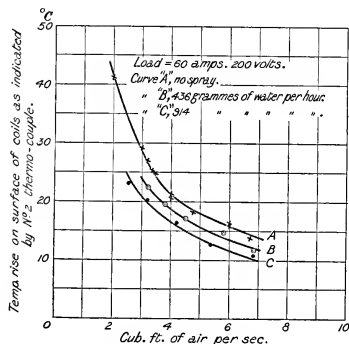

FIG. 12.—Comparison between Air and "Fogged" Atmosphere as Cooling Media.

passed through. The atomizer used in these experiments does not completely fulfil these conditions.

Plant is now manufactured capable of producing very large quantities of "fogged" air eminently suitable for cooling purposes. In one type of plant the air is washed free from dust particles and cooled, and delivered with an amount of free water in suspension which varies from zero

to about two or three per cent of the total volume of the mixture according to the design. The cooling efficiency with plant of this description ought to be fairly high, but no time has been available up to the present in which to make actual tests.

As regards the insulation resistance, in these experiments no injury was done to the insulation by the water. The

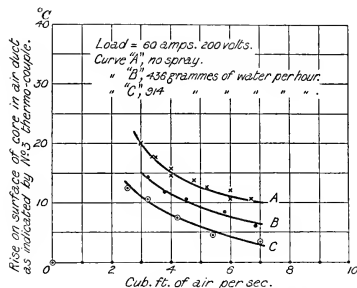

FIG. 13.—Comparison between Air and "Fogged" Atmosphere as Cooling Media. (Top of Ventilating Duct.)

insulation resistance was low immediately after a test, but this was due to the fact that moisture condensed on the bare ends of the windings. When these were dried, the insulation resistance was normal, namely, to megohms.

THE RATING OF THE TRANSFORMER.

The next set of experiments was conducted with the object of finding how the output of the transformer varied with the number of cubic feet of air supplied per second, the basis being a mean temperature rise of the coils of 50° C. The curves shown in Fig. 14 were obtained.

From these curves, and from the wattmeter measurements of the losses in the transformer, the following figures are obtained, and have been plotted in Fig. 15:—

Mean Temp. Rise of Coils	60 amperes		77 amperes		84 amperes	
	Cub. ft. of air per sec.	Total watts loss	Cub. ft. of air per sec.	Total watts loss	Cub. ft. of air per sec.	Total watts loss
Degrees C.						
40	2.7	928	4.75	1,306	7	1,683
50	2.1	955	3.9	1,348	5.7	1,738
60	1.7	981	3.30	1,385	5	1,789

These figures suggest that for any particular value of the total watts loss—

cub. ft. of air per sec. \times mean rise of temperature of coil
= constant (K).

Tabulating this product for various values of the total watts loss the following figures are obtained:—

Total Watts Loss	40° C. Mean Rise	50° C. Mean Rise	60° C. Mean Rise
1,800	304	300	300
1,600	259	255	252
1,400	213	210	204
1,200	167	164	156
1,000	122	116	108

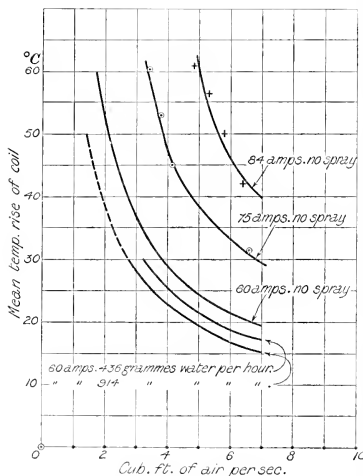

FIG. 14.—Curves showing Mean Temperature Rises on Coils for Various Loads at a Pressure of 200 Volts.

It is seen that for all practical purposes K is a constant for any given value of the total watts loss, and for a given type of transformer. This should prove of value to the designer, since all the values of K can be determined, for any one type of construction, from the product (cub. ft. of air per sec.) \times (mean rise of temperature of coil) at two different values of the watts loss, since the relation is practically a straight line (see Fig. 16).

By extrapolating these curves it is found that for a load of 8 k.v.a. no air at all is required, and for 20 k.v.a. 9 cub. ft. of air per sec. is required. These two estimated points have been plotted with the three actual points for

* 8 k.v.a. at 200 volts, with no air, gave a mean temperature rise of the coil of 50° C. by actual subsequent test.

12 k.v.a., 14.6 k.v.a., and 16.8 k.v.a. in Fig. 17, which gives the rating of the transformer for various quantities of air.

Only one "water spray" point has been plotted; this

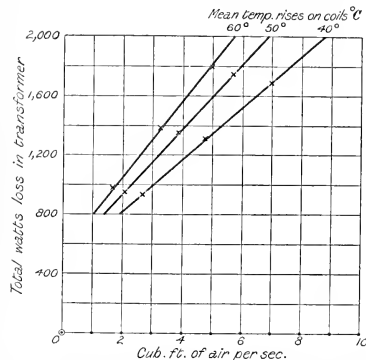

FIG. 15.—Curves showing the Connection between Total Watts Loss and Cub. Ft. of Air per Sec. for various Mean Temperature Rises on Coils.

shows a marked improvement in the rating of the transformer.

The improved rating is about 10 per cent at this point, but for the same quantity of water it will decrease as the

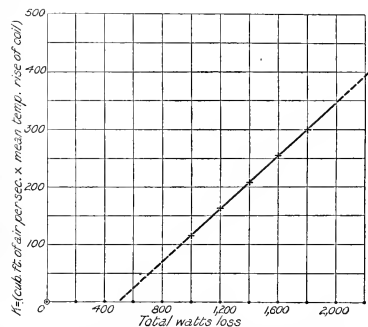

FIG. 16.—Curve showing Relation between "K" and Total Watts Loss for the type of Transformer described.

rating increases, since the cooling effect of the water becomes relatively less important.

In the near future it is hoped that the results of similar tests on the transformer with the chamfered core and no air duct will be available.

In connection with these experiments the following general statements may be made:—

1. The temperature rise of the transformer is independent of the temperature of the inlet air within ordinary limits, provided that the surfaces to which the heat is radiated, that is the walls, etc., of the room, are at the air temperature.

2. Variations in the barometric pressure only affect the temperature rise to a small extent, and the correction is negligible for the small variations in the barometric pressure from day to day.

3. The humidity of the air, up to the point of saturation, has no appreciable effect on the temperature rise.

The accuracy of these statements is borne out by the results given in the various papers referred to in the bibliography.

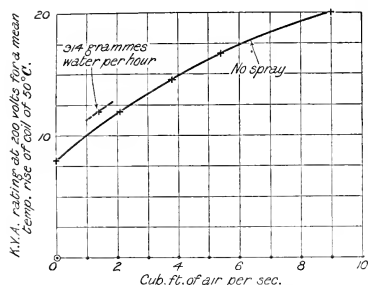

FIG. 17.—Curves showing the Connection between "Heat Rating" and Quantity of Air, with and without Water Spray.

In conclusion, the author wishes to thank Dr. E. W. Marchant for the many valuable suggestions that he has offered during the preparation of this paper, Mr. F. J. Tindall for the very valuable help that he has rendered in taking observations and working up results, Mr. J. F. Gill for the particulars regarding the differential multiplying manometer, Mr. J. K. Catterton-Smith for the details of the electrical design of the transformer, and the Council of the University of Liverpool for the special apparatus supplied.

APPENDIX I.

DIFFERENTIAL MULTIPLYING MANOMETER.

Let ρ_1 = density of liquid in right-hand limb,

ρ_2 = density of liquid in left-hand limb,

a = cross-sectional area of small part of tube,

A = cross-sectional area of large part of tube.

When $P_1 = P_2$, let $A B$ be the common surface.

Now $\rho_2 l = \rho_1 L$, $\therefore \rho_1 l \rho_2 = l/L$.

When $P_1 > P_2$, let $P_1 - P_2$ be represented by a column of water of height H , and let the common surface be $A' B'$.

Then since $h_1 = h a/A$, we have—

total pressure in right-hand limb above common surface

$$= H + (\rho_1 L - \rho_1 h a/A) + \rho_1 h,$$

total pressure in left-hand limb above common surface

$$= (\rho_2 l + \rho_2 h a/A) + \rho_2 h.$$

These are equal,

$$\therefore H = \rho_2 l - \rho_1 L + \rho_2 h a/A + \rho_1 h a/A + \rho_2 h - \rho_1 h,$$

and since $\rho_2 l = \rho_1 L$,

$$\therefore H = h \left\{ (1 - \rho_1/\rho_2) + (1 + \rho_1/\rho_2) a/A \right\} \rho_2.$$

Putting $\rho_1/\rho_2 = l/L$ and $a/A = h_1/h$,

$$\text{we have } H = h \left\{ (1 - l/L) + (1 + l/L) h_1/h \right\} \rho_2.$$

If the liquid in left-hand limb is water, then $\rho_2 = 1.0$, and

$$H = h \left\{ (1 - l/L) + (1 + l/L) h_1/h \right\}.$$

APPENDIX II.

THE WEIGHT OF A VOLUME OF MOIST AIR.

Let H = barometric height in mm.,

T = absolute temperature, $^{\circ}\text{C.}$,

e = pressure of the aqueous vapour in mm.

From Dalton's laws this means calculating the sum of the weights of a volume of dry air at a pressure of $(H - e)$ mm. and absolute temperature T , and an equal volume of aqueous vapour at e mm. pressure and absolute temperature T .

1 cub. cm. of dry air at 0°C. and 760 mm. = 0.001293 grammes.

Specific gravity of aqueous vapour, referred to air at same temperature and pressure = 0.622.

Mass of 1 cub. cm. of dry air at $T^{\circ}\text{C.}$ and $(H - e)$ mm.

$$\text{pressure } W_1 = 0.001293 \times \frac{273}{T} \times \frac{H - e}{760}.$$

Mass of 1 cub. cm. of dry air at $T^{\circ}\text{C.}$ and e mm. pressure

$$= 0.001293 \times \frac{273}{T} \times \frac{e}{760}.$$

\therefore mass of 1 cub. cm. of aqueous vapour at $T^{\circ}\text{C.}$ and e mm.

$$\text{pressure is } W_2 = 0.622 \times 0.001293 \times \frac{273}{T} \times \frac{e}{760},$$

and $W = W_1 + W_2 = 0.0004646 (H - 0.378e)/T$.

Also since 1 cub. cm. of water = (approximately) 1 gramme at any temperature, \therefore 1 in. of water = $1/W$ in. of moist air.

APPENDIX III.

COOLING EFFECT OF WATER.

If Q represents the total quantity of heat required to raise a mass of water from 0°C. to $t^{\circ}\text{C.}$ and then evaporate it, we have according to Regnault that—

$$Q = 666.5 + 0.305 t \text{ calories per gramme,}$$

$$\text{or } Q = 666.5 + 0.305 t - f,$$

where t = temperature at which the water is evaporated, and f = initial temperature of the water.

APPENDIX IV.

METHOD OF MAKING HEAT RUNS FOR TEMPERATURE RISE.

The final temperature rise in all cases was obtained by running the plant for intervals of time sufficiently long to reach the desired state, keeping the working conditions as constant as possible throughout these intervals. The plant is not of large capacity, and from three to four hours was found long enough to reach the first steady point for some particular value of the load current with the maximum amount of air possible for accurate measurements (7 cub. ft. per sec.). When this final rise had been reached the amount of air was cut down by about 1 cub. ft. per sec., the load being kept constant, and the next rise was obtained.

This run would occupy about $1\frac{1}{2}$ hours, and was immediately followed by one with less air, and so on until the final rise was as high as that required, this process being repeated for different values of the load current.

Theoretically, the time required to reach the final rise is very great, but the observations were carefully made when approaching the steady state, and may be taken to be within 1 per cent of the true values.

On a few of these runs the method suggested by Dr. S. P. Thompson for estimating the final temperature rise was tried. On eliminating the preliminary "kick" by drawing a fair curve through the points obtained, the final estimated rise was in every case practically identical with the actual observed final rise.

APPENDIX V.

METHOD OF OBTAINING THE RATIO $\frac{\text{MEAN}}{\text{CENTRE}}$ VELOCITY.

Assume the air pipe divided up into narrow annular rings of equal length.

Let x = width of annular rings,

R = radius of air pipe,

V = mean velocity of air through pipe,

v = mean velocity of air through one annular ring,

d = mean diameter of this annular ring ;

then πdx = area of annular ring,

$\pi dx v$ = quantity of air through annular ring,

$\pi x \Sigma d v$ = total quantity of air through pipe,

πR^2 = area of air pipe,

and $V = \frac{x}{R} \Sigma \frac{d}{R} v$.

That is, the mean velocity is obtained by summing the

products $\frac{d}{R} v$ and dividing the result by the number of annular rings.

The air pipe was divided into 10 annular rings, each 0.385 in. wide, in these experiments.

DISCUSSION.

Mr. J. FRITH: The whole subject of air-cooling interests me very much, and I think that it will become increasingly important. Though the air-cooled transformer is rather a thing of the past, the oil-cooled type being so much better for high-tension work, a great deal of the information given in the paper can be applied to air-cooling of other electrical apparatus, and I am convinced that in a few years the idea of running a machine in the ordinary atmosphere of the engine-room will be looked back upon with surprise. So

much is now known about commutation that the limit of the output of the continuous-current machine is no longer a question of commutation, but almost entirely one of temperature rise; and to run a machine without proper ventilating ducts seems to me to be blameworthy, since a much greater output can be obtained from a machine where proper provision is made for ventilation. It is possible that we may eventually adopt a suggestion that I made some time ago, of compressing the air outside and

letting it expand into the case of the machine. This seems to me to carry the heat away in a controllable form. Mr. Cramp, who is very interested in that part of the paper dealing with air velocity measurements, wished me to congratulate the author on the use of baffle plates. The resulting curves given in Fig. 6 are exceedingly good, and the very regular velocity curves across the tube up to the sides are very good experimental results, and they have advanced the science of air measurements very considerably. It was always a trouble to measure the unequal velocity across the air ducts, and the baffle plates seem to do their work admirably. I see that the author finds the coefficient of the ratio of the mean velocity to the velocity at the centre to be something over 0.9. There, I think, Mr. Cramp would agree with him. Most authorities place the coefficient somewhere between 0.6 and 0.9, but Mr. Cramp's results give a value of about 0.9. The fact that the two Brabée tubes of such different sizes give such a near approximation is rather extraordinary; I should have expected this to be much more influenced by the diameter of the air tube.

Mr. H. MAWSON: I am particularly interested in the first part of the paper, namely, that dealing with the measurement of air quantities. Only quite recently I have been carrying out a series of experiments on a fan where it was necessary to measure the quantity of air discharged. The Sirocco fan was of 1.5 h.p. and ran at a normal speed of 900 revs. per min., but unlike the one used by the author it discharged into a square duct 10 in. by 10 in., and in order to find the amount of air flowing it was necessary to connect the mean velocity of flow with the velocity measured at the centre of the duct. For this purpose a Pitot tube very similar to the Brabée tube employed by the author was used, but the manometer was different, being a sloping tube at an angle of $\sin^{-1} 0.1$ with the horizontal, thus giving a magnification of 10 upon the ordinary water U-tube. A further magnification was obtained by using paraffin of density 0.825; this was found to flow more freely in, and did not stick to the walls of the tube, which was of about $\frac{1}{8}$ in. in. bore. This manometer worked well and gave satisfactory results. In finding the mean velocity across his circular duct the author has confined the movement of his Pitot tube to one diameter, assuming—which in the case of a circular duct is a fairly legitimate assumption—that what occurs on one diameter occurs on all diameters. With a square duct, however, no such assumption could be made, as the corners produce a marked effect upon the velocity of flow in their region. In order to get over this difficulty I had a tube constructed so that it could move both horizontally and vertically, and could be placed in any position over a half-section of the duct. The method which was followed was first to traverse with the tube a vertical line passing through the centre of the duct, taking readings of the velocity heads at a number of points along this line. The tube was then moved a convenient distance to one side of this line in a direction at right angles to the direction of flow, and a number of readings were again taken along a vertical line. In this manner the half-section of the duct was covered and in all 120 different readings were taken. On each of these vertical lines as a base the velocity heads were plotted and the mean was found for each line. These mean values were then plotted along another line taken at right angles to the direction of flow,

and were set up at distances differing from one another by the distances apart at which the vertical lines traversed by the tube had been taken. The mean of this curve was estimated and hence the velocity head over a half-section of the duct was obtained. The square roots of all the velocity heads measured was found and these were also plotted in a similar manner, the mean value then being determined. This last result gave an indication of the mean velocity in terms of the velocity at the centre, and the former result gave the value of the mean velocity head compared with the velocity head measured at the centre of the duct. In the experiments referred to it was necessary not only to vary the speed of the fan but also its output, and it was customary in fan experiments to separate the energy of discharge into two parts, one being that utilized in overcoming the static pressure head and the other that used in creating the velocity head, and it was for this latter purpose that the mean velocity head was calculated. In order to get smooth curves it was necessary to resort to baffling, but the mesh which was used was much more open than that used by the author and had only 100 meshes to the square inch. When the fan was running at the lower speeds and the velocity of flow was small, very smooth curves like those shown in Fig. 6 were obtained, and for these cases it was found that the mean velocity of flow was 0.92 of the velocity as measured at the centre of the duct. The mean velocity head was seen to be 0.855 of the velocity head measured at the centre. At higher fan speeds and greater velocities of flow, even with the baffles, the smooth curves were not obtained, but curves more like the upper one in Fig. 7b were found. Having noticed in some tests on fans that instead of finding the mean velocity head in order to obtain the kinetic head some experimenters had taken the square of the mean velocity to obtain this value, for curiosity I worked out the two values. The mean square value gave a coefficient as stated of 0.855 and the square of the mean value one of 0.846; the latter though scientifically incorrect was not very far in error. The author apparently was in the fortunate position of being able to destroy some nine-tenths of the energy of his fan in order to get the remaining tenth steady, for excessive baffling was like putting a high resistance in the circuit. If his object had been to test the fan this could not have been done, for he would have destroyed most of the energy in order to obtain steady motion. In the testing of fans I believe that as steady flow cannot be obtained without a great deal of baffling, a better method would be to discharge the air into a large box where its velocity would be destroyed, and then allow it to flow through an orifice where at the same time the difference of pressure head on the two sides could be measured. Provided the cross-sectional area of the orifice was less than $\frac{1}{20}$ th part of that of the box, consistent results could be obtained.

Mr. C. C. ARCHISON: I notice that on page 563 it is stated that two transformers are cooled by air passing through a single duct; apparently that air has also been cleaned with some apparatus at the entrance to the duct. I have recently had to deal with this question in connection with air cooling for generating plant when installing one cooling plant for three different machines. At the time when this matter was first considered the air passing through one cooler and along a number of ducts to the individual machines seemed to be satisfactory, but lately there appears to have been

Mr.
Mawson.

Mr.
Archison.

Mr. Atchison.

some trouble in certain cases on account of the machines not taking the same amount of air. If all three machines are working, each drawing equal quantities of air, everything operates satisfactorily, but if one of the machines is not taking the same amount of air as the others, or if only one machine is working, the eliminator plates may not then be thoroughly effective. In order to get over this difficulty it is found necessary to carry division plates not only through the eliminator section but also completely through the whole filter. There are a number of types of machines arranged for air cooling and cleaning purposes, and the process of first "fogging" the air and then taking the waste moisture out of it seems as if things are being done twice over. If the air can be washed without fogging it very much there is considerably less need for the eliminator plates, and there is less likelihood of getting free moisture carried through to the generator. Two people have to be dealt with, the manufacturer of the generator, who cannot allow any free moisture in his machines, and the manufacturer of the air-cleaning plant, who has to put water into the air and then take it out. I have tried to get some standard form satisfactory to the generator manufacturer, and to which the air-filter maker could reasonably conform, and after going into the whole subject very carefully I feel that there is some uncertainty. It does seem fairly safe, however, to say that if air is to be led into a generator there is a certain margin of safety owing to the temperature of the generator tending to vaporize any small excess of moisture. I am not enthusiastic about forcing air through generators, but in some cases it is impossible to avoid bends in the ducts and to restrict them to reasonable lengths; a supplemental fan then becomes absolutely necessary. Mr. Frith said that air-cooled transformers were not going to be used. I think, however, that this remark needs modification; for smaller sizes I see no necessity to install oil-cooled transformers, but larger transformers placed in the sub-stations of supply authorities may very well be oil-cooled; whether it is advisable to place them on consumers' premises unless in a separate building is a matter which I think requires consideration. In any case, if the oil is cooled by water circulation I should prefer to draw the water through the cooling coils than to force it through, as any leakage in the latter case would tend to put water into the transformer casing.

Dr. Worral.

Dr. G. W. WORRAL: I have been much interested in that part of the paper dealing with "fogged" air. There is undoubtedly a future before this system of ventilation, more particularly in the case of turbo-generators, as it not only ensures the air being thoroughly clean but also increases its cooling properties. There must of course be no loose water about, and the question whether the change of pressure and the temperature of the air in passing through the machine would cause condensation must be studied. Although it is generally considered that the presence of water vapour is detrimental to the windings, I do not think that the injury results from the water vapour so much as from what it carries. The chemical vapours usually associated with a moist atmosphere are very injurious, and exposure to them even for a short time does untold damage to the windings of an electrical machine. I have, however, known a case in which some large machines stood for two years in a moist atmosphere and had an insulation resistance of zero yet suffered no

injury whatever, but the situation was free from all chemical fumes and the water vapour was pure. It is of the utmost importance that the air be cleaned in some way, as with the forced ventilation obtaining in modern turbo-generators the ventilating ducts are soon choked if the air is at all dirty.

Mr. Faye Hansen.

Mr. K. M. FAYE-HANSEN: The author claims very remarkable accuracy for the differential manometer which he uses. I do not quite see that he can expect to obtain this accuracy when he has calibrated the apparatus by means of an ordinary U-tube manometer, as he cannot expect then to get a higher accuracy than such U-tube manometers give. I have also made a number of air tests with the same type of manometer as that described by Mr. Frith, and I have found this to act very well indeed. As to the ratio between the velocity at the centre and the mean velocity, looking at the curve I think that a mistake has been made. Taking the area of curve A, Fig. 6, I find by means of the planimeter that the ratio between the area of this curve and the area of the rectangle enclosing it is approximately 0.97. To obtain the ratio between the mean and the centre velocity, however, one has to plot a curve showing the products of the velocities and the corresponding radii as ordinates, and the radii as abscissae. The ratio between the area of this curve and that of a similar curve with the velocities of the air at the centre multiplied by the radii as abscissae gives the desired ratio between the mean and the centre velocity. In this way it will be found that according to curve A the ratio between the mean and the centre velocity is approximately 0.94 and not 0.972. I think it would be useful if the author in his reply would correct all his figures for this ratio in the way indicated. It would show still more clearly the improvement obtained by fitting baffles. It is very interesting to notice the large difference between the temperature measured by a mercury thermometer, by a thermocouple, and by the toluol thermometer. I have sometimes measured such differences, but have never found them so large. In this case the thermometer is of course between the high- and the low-tension coils, and therefore in the strongest leakage field. I should not expect, however, that this field in such a small transformer would be sufficient to explain the discrepancy if the mercury bulb is not exceptionally large and its contact with the coil rather poor. In regard to the curves showing the temperature rise for "fogged" atmosphere, I should like to know whether the temperature rise above the surrounding air was taken before or after the latter was "fogged." From the figures given I believe that it must be above the temperature of the air before it was "fogged," and that the reduction in the temperature of the incoming air has not been considered, so that the fogging has been credited with the reduction in the temperature of the incoming air due to this air becoming saturated. I do not, generally speaking, think that fogging increases the rate of cooling sufficiently to make its use worth the risk for high-voltage apparatus. One only obtains an increase in the rating of about 10 per cent, and the same increase in the cooling effect can be got by forcing slightly more air through. In addition there is the comparative cost of the two cases, and the risk of getting moisture on the windings which are under pressure, and thereby causing surface breakdown of the high-voltage apparatus. Of course, I do not

now refer to washing the air and drying it afterwards so that there is no free moisture when the air is carried into the machine. In this way we get the advantage that the air is somewhat cooler and cleaner and we have not the risk of getting the free moisture on the windings or other live parts. The constant K referred to on page 569 is only another way of expressing what was stated in Messrs. Symons and Walker's paper,² that the cooling effect of the air is proportional to its speed. It comes exactly to the same thing. The only difference is that Messrs. Symons and Walker's statement can be applied for somewhat wider limits. If we take a case where the amount of air flowing through is very small, so that the amount of heat which the air takes is not large compared with the amount carried away by radiation, K will be far from a constant. If the amount of air is large compared with the section through which it has to pass, K is not constant owing to the amount of heat which is being put into the air to force it through the machine. The expression given by the author must therefore be used with great caution if trouble is to be avoided.

Mr. A. E. McKENZIE: A previous speaker may have given the impression that it is very unwise to install one common wet-air filter for several machines. This may be true of some wet-air filters, but it is certainly not true of them all. The station with which I am connected has installed a wet-air filter which is dealing with 50,000 cub. ft. of air per minute, and the wet-air filter is always in circuit whether there are three machines running or only one; the only thing one has to be careful about is to see that a certain portion of the filter is put on, or shut off, whenever the number of machines running is varied, so as to keep the velocity of the air passing the baffle plates constant. I make these remarks because I feel sure that the wet-air filter will shortly displace all the dry-air filters. There is very little difference in the first cost, but the cost of upkeep of the wet-air filter is very much smaller.

Mr. W. A. BRISTOW: I should like to ask the author to explain more fully the effect of the initial temperature on the temperature rise. He states that "the temperature rise of the transformer is independent of the temperature of the inlet air within ordinary limits." Does this mean the ordinary limit of variation which is found in this country, say 15°C., or were experiments made with air artificially heated so as to reproduce the conditions prevailing in the tropics, where it is sometimes necessary to deal with initial temperatures as high as 120°F.? It has become increasingly necessary in recent years to have some exact data on this point as many very large generators and motors are designed for service in India and other hot countries, and if the author has any exact figures with regard to this matter they would be of great interest to designers. As showing in a practical manner the relation between air cooling and output, I should like to mention a case where an enclosed ventilated generator was being tested in the presence of the buyer's consulting engineer. At 5 o'clock the 6 hours' full-load run was complete and 25 per cent overload was put on for 2 hours. The consulting engineer was considerably astonished to find at 7 o'clock that the temperature was much lower than the temperature at 5 o'clock. A somewhat minute examination of the arrange-

ments showed that the engineer in charge of the test, Mr. Bristow, being anxious to show the best results, had led a small branch from the firm's compressed-air system into the machine. He overlooked the fact that when the rest of the works was shut down at 5 o'clock the air-cooling arrangement would greatly increase in efficiency, hence the somewhat startling result.

Mr. J. L. THOMPSON: I should like to know why a core-type sandwich-winding transformer was used. In my opinion it is the most unsuitable type that could have been chosen, since judging from the shape of the coil a minimum coil surface is obtained for a given volume. In practice it is found that shell-type transformers having a large number of coils each with a maximum practicable surface and with distance pieces between the coils give the best results. If it were necessary to use a core-type transformer, then a concentric winding would have given more useful results; for this type would allow air ducts to be provided between the primary and secondary windings in the same direction as the flow of air, and also between the secondary winding and the core. This type would give a much greater area in contact with the flowing air, and somewhat different results as regards the temperature of the coil surface would have been obtained. With this type of winding and ventilation the curve in Fig. 10 would have been much steeper, or in other words the ratio of the mean temperature to the surface temperature would have been greater. With regard to Fig. 8 and the discrepancy between the temperatures recorded by thermo-couples and by mercury thermometers on the surfaces of the coils, I suggest that this is due to local heating of the mercury in the bulb due to eddy currents, these eddy currents being generated by the alternating leakage field passing between the coils. With regard to the positions of the thermo-couples, if couples 2 and 4 had been placed between the top two coils, higher temperatures would have been recorded. These temperatures would have been of more value than those obtained, since in any piece of electrical apparatus in which fibrous and treated insulations are used the rating is fixed by a maximum temperature and not by a mean

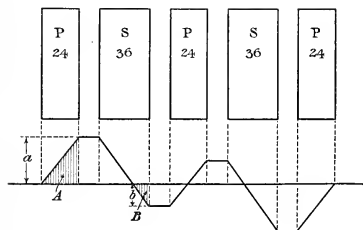

FIG. 8.

temperature. The temperature here would have been greater owing to its higher position on the leg, and also owing to more heat being present on account of eddy currents in the copper of the coils. The eddy currents

* H. D. SYMONS and M. WALKER, The heat paths in electrical machinery. *Journal I.E.E.*, vol. 48, p. 674, 1912.

Mr. Thompson.

in the copper of these coils will be more marked owing to the unsymmetrical grouping of the primary coils, which causes a heavy leakage field to cut these top two coils and the gap between. This will be seen from Fig. A herewith, in which the ordinates a represent the maximum intensity of the leakage field cutting the end coils, and b that cutting the middle coils, where the author placed his thermo-couples. The excess eddy currents therefore present in the end coils is proportional to the square of the ratio of the areas A and B . This, as will be seen, will account for an extra rise in temperature as suggested.

Professor Marchant.

Professor E. W. MARCHANT (*communicated*): One of the most important points in this paper deals with the measurement of air flow. The accuracy of the Brabbé tube as a means of measuring the velocity of air flow is of considerable importance. The problem of accurate measurement of flow along a short tube is not an easy one to solve and the method adopted of baffling the ends of the air pipe should be of value. It is well known that the eddy currents induced in the mercury of a mercury thermometer cause it to become heated, but it was not anticipated that the amount of heat so produced would be such as to double the measured temperature rise. Mercury thermometers evidently require to be used with great care when measuring the temperature rise on alternating-current machinery. The use of water in the form of fog in the cooling air is not a device which would naturally appeal to the electrical engineer. Mr. Evershed in his paper on insulation resistance* showed that water was the evil genius of nearly all insulating materials, and that when moisture was present it generally meant bad insulation. In these experiments, however, the moisture was evaporated before it came in contact with the heated coils and there was no deposit on the surface of the coils. The experiments showed that under these conditions water does very little harm, and if for no other reason they should be of value as tending to diminish the suspicion with which the wet-air filter for cleaning the air used in the cooling of machinery is still regarded. The use of a spray in the air inlet for emergency purposes when a machine has to be temporarily overrun and there is a risk of burning out the insulation, is one which might be seriously considered. A much better way of meeting such a contingency would be to increase the air blast; but this might of course be impossible in a station, whereas the starting of a spray would be a very simple matter. The paper hardly indicates the amount of work and time involved in its preparation. Each point on the curves shown in Figs. 12 and 13 involved a run, under carefully regulated conditions, of at least 2 hours and in many cases more.

Mr. Catterson-Smith.

Mr. J. K. CATTERSON-SMITH (*communicated*): I am very pleased to see the linear relations in Fig. 15, as it confirms the rule universally assumed that doubling the quantity of air through a transformer halves the rise of temperature. The author's test records in Fig. 15 show that for a 2-kw. loss a mean temperature rise of 60 degrees C. took place with 570 cub. ft. of air per second, and a 40 degrees C. rise with 870 cub. ft. of air per second. Now $60 \times 57/87 = 39.3$ degrees C., which confirms the validity of the above assumption. I am not clear as to the use of the quantity

* S. EVERSHED. The characteristics of insulation resistance. *Journal I.E.E.*, vol. 52, p. 51, 1914.

called the constant (K). It is obvious that "cub. ft. per second \times mean temperature rise" cannot alone be a constant; this is shown immediately below in the table. I prefer the more usual "cub. ft. of air per second per kw. loss for 1 degree C. temperature rise," which is nearly a constant; this, of course, is the reason for the straight line in Fig. 16. Values of this latter constant may be called q ; that is $q = \text{cub. ft. of air per second used} \times \text{mean temperature rise observed} \div \text{kw. loss}$, and therefore for any specified rise by taking an appropriate value of q the quantity of air necessary $= q \times \text{kw. loss} \div \text{temperature rise in degrees C.}$ The values of q from the author's tests (Fig. 15) are with 1 kw. loss as follows:—

Mr. Catterson-Smith.

40 degrees C. temperature rise	$q = 122$
50 " " " "	$q = 116$
60 " " " "	$q = 100$

A comparison of these figures with some of those at present in use is of interest. Dr. Kapp* gives $q = 106$ for moderate blasts and 240 for strong blasts. In ordinary commercial practice q is often taken at 100 for large transformers of 500 or 1,000 k.v.a. ratings, whilst for smaller sizes $q = 120$ is ample. It is evident from these figures that the small laboratory plant is capable of affording data on the question of cooling which is of use when dealing with large apparatus; and I think that Mr. Teago is to be congratulated upon obtaining figures that are in accordance with practice in this respect. Mr. Roberts† gave 100 cub. ft. of air per minute per kw. loss for 30 degrees F. rise of the air in its passage through a continuous-current turbo-generator rated at 40 degrees C. mean rise, or $q = 40 \times 100/60 = 67$, which is much lower than that corresponding to a transformer, due presumably to its better heat-abstracting properties consequent upon the churning action in the machine. It seems to me that the quantity of air used must depend to some extent upon the distance between the coils and the case, and I think it might prove useful if Mr. Teago would investigate this with a view to ascertaining to what extent it is responsible for the change in the quantity q which takes place at other values of the loss. I am inclined to think that the use of "fogged" air would be very restricted, as the risks attendant to its use in ordinary high-tension power transformers would be far too great, for in spite of the author's statement that the air will not deposit water, one cannot help feeling that it might do so one day with inevitable disastrous results. If it is proposed to obtain some economy by the addition of atomizing apparatus, which must occupy space, I am of opinion that it might be found more advantageous to install a refrigerating plant and a battery of pipes to chill the cooling air, as was suggested in Mr. Roberts' paper. I gave some particulars of this plant in the discussion following that paper. The proposal is to circulate air continuously between the cooling apparatus and the transformer over and over again, so that once in circulation it may be kept in a clean and dry condition. A battery of pipes containing the cold brine can be fitted in a space of sectional area very little greater than that required in any case for the air-supply ducts. It again seems possible that the author might obtain valuable results on this cooling

* G. KAPP. "Transformers," p. 57.

† R. J. ROBERTS. The mechanical design of direct-current turbo-generators. *Journal I.E.E.*, vol. 48, p. 127, 1912.

process now that the measuring apparatus is available, and I should like to ask him to consider this proposal.

Mr. F. J. TEAGO (*in reply*): With regard to Mr. Frith's remarks, I might say that these experiments were made to obtain more definite information concerning the relation between the quantity of air supplied and the consequent temperature rise, and to bring forward the value of "fogged" air as a cooling medium, rather than to justify the air cooling of transformers. The reason why a transformer was chosen for the "fogged" air experiments is that, owing to the straight air passages, the "fogged" air has ready access to those parts which are to be cooled. If the experiments had been made on a generator, for example, the probability is that little extra cooling effect due to the water would have been observed, the reason being that practically all the moisture would be deposited in the air passages in the frame. To get the water particles into the windings, etc., the air passages must be straight and free from obstruction.

Another point to be observed is that no matter how perfectly the atomizing is done in the first place there is a tendency for the water particles to coalesce, and to be almost immediately deposited if too much water is introduced into a given quantity of air.

With reference to the value of "fogged" air as a cooling medium compared with air chilled by refrigeration, it is advisable to keep in mind the latent heat of vaporization of the water. This is so much more important than either the specific heat of water vapour, or air, that it is doubtful if a refrigerator could compete successfully, as regards cost for equal effect, with plant designed to "fog" the air.

In regard to the value of the ratio (mean velocity)/(centre velocity), the paper by R. Threlfall² contains the results of experiments made to fix the value of this ratio, and there the average value is stated to be 0.873.

The results of the present experiments indicate a higher value for this ratio than that given by Mr. Threlfall, and it is a very important point to notice that the investigations by Mr. Cramp confirm this higher value. The effect of the baffles used in the present experiments is to make the ratio rather higher than it would be without them.

Mr. Mawson's remarks are of great interest, and his results are very important. They, too, place the value of the ratio (mean velocity)/(centre velocity) higher than that given by Mr. Threlfall. In this case it must be remembered that a square pipe was experimented on.

In regard to Mr. Atchison's remarks, I can only say that up to the present the two transformers have never been put in parallel on the air supply, and there has therefore been no opportunity of observing their behaviour in regard to each taking its proper share of the air supplied. It will be noticed from Fig. 1 that arrangements are made so that it is possible to work both transformers at the same time if desired. With reference to the ventilating ducts, the transformer with the rectangular core has one duct, and the one with the chamfered core has no duct. Personally, I am of opinion that the most satisfactory air filter is the wet type, and that those designed on the lines of the one used by Mr. Christie at Brighton are the best of the wet types. These have the advantage that they allow the possibility of varying the condition of the air with respect

to the suspended moisture. To my mind the trouble with Mr. Teago's free moisture is to get it into the windings, and not its effect on the windings. If, as stated in the paper, the "fogging" is correctly done, no moisture would be deposited on the windings, because as soon as the particles of water touched the windings they would be evaporated.

Dr. Worrall's policy in regard to the machines that he mentions is justifiable since the danger of moisture lies almost wholly in its impurities. In "fogging" the air for use in electrical machinery it would be a simple matter to use water free from these impurities. I must point out, however, that the insulation did not get soaked in these experiments; this is borne out by the fact that when the back of the terminal board was dried the insulation resistance was 10 megohms.

With reference to Mr. Faye-Hansen's remarks about the limiting percentage error in the readings of the velocity head, the multiplying manometer was calibrated by placing it in parallel with a water U-tube, the readings of the water U-tube being very carefully taken by means of a high-power microscope. I think a possible 1 per cent error is an overestimate rather than an underestimate. The great difficulties in attempting to make accurate measurements of air flow are the oscillations of the manometer liquids due to fluctuations in the air flow, and the effect of the liquids sticking to the sides of the tubes. It is obvious that the greater the sensitiveness of the manometer the more troublesome do these things become. In the "sine" gauge it is very doubtful if the bore of the tube approximates to a straight line sufficiently well to permit of the magnification of 400 being used with any real benefit, and it is quite possible for the observation error to be larger with these high magnifications than it would be if a comparatively small magnification were used.

In regard to the mixture of air and water, if the air and water are at different temperatures before being mixed an exchange of heat will take place. Since, however, the latent heat of vaporization of the water is the predominant factor, the exchange of heat could have but little effect on the final result. The whole of the extra cooling effect of the mixture can therefore be attributed to the presence of the water particles. That the cooling effect of air is proportional to its velocity within wide limits in the case of electrical machinery is due to the churning of the air. Each particle of air must come in contact with the hot surfaces for this to be possible. The law holds, however, for the case where air is forced through narrow ducts even though the motion is not turbulent.

With further reference to the relation between the quantity of air and the consequent temperature rise, Fig. 16 shows that it is incorrect, for transformers at any rate, to write—

$$\text{cub. ft. of air per sec.} \times \text{mean temperature rise} \div \frac{1}{2} \text{ kw. loss} \\ = \text{a constant}$$

It is correct, however, to assume that the product of cub. ft. of air per sec. and mean temperature rise is equal to a constant, provided that the loss remains constant. This is important in view of the present-day practice relating to the computation of the amount of air required for cooling electrical machinery.

The point was raised as to the value of the ratio (mean velocity)/(centre velocity). In Appendix V the method of

* R. THRELFALL. Velocities of gases in pipes. *Institution of Mechanical Engineers, Proceedings*, 1904, p. 245.

Mr. Teago. calculating this ratio is given. On checking the calculations it was discovered that the factor d/R had been inadvertently omitted. The error has been corrected in the text, and I am greatly indebted to Mr. Faye-Hansen for drawing attention to this matter.

In answer to Mr. Bristow's question, in these experiments it was only possible to observe the effect of the variation of the inlet air temperature on the final temperature rise within the limits 14 C. and 20 C. Over this range the correction to the final temperature rise is certainly negligible, but fuller information on this point can be obtained by referring to some of the papers mentioned in the bibliography.

In reply to Mr. Thompson, the reason for using core-type transformers with sandwiched coils is that they were

already part of the transformer-room equipment and were the most suitable of that equipment for my purpose. To find the exact position of the maximum temperature rise it would have been necessary to explore by means of the thermo-couples the whole of the exterior surface. A complete survey on these lines would have been interesting, but a knowledge of the maximum temperature rise would not, in itself, have helped the investigation.

With reference to Mr. Catterson-Smith's remarks, as pointed out in my reply to Mr. Faye-Hansen Fig. 16 shows that in the present case at all events q is not a constant. K , the product (cub. ft. of air per sec.) \times (mean temperature rise), is almost constant, however, if the watts loss remains constant. Thus the use of a line such as that shown in Fig. 16 would be more accurate than the use of q .

ELECTRIC LIGHTING OF COTTAGES.

By W. FENNELL, Member.

(Paper first received 7th November, 1913, and in final form 4th March, 1914; read before the BIRMINGHAM LOCAL SECTION, 25th March, 1914)

Electricity has for so many years been looked upon by the public—and even by electrical engineers themselves—as a very convenient but rather expensive form of lighting, that it requires considerable imagination, even to-day, to contemplate the installation of electric light in hundreds of cottages inhabited by the poorest people and rented at say 3s. to 4s. per week.

It may, and perhaps will, be said that while electric lighting would confer great benefits upon the tenants of cottages by supplying a healthy light which would not vitiate the air in already overcrowded rooms, it is not reasonable to suppose that this can be done profitably at a cost within the means of the consumer; and that any such proposal is doomed to failure, if only on the ground that such tenants are unreliable as well as careless, and would not properly use or appreciate the supply.

In introducing the subject, it may be well to set out the reasons that led to the consideration of this question. Wednesbury, like many Midland towns, is not an attractive residential area, the richer people for the most part live outside, and the workers form nine-tenths of the population. In developing the demand for electricity on the usual lines, most of the larger houses and shops were soon connected. Reduced rates for licensed premises brought almost all these houses on the mains, and the smaller shops followed when a free-wiring scheme was introduced; but not even free-wiring coupled with the rateable value system of charge, or slot meters, induced the £8 to £18 householder generally to take a supply of electricity. With these small consumers the convenience of gas for cooking and the cheapness of the apparatus are greatly in its favour. This class of consumer will not as a rule use both electricity and gas, and has no money to spare for the purchase of expensive cooking stoves; it is therefore useless to expect to make much headway until cheap electric cooking apparatus can be offered. It

appeared that the limit of the lighting demand was being reached.

At first sight it seems to be hopeless, having failed to reach the lower middle class, to look to the class below—the labourer, living in a cottage. It was, however, obvious that if this class could be catered for, a very large new field would be opened, as there are hundreds or thousands of these cottages and small houses in most industrial towns. The conditions in these cottages are such that the gas stove offers no attractions. In the first place a fire is always burning in the living-room, and the stove provides hot water by means of a slung pot or kettle and has a good oven. Lighting only is required; but not only "free wiring," but free lamps are essential. Such consumers cannot afford to pay at once for the wiring; or 2s. 8d. for a lamp; and experience of the £8 to £18 householder showed that unless lamps were supplied free, the result would be the use of cheap carbon lamps, followed by disuse of the electricity supply and the installation of gas. Again, allowing a five years' life, a slot meter costs 10s. per annum. It is also a very unsatisfactory article, and repairs (or loss of revenue) are heavy.

Slot meters being out of the question, and quarterly accounts quite impossible, the author considered the possibility of establishing a weekly payment system. He therefore consulted a local tradesman doing a large weekly payment business. The report was practically as follows:—

"The poorer people are the best class of payers. A debt of only one or two shillings is a worry to them, and they will pay much better than the lower middle classes who have more assurance. It will be found that they are more easily pleased and are anxious not to give trouble; and as they are accustomed to weekly payments for rent, clothes, and furniture, they usually set aside their money regularly for this purpose before spending the balance."

In view of this very favourable report, the author felt safe in adopting a weekly payment system for electricity, and the following is a summary of the arrangements adopted.

SERVICE CONNECTIONS.

In this respect the circumstances favour the proposal. These small houses are in blocks, and one service will supply from 5 to 15 houses. The plan adopted is to put an ordinary 7/18 S.W.G. service into the most convenient house, terminating it in a service fuse. Space is allowed for fixing a meter if desired to check the consumption for each block. From the fuse a twin lead-covered cable is carried either inside or outside the houses, along the row, and is looped into each house to be supplied. If any house in a row is not to be connected, a loop is left in the wire ready to insert when the tenant decides to come on, which is almost certain when a change of tenancy occurs.

It has been found that the cost of the service averages 15s. per house, whereas the cost of an ordinary service for a few lights is about £3 8s. The saving in capital charges is therefore very considerable, and must not be lost sight of when considering the value of these small consumers as compared with ordinary consumers.

With regard to wiring, each house is provided with a wall-plug socket, which takes the sub-service wires; the plug itself is connected by means of flexible wires to a pair of bow cut-outs. This arrangement provides a double-pole fuse and switch ample for disconnecting a 120-watt installation, and is cheaper and less liable to corrosion, etc., than an ordinary double-pole switch. The wiring, which commences at the bow cut-out, is quite ordinary and requires no comment.

The cost of the wiring and fittings without lamps averages £1 10s. to £1 13s. 6d. per house. A local switch is at present allowed for each light, but the substitution of key-holders is being considered. Experiment is necessary to see whether the extra consumption due to the absence of easy switching is of more importance than the reduced cost of wiring.

LAMPS.

Three lamps are supplied, two being 40-watt metal-filament lamps (one for each of the downstairs rooms), and one an 8-c.p. carbon lamp for the front bedroom. Contrary to expectation, it is found that there is no demand for light in the other bedroom or bedrooms.

With any rental system of supply it is necessary to prevent any but authorized lamps being used; and in order to do this, the simple expedient of using Edison screw caps and lamp-holders is adopted. This has been quite effective; lamps with this cap cannot be bought in small quantities, yet there is no extra expense for either holder or lamp, because it is the Continental standard. The only screw lamps stocked at the works are 40-watt metal-filament or 8-c.p. carbon; no mistake can therefore be made. When lamps are supplied free of charge it is unlikely that consumers will buy lamps by the dozen in order to defraud the supply authority. The weekly visit of the collector also acts as a check.

FINANCIAL DETAILS.

The charges must cover the cost of supply of electrical energy, free wiring, lamps, repairs, and the expenses of

collection. It was estimated that an average of about 7½d. per week per house would easily cover the cost. The cost of supplying electricity at Wednesbury is, including all charges such as interest on and repayment of loans, £7 per kilowatt of maximum load on the power station plus 0·35d. per kilowatt-hour. These figures leave a small margin. The assumption was made that the absence of a meter would mean a certain amount of waste, so a fairly high average consumption has been taken, viz. 6 hours' use of the maximum demand per night throughout the year. It was assumed that the average maximum demand at the time of the peak load, which is between 4 and 5.30 p.m., would be 50 watts; but experience has shown this to be rather too high a figure. The lamps in use are easily counted, without calling at the houses, by taking note of the illuminated windows. Visits show that the number of lamps in use between 4.45 and 5.30 p.m. amount to 108 per 100 cottages. Later on, after tea, the demand is higher, but that does not matter because the power load must be "off" when the workmen and women are at home. One is therefore certain of a high diversity factor for this demand.

Based upon a peak-load demand of 45 watts per house, and a 6 hours' use of this load per day, an annual consumption of 100 units is obtained. The cost of electricity supply is 5s. 6d. per annum for the standing charges, and 2s. 11d. for the energy consumed, or a total of 8s. 5d. The revenue at 7½d. per week amounts to £1 12s. 6d. per annum. The 7½d.-per-week average income is obtained as follows: June and July 5d., May and August 6d., April and September 7d., March and October 8d., February and November 9d., January and December 10d., so that consumers pay approximately in proportion to the use at different times of the year, and new consumers may—and do—start taking current on a fair basis at any time.

Collection is carried out on a commission basis; which has been found to be satisfactory. A collector working insurance or other business is engaged, and he knows how to deal with these consumers. Payment is made in advance on the Monday or Tuesday, and the consumer is liable to be cut off on the Monday following a failure to pay. A copy of the application form is given as an appendix to this paper.

RESULTS.

The scheme is extremely popular; it has grown from an experimental 25 consumers to 250 within 18 months, and this without any canvassing or pushing. It is quite usual for a poor woman to call for a few forms, say a dozen, and to bring them back again signed within a week. It may be mentioned that gas is 1s. 11d. per 1,000 cubic feet, so that it cannot be said that dear gas is the cause of the success of the scheme.

The actual experience obtained with regard to the following points is of great importance.

Arrears.—These keep fairly steady and are on an average about equal to one week's rental.

Lamp breakages.—These do not average one lamp per socket per annum.

Empties.—These are no more numerous here than in other premises, and further, those houses fitted with electric light are sought after.

Disconnections.—Although consumers are in no way bound to continue the supply for a definite period, there

have been very few permanent disconnections, certainly not more than 2 per cent.

Bad debts.—These can be kept as low as desired; payments are made in advance. Even with fairly lenient treatment the bad debts have not exceeded 1 per cent.

Waste.—This subject deserves a paragraph to itself. There are several causes which tend to check waste. The first, and perhaps the greatest, is the sense of fairness which exists in the working class, and the second is the weekly visit of the collector. The consumers live in blocks, and the doings of any one tenant are known to all, so that one person at least will report waste, due perhaps to a feeling of honesty, or perhaps to differences of opinion on other questions. However, it is not to be believed that one consumer in ten will burn, say, one lamp continuously day and night, or two lamps all night, but if that is assumed, the cost of the extra consumption is 10s. per annum. Even if it is not balanced by others who use the light less than 6 hours per night, it barely exceeds the annual charge on a meter in that one case; and of course if the meter were put in every house, as would be necessary, the annual cost would be £5 for meters, to save a possible 10s. waste. As a matter of fact, the energy consumed costs so little that any possible waste can be ignored. The important point is not waste of energy, but excess maximum demand. This is easily observed, and it has been shown that it does not occur.

The revenue account works out as follows:—

Electricity		s.	d.	Per Annum
Kilowatt charge (45 watts at £7 per kw.)=		5	6	s. d.
Unit charge (100 units at 0.35d.)=		2	11	
				8 5
<i>Lamps</i>				
Two metal-filament and one carbon		4 3
<i>Repairs</i>	1 0
				13 8
<i>Income</i>				
52 weeks at 7½d.	£ s. d.
		1 12 6
Less commission, 7 per cent		2	4	
Less bad debts, etc., 3 per cent		1	0	
		3	4	
				1 9 2
Profit per consumer		15 6

The word profit here means surplus after paying all charges, including interest on and repayment of loans for machinery and mains. If these interest charges were based on the cost of extra plant and mains instead of on the old costs, the result would be even more favourable.

We may take half the profit, say 8s. per annum, and use it to write off the entire cost of wiring in four years, leaving a balance of 7s. 6d. net profit per consumer per annum for four years, and 15s. per annum afterwards.

In conclusion a net profit of 7s. 6d. per annum per consumer, or about 25 per cent of the income, after paying all expenses is a far better return than can be shown on any other class of consumers. Putting it another way, 1 kilowatt of maximum demand produces a profit of over £9 per annum, and over double that sum after four years. Many of the ordinary consumers barely produce a gross income of £9 per kilowatt of the peak demand, to say nothing of profit.

The author is indebted to the Light and Water Committee of the Wednesbury Corporation for the confidence that they showed in his recommendation by embarking on the scheme, knowing that it was an experiment. Special thanks are due to his Mains Engineer and Chief Assistant (Mr. J. P. Smith), who has co-operated in every possible way in carrying out the scheme.

APPENDIX.

Wednesbury Corporation.

ELECTRICITY SUPPLY IN SMALL HOUSES.

In order to encourage the use of electricity in small houses and to avoid the use of slot meters, the Electricity Committee have decided to give a supply without meter in small houses for three lights, for weekly payments as follows:—

June and July	5d. per week.
May and August	6d. "
April and September	7d. "
March and October	8d. "
February and November	9d. "
January and December	10d. "

Two lamps will be each 32 candle-power in the living-rooms and the other will be smaller, suitable for bedrooms, etc.

The wiring, lamps, and all fittings will be supplied by the Corporation on loan, and remain their property. Extracts from the Electric Lighting Acts are printed on the back of this form [Sections 16 & 17 of 1909 Act, and Sections 24 & 25 of 1882 Act]. The wiring and lamps will be kept in good order, free of charge, by the Corporation, provided they are treated with ordinary care, so the consumer has free wiring and free lamps, the only charge being the weekly rental. This must be remembered in comparing the charges with the cost of lighting by oil-lamps or gas, in which the user has to pay for lamp-glasses, or mantles, in addition to the charges for the actual oil or gas.

It will be noticed that the charges are arranged so that the supply may be commenced at any time, and the weekly charge will be a fair one for the time of the year.

Charges are payable weekly, in advance, on Mondays. Any consumer paying four weeks in advance at one time will be allowed a discount equal to ¼d. for each 5d. paid. A book is provided for each consumer, in which all payments will be entered.

FORM OF APPLICATION FOR SUPPLY.

To the Engineer and Manager,
Electricity Department,
Camp Street, Wednesbury.

I.....of.....
accept your offer as above to fit two 32 candle-power Lamps,
and one 8 candle-power Lamp in the above house, and I
agree to receive and to pay for the supply on the terms and
conditions as printed hereon. I will also pay for any damage
to Lamps or Fittings caused by carelessness or misuse.

Signed.....

DISCUSSION.

Mr. R. A. CHATTOCK: While agreeing that a scheme of the kind described by the author is probably quite workable for a concentrated community, where personal touch can be maintained with the consumer, I am afraid that when applied to a city such as Birmingham, where the number of small consumers may easily reach 100,000, the personal touch would be lost, and it would be impossible to tell whether waste was occurring or not. With regard to the financial details of the scheme, I see that the author estimates that 100 units will be used per house per annum, on the basis of a demand of 45 watts per house at peak-load times. Now 45 watts represents only about 40 per cent of the number of watts installed in each house, and for lighting of this character I consider that his estimate is far too low. An average figure for the maximum demand in the case of ordinary lighting is 60 per cent of the number of watts installed: with the class of lighting referred to in the paper the diversity factor is very much smaller, and in my opinion the maximum demand would considerably exceed 60 per cent. If this is so, there is no doubt that the kilowatt charge may quite easily be doubled, whilst the unit charge will probably be increased, with the result that the estimated profit would practically disappear. As regards the unit charge, I should like to know whether the author has checked his estimate of 100 units per house per annum by means of installing check meters. It would certainly be worth while to do this in a number of instances, rather than to rely upon a pure estimate. The item of 4s. 3d. for lamp renewals seems too low in view of the figure mentioned in the paper of 2s. 8d. per metal-filament lamp. In regard to the service connection, the author mentions a switch as well as a double-pole fuse, but in the sample apparatus which he showed I did not see any switch included. I should like information on this point. I also noticed that he used a twin lead-covered cable, either inside or outside the house, along the row. I should like to know if he has any trouble in obtaining wayleaves from the owners of houses who do not propose to use electric light. I anticipate that there would certainly be such trouble if the scheme became at all widely adopted, and payments would probably have to be made for the purpose.

Mr. S. T. ALLEN: Several engineers have tried different schemes for supplying electricity to workmen's dwellings, and a number of such schemes have been abandoned. I consider, however, that a great deal will be done in the future in this direction, not only as a result of decreased costs and more extensive hiring powers, but also because the Health Departments of the various local authorities will more and more realize that electricity supply for workmen's dwellings is as important to the welfare of the occupiers as are good sanitation and pure food. With regard to some of the author's figures, some results given by Mr. Sillar of Colchester about nine years ago in a paper which he read before the Incorporated Municipal Electrical Association* may be of interest. Mr. Sillar's supply was metered in each house, prepayment meters being used. Taking 82 consumers, the average number of lamps per house was 5,

the average revenue was 10s. 10d. per week, and the average profit shown to be obtainable was 8s. 2d. per consumer. With these five lamps, however, Mr. Sillar showed that the average number of units used per annum was 100. This seems to show that the author's estimate of 100 units per annum for a 3-lamp installation is liberal. With regard to the cost of services, averaging 15s. per house, it would be interesting to know how many main services the author has installed for the 250 houses referred to. His main switch does not appeal to me. I do not consider that for such houses a wall plug with a flexible attachment should constitute a main switch, especially considering the class of children to be found in houses of this character and possible trouble due to their interference with the installation. I would strongly recommend an ironclad switch, which after all would not add much to the expense of the installation. It is stated that the substitution of keyholders for ordinary switches is being considered. I strongly recommend a wall switch for each lamp, and consider that switch lampholders are not at all suitable for such houses. Even in his printed agreement the author has restricted the users under this scheme to three lamps. This might suit some special conditions in Wednesbury just now, but if the system is to be universally adopted provision for any number of lamps should be made when drawing up the charges. The use of Edison screw-cap lamps is a very good idea and well worth copying. The author's experience that for 120 watts connected for lighting only 45 watts is recorded as peak-load demand, is certainly interesting. The mode of collecting the accounts weekly on the commission basis is certainly very good, but I am doubtful whether all authorities would agree to such a system. I think the author's balance sheet would have been more correct if it had shown the annual charges due to the wiring and the installations. He has also been too generous in only allowing four years to write off the entire cost of the wiring. This could well be extended to eight years. There is one main point in which I disagree with the author's scheme, namely, that in the main services or sub-services no provision is made for cooking, heating, or other possible loads in the future. I am not alone in holding the view that there are enormous possibilities in the future in this direction, especially when the cost of electricity supply is still further reduced and when electric cookers, heaters, etc., can be hired out at the same price as is gas apparatus at the present time. I think that in laying new mains and sub-services such loads should be allowed for, thereby preventing complications and great extra expense in the future.

Mr. W. E. MILNS: Such a scheme as that of the author would doubtless be vigorously promoted in a town like Wednesbury which has a very large power supply but a comparatively small lighting load, while in other towns with a heavy lighting peak no special effort would be made to obtain this class of business. The plug switch referred to would not, I think, pass the Institution Wiring Rules. Some charge should be made for lamp renewals, say 6d. per lamp; this would be a check on any waste of current and breakages of lamps, as the consumer would know that the life of the lamp depended upon the number of hours of use. The revenue shown in the paper repre-

* A. K. SILLAR. Electricity supply by free wiring and prepayment meters. *Proceedings of the Incorporated Municipal Electrical Association*, 1905, p. 119.

Mr. Milns. sents 16s. per 60-watt lamp per annum. This seems very high compared with the revenue from similar houses taking current through prepayment meters, which represents 6s. 6d. per 60-watt lamp per annum, and about 4s. 6d. per 30-watt lamp from large houses.

Mr. H. HOLDEN: I should like to know the method employed when disconnecting defaulting consumers. It is surprising to hear that electrical energy is anywhere so cheap that waste may be ignored. The cost of meters is, in my opinion, overestimated by the author. A first-class continuous-current $\frac{1}{2}$ -ampere meter can be obtained for not much over 30s., and alternating-current meters for less than 30s. Such a meter would certainly last 10 years and could be maintained for 5 per cent per annum, so that 5s. or 6s. per annum is ample to cover its cost. Then there are electrolytic meters, which would probably be obtainable at a still cheaper rate. The absence of a meter confines consumers to the use of current for lighting purposes. Although the use of current by such consumers for heating or cooking is not probable at present, yet if the great advantages and direct saving to be effected by the use of laundry irons were to be properly explained to these consumers they would be adopted at once, provided they could be obtained on hire at favourable terms.

Dr. A. H. RAILING: Whilst I agree with Mr. Milns that it is more profitable at the present moment to look after the £50 houses, I am of the opinion that in all the big manufacturing centres, including Birmingham, it will eventually be essential to tackle the problem of workmen's cottages. I agree, however, that local conditions play a very important part, and that the method of solution will largely depend on such local conditions. I do not agree with Mr. Holden that meters should be installed. On looking at the revenue account it is seen that the unit charge and the kilowatt charge per house come to about 8s. 5d.; the extra item of 2s. for meters, even if these are of the cheapest kind, is therefore an important percentage of the total cost, and is almost as important as the cost of lamps when considering the feasibility of such installations. Two kinds of waste have been mentioned. First, the consumer tries to use more current-consuming apparatus than he pays for, such as irons, lamps of higher candle-power, additional lamps, etc. In some supply undertakings controlled by my firm we have been trying, in order to prevent such waste, one of the various classes of current limiters which are on the market. It is an ordinary flicker limiter which can be bought for about 2s. Our experience proves, however, that the current consumption with the flicker meter has not been less than in similar installations where the flicker meter was not installed, so that this seems to prove that it is hardly necessary to use such apparatus. The second class of waste lies in the possibility that the consumer may omit to switch off his lamps. This, of course, may happen, and the estimate should allow for a certain percentage of waste. At the same time it seems hardly credible, especially if a certain amount of supervision is exercised, that wilful continuous waste should take place, especially at the time of peak load, when of course it would be most important. As a matter of fact the author shows that between 4.45 p.m. and 5.30 p.m. the number of lamps in use amounted to 108 per 100 cottages, which indicates roughly a waste of about 8 or 10 per cent. If this is the average waste, no doubt it would not pay to eliminate it

by meters. As regards details, I do not particularly care for the wall-plug arrangement which the author employs, although I agree with him it is cheap: but perhaps by paying another 1s. it might be possible to obtain some cheap kind of switch-fuse which would answer the purpose. The author mentions that he used an 8-c.p. carbon lamp for the front bedroom. I do not see why he should do so. An 8-c.p. lamp requires about 30-32 watts, whereas by using 15-watt tungsten lamps, which are now obtainable, the current consumption in that room would be reduced to one-half. The author's method of preventing the use of lamps of higher candle-power, viz. by adopting Edison's screw lampholders, is of course quite effective, but if the scheme were adopted on a somewhat larger scale I am afraid that such lampholders would not be sufficient safeguard. It would, however, be easy to devise some other means. I remember, for instance, that when tungsten lamps were first introduced, and their price was comparatively high, a special device for locking the lampholder had to be devised so as to make it impossible for unauthorized persons in public buildings and streets to remove the lamps. It is a very simple device and allows a lamp to be removed only by the use of a key or special screw-driver. With regard to the collection of the money, I wonder whether a system which is successfully employed in some places on the Continent has ever been tried in this country; it consists in making the landlord responsible for the collection of the money. In the case of some large flats a fixed rate is there charged per flat, and the landlord collects the money, against a small commission, for the electric supply undertaking. Perhaps some such scheme might also be applicable in this country. In regard to lamp breakages, I agree with some of the previous speakers that a lamp should last more than one year. Perhaps if breakages are very numerous it would be necessary to take some such step as that advocated by Mr. Milns, namely, to charge a certain amount per lamp; if possible, however, I would prefer to avoid any additional charges. Success is only possible, as the author points out, if the small householder knows exactly what he has to pay per week, and therefore uses electricity in the same way as he uses water.

Mr. F. W. FOSTER: The final success of any scheme such as that outlined by the author would depend largely on the development of the $\frac{3}{4}$ -watt lamp. I do not share other speakers' fears as to the undesirability of a cottage load in any district, as the maximum demand for the lighting of cottages could not coincide with the maximum demand on any power station except where cottages only were supplied. The variable charge for different seasons is a valuable feature, and the "insurance collector" idea is novel. I notice that the balance sheet is incomplete, such important features as the cost of wiring and book-keeping being omitted. From the balance sheet it may be inferred that a gross revenue of 4d. per unit was obtainable, and I should like to know if this is the actual revenue per unit delivered to the distributing mains serving this system. Also, can the author state any figures giving the loading per mile of distributor in comparison with figures for ordinary residential lighting.

Mr. F. FENNELL (*in reply*): It is gratifying to find an almost unanimous opinion in favour of extending the benefits of electricity to the artisan, and Mr. Allen goes so

Fennell, far as to say that it will eventually be demanded. The chief object of my paper is therefore served.

Mr. Chattock's objection to my plan on the grounds that Birmingham is too big, and that its working classes are not all equally honest, will I think disappear if certain districts of a town are avoided. Mere size is no disadvantage but rather the reverse; it costs less per consumer to supervise 10,000 than it does 300, and the profit is shown as so much per consumer. Mr. Chattock in his figures as to maximum demand takes no account of the diversity factor and has probably not noticed the definite statement in the paper to the effect that the figure of 45 watts is the result of careful investigation of the actual number of lamps in use at the time of peak load on the station. Mr. Chattock's suggestion that the figure might be 90 watts is therefore contradicted by the facts. I would go further than Mr. Chattock and say that the consumer's individual maximum demand is not merely 60 per cent but is 100 per cent of the connections, but it occurs at "off peak" times. It would be useless to install a current limiter for a 3-lamp installation. One must allow that at times all the lamps will be required, say on Sunday evenings and Bank Holidays. The habit of Sunday and holiday visiting helps to fill up the load on the power station on the days of least demand. I cannot see how the maximum demand at the time of peak load on the station could be more in an industrial district than what I have allowed. It would be more in a residential area, no doubt, but the figures given are confined to a district having the heaviest peak load between 4 and 5.30 p.m.

With regard to the number of units per annum per house, there are no figures available, but this figure is not of very great importance because, if doubled, it only adds 3s. per annum to the cost. The low running cost (0.35d. per unit) allows the meter to be dispensed with, simply because the interest, etc., charges on a meter exceed the value of the electricity which would be saved if it were used as a check on waste. If the running cost were 1d. per unit the meter could not be dispensed with. There is to my mind no difficulty in keeping the unit consumption down to something like 100 units per annum, if there is the same amount of supervision exercised as that adopted by Water Companies under exactly similar circumstances, viz. to keep waste down to such a figure that it does not pay to charge on a meter basis.

There have been no serious difficulties in securing way-leaves for the looped services. The tenants want the light, and it is to the interest of landlords to let them have it, because it reduces the cost of whitewashing and papering. In the only case that I can remember where a landlord objected, most of the tenants threatened to leave.

Mr. Allen and others stated that I had not gone far enough because no provision was made for heating, etc. This was welcome and unexpected criticism, as I had feared condemnation for going so far; it lends support to my case. I gave reasons in the paper (the always-burning fire providing all the heat required) why in Wednesbury there was no heating demand in this class of house. I agree that if we are to cater for heating, a meter must be used, and I have no doubt that in flats where there is a difficulty in delivering and storing coal, or in districts where coal is dear, something may be done in this direction. The framing of systems of charging, like all

other details of management, should be based on a Mr. Fennell's careful study of local conditions and local human nature. The conditions in "coal districts" will be, for some years at least, as described in the paper, but when a consumer wants a supply for heating he can have it as a separate supply through a "cheap" meter. Why go to the expense of installing 300 meters because 30 consumers may want a flat-iron or grill?

The slot meter has failed in most places because it does not fit in with human nature. It gives the consumer an exaggerated idea of cost—the money found in the meter never amounts to anything like the amount that the consumer imagines has been supplied. It produces less revenue, only 6s. 6d. per lamp against 10s. 10d. with the rental system. Consumers were hard to get and to keep with slot meters, but they are easy to obtain with this system because, I believe, money is scarce from Tuesday to Friday. The capital and maintenance costs of slot meters made their use unprofitable. I cannot agree that it would be wise to charge even 6d. each for renewal lamps. Difficulties would arise due to changes of tenancy. It must be remembered that the success of the rental system is due to the certainty of the charges—the housewife knows exactly how much money to leave out for the collector; there are no extras; nothing to pay for wiring, lamps, and repairs. Compare this with a weekly meter reading, with disputes as to the amount used, a meter being generally assumed to be an inaccurate instrument. Remove even one of the above characteristics and the rental system no longer suits the people, and becomes unpopular, book-keeping becomes heavy and involved, and collection is more expensive. With regard to Mr. Holden's suggestion that we cannot afford to give units away however cheap they may be, I must remind him that apart from the actual cost of the meter being more than the possible saving of electrical energy by its use, we have to remember that a non-technical collector works the business easily at present—a meter reader and accurate reckoner of accounts is required for a weekly meter system.

Several speakers thought the wall-plug switch to be dangerous to children. I omitted to state in the paper that it is fixed 5 ft. or 6 ft. from the ground. I cannot see that a 5-ampere plug is unsuitable for breaking half an ampere, or that it is as dangerous as when used in its usual position on a skirting-board where children can play with it. It is satisfactory to hear from wiring contractors that the allowance for wiring is ample, and it is pleasing to hear from Mr. Milns that too much has been allowed for lamp renewals. I wished to be on the safe side, but I agree that lamps will last longer and will soon cost less. I agree that 4 years is too short a period for writing off the cost of wiring. Those engineers who can obtain 7- or 10-year loans will obtain a better result in the early years than that shown in the paper. I think that the twin-flexible surface system has not sufficient mechanical strength for these houses, and I would mention that in many cases the premises are not very clean. Several applications have been refused for this reason. The lead-covered twin system is the most suitable.

With regard to Dr. Railing's suggestion to use a metal-filament lamp of low candle-power in the bedroom instead of a carbon lamp, this has been considered, and it might

Mr. Fennell. reduce the risk of consumers using the bedroom lamp as a night-light. This is the one practical difficulty which has arisen, and there are at least five ways of dealing with it: (1) To forbid it under penalty of removing the bedroom light. (2) To provide a time switch to cut off at midnight. (3) To provide a metal-filament lamp which will be uncomfortable. (4) To provide a turn-down lamp and allow it to be used as a night-light. (5) To provide a pear-switch at the bed. The first-mentioned policy is being adopted in Wednesbury with fairly good results, as the threat of disconnection raises visions of a return to the bad old days of candles or cheap oil-lamps. In my opinion the provision of a pear switch at the bed would entirely remove this trouble.

With regard to the suggestion made by Dr. Railing that the landlord might collect, we have purposely avoided this. We often get paid in preference to the landlord—it is easier to pay 5d. or 10d. than it is 3s. or 4s. By putting the two things together the electricity arrears would at best increase largely and there would be a risk of the landlord claiming payments on account as being for his rent and not for the electricity. I am pleased to find that Dr. Railing, who has had experience of

rental systems, confirms all the important principles on Mr. Fennell which I based the system for Wednesbury.

Replying to Mr. Foster, I could not add the cost of wiring before arriving at the profit because every one has his own idea as to the number of years to be allowed for writing off this cost.

Cost of book-keeping is not omitted—it is included in the collector's commission, to the extent of almost nine-tenths, and the remaining one-tenth is included in the £7 per kilowatt of maximum demand, which covers all the station distribution, clerical office, and capital charges (excluding wiring). I think Mr. Foster is wrong in asking for the revenue per unit, because it means nothing when given. Electrical energy does not "cost so much per unit," and that is the whole basis of the system. The loading of the distributors is so small as to be practically negligible. If there were one consumer for every 5 yards, the loading would be under 40 kw. per mile if all the lamps were alight at once.

Replying to Mr. Holden as to the method of disconnection, the fuses are removed and the three pendants are taken down, being used for the next consumer connected.

DISCUSSION ON

"REACTANCE AND REACTANCE COILS IN POWER CIRCUITS."*

NEWCASTLE LOCAL SECTION, 26TH AND 30TH JANUARY, 1914.

Mr. P. V. HUNTER: At the commencement of the paper it is stated that recent developments in the design of generators have tended to reduce the self-induction of the armature, but my experience is that the most recent practice is to increase the self-induction of the armature, and in fact designers have endeavoured during the last year or two to increase the self-induction without sacrificing mechanical rigidity. The author calculates the short-circuit current of a power-supply system having a capacity of 50,000 kw. of generating plant to be 120,000 amperes. It would, I think, have been of more interest if the voltage of the system had also been given. The use of reactance in busbar section switches is proposed in power stations, and there are arguments in favour of its use in this position, but there is an important argument to the contrary, namely, that on an ordinary transmission system the busbar sections are also connected together, through the transmission system, in parallel with the busbar section switches. A busbar reactance having a substantial difference of pressure across its terminals when loaded would therefore shunt a somewhat heavy current through those feeders connected in parallel with it. If, to meet this objection, the use of such parallel feeders is avoided, a large network then becomes an uneconomical aggregation of small networks, and the cost of it would be prohibitive. The author suggests the use of reactance coils in feeder circuits, but I must say that my experience is entirely

opposed to their use in such a manner; in fact one of the transmission difficulties in this district is the reduction, due to the reactive drop, of the effective transmission distance of overhead lines compared with that of cables. This has necessitated considerable expenditure in regulating apparatus. Any proposal therefore to add reactance to the underground cables would be regarded with distinct disapproval. Reference is made on page 257 to reactance and regulation, but I am unable to agree that voltage variation is unimportant; according to my experience it is a matter of some difficulty to keep the pressure at the consumer's terminals reasonably constant without incurring expenditure in special voltage-regulating apparatus. On systems operating with a lagging power factor the use of reactance would involve a substantial increase in the cost of the transmission system. I have not found it necessary to use a special reactance in generators. It will generally be found convenient to step up to a higher voltage through a transformer, and it is very easy to incorporate a reasonable amount of reactance in transformers without additional expense. The author gives a very apt description of the way in which high-frequency surges flowing into a transformer break like waves against a breakwater, and he recommends the use of reactance coils to protect the transformer; it seems to me, however, that the same purpose is served by specially insulating the end turns of the transformer. The author states that up to recent years consulting engineers have

* Paper by Mr. E. P. Hollis (see p. 254).

Hunter. specified transformers with low reactance, but that they now specify high reactance. While this may be true so far as his experience goes, it is certainly not the policy of the firm with which I am connected. Reference is also made in the paper to the methods of obtaining high reactance in transformers in order to reduce the short-circuit current and consequent mechanical damage. I consider such reactance to be both objectionable and unnecessary in power transformers, as they can be constructed without materially increased cost to withstand short-circuit currents of 40 times the full-load current. This corresponds to a full-load impedance of $2\frac{1}{2}$ per cent, and a regulation on ordinary power factors of the order of 2 per cent, which may be considered satisfactory. I gather that the author's calculations apply to the sandwich-coil form of transformer and not to the concentric form which is, if anything, the more commonly used type. The point to which the author draws attention respecting the weakness of using iron in the leakage paths is distinctly good. There is generally, however, an air-gap in these leakage paths and the tendency to saturation is not as great as one would expect. It is very fortunate that in this country the troubles described on pages 258 and 259 do not arise. It must be a very difficult matter to transmit energy over such long lines and maintain reasonable voltage at the far end. The suggestions made by the author to overcome these troubles offer technically a real solution, but the adjustable reactance would, I fear, present considerable difficulty. However, I have no doubt that some compromise can be obtained which would be an improvement on present arrangements. The author's suggestion for obtaining a constant-potential transmission system is most interesting, but the amount of costly synchronous plant which would have to be installed would be prohibitive. On page 260 the author suggests the use of reactance coils to protect the end turns of high-tension induction motors. I would suggest the use of a transformer. I think that the stator of a motor is not the place for a high-tension winding. Such a winding becomes uneconomical on small motors and there is increased probability of shock and breakdown. The suggestion of using a continuous-current coil for superimposing a continuous flux on a reactance in order to render the reactance adjustable is most interesting, but it seems to me that the graph of the alternating current through the reactance coil would have dissimilar shapes for each half of the wave.

Gregory. Mr. R. W. GREGORY: I hope that the author will not persuade anybody to fit to power-station busbars reactance coils such as those illustrated. They may be of use in other places, but I think it should be an axiom among switchgear designers and engineers to keep power-station busbars as simple as possible and free from apparatus of any sort.

Ireus. Mr. J. R. ANDREWS: I should like to point out that overhead lines are not "loaded" in England, although the practice is very prevalent in America, where it is claimed that there is a great saving in copper by using loading coils. In the case of overhead wires conversation is possible over a distance of about 1,600 miles, as against about 36 miles for standard underground cables; loading coils are used, however, in the latter case to increase the distance, series loading being found the better arrangement. In international telephone cables the following

Mr. Andrews. three methods of increasing the speaking mileage are used: (1) By using heavy copper conductors with large interspaces, whereby the capacity is reduced; (2) by using an additional wire for continuous loading; and (3) by interspersing telephone coils as antidotes to the capacity effects.

Mr. J. SCHULZ: In America inductance coils are largely used by the various Edison companies. The fact that one of their engineers is the designer of the porcelain-clad type may have something to do with this. There is, however, no question but that such coils are valuable. The engineers of the Washington power station told me that owing to short-circuits one of the generators had been burnt out twice, laying it off 8 months altogether. Since the introduction of the inductances, no breakdowns had occurred on the machines—a valuable asset where the station is fully loaded.

Mr. J. R. BEARD: While I agree with the author as to the advantages of additional internal reactance in alternators and transformers, I think he views the use of special external reactances in somewhat too favourable a light. As an external reactance coil is an additional potential source of breakdown, its use requires justification, and glancing at the various uses which the author proposes for it, I do not see much justification for its application to the cases of alternators, transformers, or feeders, except in special circumstances in the last-mentioned case. As regards alternators, manufacturers can readily build machines with sufficient internal reactance to limit the maximum momentary peak of the short-circuit current to less than 12 times the R.M.S. current at normal load, and, in addition, on large systems there is the reactance of the step-up transformers to be considered. Apart from other disadvantages, I should imagine that if a part of the reactance were external to the machine it would be more costly, particularly if account be taken of the additional space occupied, and I should therefore be interested if the author could give some actual comparative figures on this point. It has been proved by very extensive short-circuit tests carried out in this district on transformers made by several firms that when designed on ordinary commercial lines with a regulation of say 2 or 3 per cent at 0.8 power factor, transformers can be constructed so that they will stand up without damage to a "dead" short-circuit on the secondary with full terminal voltage maintained on the primary. Turning to the question of the use of reactance coils in high-tension feeders, it is evident that if they were used indiscriminately on say a 20,000-volt system the effect for all practical purposes would be to reduce the 20,000-volt system to the equivalent of say an 11,000-volt one. The author of course does not propose such indiscriminate use, but I gather that he favours the use of such coils for all feeders from a power station, since he states that "reactance coils in feeder circuits naturally follow for limiting the power on short-circuit." I cannot agree with this as applied to the general case of main feeders to a large distribution system. As it is uneconomical to tap a main feeder near to the power station such feeders are usually of considerable length, and thus they have sufficient impedance to prevent excessive current flowing into a short-circuit at their far end. Further, a breakdown on the feeder itself is scarcely more probable than would

Mr. Beard. be a breakdown in the reactance coils, and in any case the switch at the power-station end must be designed for the latter contingency. For short high-tension feeders to sub-stations near to the power station the case is different, and I agree with the author that reactance coils should be used if the power station is large. The drop in pressure which they cause does not matter as there is practically no drop in the feeders. They also have the very great advantage that not only does the effect of a short-circuit on the sub-station or on the consumer's apparatus prove to be a less severe strain on the system, but in addition ordinary sub-station switchgear can be installed by the supply authority and the consumer can safely use standard commercial switchgear; whereas if no means were taken to limit the short-circuit current, the supply authority would have to install power-station type of switchgear at the sub-station, and the consumer would be similarly obliged to install at considerable extra expense special switchgear designed for the most severe conditions. The author also recommends reactance coils for sectioning extensive high-tension networks. On many systems this may be done with advantage, but in this district the conditions are rather special as, owing to the large number of waste-heat stations running at practically constant output, the power is transmitted in entirely different ways at different times. Consequently whatever sectioning points are arranged for there will be heavy currents flowing through them at one time or another, and, if reactance coils were installed, large voltage drops would be produced, which would necessitate further additions to the already complicated arrangements that are required on extensive systems for regulating the voltage. With regard to the descriptions that are given of actual constructions for reactance coils, I should be glad if the author could inform me whether any trouble has been experienced arising from the effect of the large stray fields in heating surrounding ironwork such as girders, etc. A well-known type of reactance coil which is not described is designed with a core partly of iron and partly of wood, the arrangement being such that no external field is produced. This type of construction has the further advantage that it enables the coil to be oil-immersed in a standard metal tank.

Mr. W. R. BAXTER: This paper would lead one to believe that there is no electrical trouble which inductance coils cannot cure, but the fact that these coils are not used to any extent on the local supply systems seems to point to the possibility that there may be other ways of obviating the difficulties referred to. In a recent case where two large fan motors at a colliery gave continual trouble on a 3,000-volt system due to "potential front," the trouble was entirely removed by arranging high-resistance nets in the main oil switches, with contacts so designed that the high resistances were momentarily connected in series with the stator winding. Such an arrangement would be much cheaper than any type of external reactance, as all that is necessary is to deepen the tanks slightly, and in fact the cost would not exceed two or three pounds.

Mr. R. C. PHILIP: For the paralleling of transformers of different regulation, capacity, or voltage, the use of choke coils is the simplest arrangement. An ingenious way of paralleling two transformers of different voltages

is to connect them by a choke coil and to take the supply from a tapping off some point in the choke coil—this point to be nearer the transformer of greater voltage. Although the use of reactance coils for transformers of different pressures is only required in an emergency, it is useful to bear it in mind.

Mr. C. S. VESLEY BROWN: In the discussion the following terms have been used:—reactance, inductance, impedance, choking coils, and choking reactance. I should be glad if the author would state which is the correct term to be employed. The value of the use of reactance coils in connection with generators has been questioned. My experience leads me to insert them wherever possible. A generator is a very expensive piece of machinery to repair, and so after having experienced the necessity of having to burn out a fault I prefer to use reactance coils. The question of their use in other directions is perhaps to be decided by experience, but so far as generators are concerned I am sure that in future a reactance or spring-loaded buffer will be necessary—at any rate when it becomes a question of protecting a plant of more than 10,000 kw. capacity.

Mr. G. N. WRIGHT: I should like to ask the author a few questions of a practical nature. He speaks of the advantage of added reactance in transformers. What are the disadvantages? He also mentioned that Mr. Hobart suggested the use of fuses in the field-coil circuits in cases of breakdown. On account of the high voltage developed when a circuit is broken suddenly, would this not lead to trouble? Would it be practicable to put a non-inductive resistance across the field-winding, or would this have to be too high to suit running conditions to be of use under breakdown conditions? On page 256 the author refers to the generators being connected to a neutral busbar earthed through a resistance or reactance coil. The usual practice would appear to be to earth only one generator, although if the machines were connected to a neutral busbar they would then share the short-circuit current. Does the author favour this latter method? Would not reactance coils introduced into circuit-breakers have to be very strongly built, since when the switch is opening under fault conditions the current has already started at a high value and has to be reduced by the reactance. In such a case the reactance would be subjected to greater stresses than if it were already in the circuit. With reference to the statement that operating engineers have gone so far as to insert reactance coils between the generator and the busbars, so as to be able to switch in a machine when it is 180 degrees out of phase, I am of opinion that this seems to be going too far, as the amount of reactance that would have to be inserted would be much higher than the author would appear to consider necessary for ordinary operating conditions. The point raised near the top of page 259, that the trouble with the rise of pressure could be overcome by reducing the size of the conductors near the receiving end so that it is just above the critical value for corona loss, is very interesting. What percentage length of the line would have to be reduced to that diameter for safety? At the top of page 260 it is mentioned that the reactance coils might be called upon to carry currents for many minutes. I should have thought that if the fault were on a cable protected on the Merz-Price system it would not be likely to last so long.

Mr. P. S. THOMSON: When certain portions of this paper were written I think the author did not give quite as much consideration as he might have done to the perfection of protective gear, which does what the author claims for his reactances, namely, to make faults local affairs. As previous speakers have remarked, the quickness of mechanical operation cannot altogether be relied on, and no doubt the author believes in tackling the matter before it becomes serious enough to necessitate the breaking of heavy currents. What would be the effect of the use of a number of these reactances on the power factor generally of the system? In the case of a short-circuit at a very low power factor an oil switch may have to contend with a condition which at zero current in the ordinary way tends to restore the circuit just when the break should occur, and I wonder what effect the reactances would have on that condition, e.g. whether it would make it easier for the oil switch or not. I was rather surprised to see the statement that it was immaterial whether steam was on the generators or not in the case of a short-circuit. We all realize that an immense amount of energy is stored up in the rotating parts. Unless steam is behind these parts I am afraid the frequency would after the first short interval of time decrease sufficiently to throw some of the synchronous machinery out of step. However, no doubt the author's statement is borne out by fact, as he refers to tests at Fisk-street power station. In the paragraph on page 257 headed "Reactance and Regulation" he says, "Increased reactance in a circuit with a lagging power factor naturally adversely affects the regulation. But this is a matter which is not so important as it was some years ago." Why?

Mr. W. D. LOVELL: In connection with the regulation of alternators, would 20 per cent be a fair figure? As regards Mr. Longman's statement with reference to reactance coils for circuit-breakers, I think the general practice for circuit-breakers of high capacity is to insert two reactance coils in series, in parallel with the main contacts, there being two sets of two contacts per pole, one set being employed for the main contacts, the other set for the reactance contacts. Have electrostatic condensers been used for increasing the power factor by connecting them across the terminals of large motors? Instead of placing reactance coils in circuit between the transformer and the slip-rings of a rotary converter to obtain voltage regulation (5 to 10 per cent) on the converter by varying the field strength, why not design the transformer so that it has a high reactance and thus do away with the coils and still have the same result?

Mr. C. O. BRETTELLE: I suppose the principal items of this paper would come under the heading of insurance of plant. It would be interesting to see some kind of curve showing the relation between the amount of damage likely to be done without these choke coils and the amount of saving to be effected by their installation. One would have to take into consideration the cost of the additional floor space needed by all the reactances, the use of which is suggested in the paper. In regard to the unsteady running of generators in parallel, could not the steadying effect be obtained from the mechanical end by adjusting the governors, and by making these less sensitive, eliminating the necessity for a reactance coil?

Mr. R. M. LONGMAN: In looking up one or two papers read recently on protective devices for high-tension transmission circuits, I was surprised to find how little attention has been paid to reactance methods. In Mr. Peck's paper of 1908* a slight reference is made, but chiefly in regard to choke coils for protecting transformers, and one is shown in the form of a flat spiral of which the dimensions are not stated. Mr. Hadley† has described the type of switches used at Rosherville. He says that a two-movement reactance switch is being installed. Does he mean that the reactance coils are actually in the switch tanks? I should like to know what size these reactances would have to be in an 80,000-volt circuit when there is a total capacity of 150,000 kw. connected. Mr. Hadley also states that 6 per cent reactances are being installed between the machines and their transformers, the latest practice being to design both generators and transformers with large internal reactances. That figure (6 per cent) is less than the 15 per cent mentioned by Mr. Hollis. I agree with the author that on a short-circuit not only the maximum short-circuit current of the generators has to be considered but also the inertia of the apparatus connected to the system, and especially that of rotating plant, such as motor-generators and rotary converters, which is connected direct to the line. Of course the time in question is perhaps 1/100 second, or even less than that. I saw a few time tests made on some switches for South Africa, and the total time from the instant at which the switch commenced to open to the final opening of the circuit was 0.65 second, including the mechanical operation and the actual interruption. The damage is usually done in half a period or at most 2 periods. In one case where several stations are running in parallel, with an interconnector 20 miles long between the two groups, a pulsating effect has been noticed. Would reactance coils have any steadying effect? I believe that the pulsation is really due to the difference between the governors on the various prime-movers. The various inductances on a system of this nature cannot be calculated. Another effect noticed has been the breakdown between the turns on regulators owing to the charging of electrolytic arresters. The frequency with which we are dealing is probably about 50,000, and it is important to know what should be done in such a case. Another interesting point has been noticed in the case of two systems running in parallel connected by two interconnectors; on one of these being opened at a synchronizing point the synchroscope pointer was observed to be oscillating, and it finally rotated—the other switch had just tripped. The oscillation of the pointer indicated hunting and instability. The problem of keeping two or three large stations in parallel is most difficult and intricate. Of course it will have to be solved, and anything that will increase our knowledge of such problems will be most helpful. In regard to the adjustable reactance referred to on page 260, I suppose the reference is to Dr. Coates' experiments some years ago, which unfortunately were not carried as far as they might have been. At the top of the same page where it is stated that reactance coils will be called upon to carry the current for many minutes,

* J. S. PECK. Protective devices for high-tension transmission circuits. *Journal I.E.E.*, vol. 49, p. 98, 1908.

Mr.
Longman.

should not this be seconds? Would the author recommend the insertion of reactance coils to steady a load that is rapidly and violently fluctuating? Referring to reactance and third harmonic currents, I have often wondered why resistances are so much favoured, as their cost and upkeep is very heavy. Of course the heating caused by harmonic currents may not be of great importance, but what about the magnetic effect on the machines? Is not this more important? With Mr. Paton, I think the 15 per cent mentioned near the top of page 257 seems rather large. On page 256 in regard to reactance circuit-breakers in parallel, to install them in series would appear to be a better arrangement, otherwise one switch is almost sure to operate sooner than the other, leaving the final breaking to a single switch. Certainly the proper thing to do in the case of a very large power station is to divide the busbars into sections and to insert reactance coils and switches between each section, so that under normal conditions there would be very little current flowing through these reactance coils, and the effect of a fault would be restricted to one section.

Mr.
Marshall.

Mr. A. H. W. MARSHALL: Reactance has in the past been looked upon as being rather objectionable for most commercial purposes: now we are told that in every respect it is a very good thing. The only comment which I have to make is that we can have too much of a good thing. I think we should not at once put reactance to all the many uses that the author suggests, and I believe that he himself would not advocate that being done. In regard to the effect of short-circuits on machines, there is no doubt that the field current does rise to a high value and that the turns of the field winding are liable to be short-circuited if they are not well insulated. For this reason rotors with completely insulated windings are less likely to give trouble than those having bare-strip end connections. The figure of 120,000 amperes which the author mentions on page 255 as the short-circuit current of a big station would, I suppose, only exist for a fraction of a second, the steady value of the current being only about $\frac{1}{2}$ or $\frac{1}{3}$ of this; and the number of kilovolt-amperes that the switch would have to break would not be so large as that mentioned. In regard to the stability of power systems, it seems to me that the insertion of reactance coils between generating stations would, as a rule, have the opposite effect to that which the author states, especially where the stations are joined by long overhead lines. Taking the case which Mr. Longman quotes of two systems each containing several stations and a big power load, there is no doubt but that the conditions of parallel operation become worse when either the resistance or reactance of the connecting mains is increased. The two systems are interconnected by a cable and an overhead line in parallel; with the cable switched out there is a greater tendency for the current to surge, and it is this which brings about the peculiar synchronizing effect to which Mr. Longman draws attention. I consider the most important use of reactance coils to be in sectionalizing the busbars of very large stations. Bearing in mind the size of generating stations in this country and the fact that the larger trunk mains take the form of overhead lines, that seems to me to be at present the only place where reactance coils can be profitably employed. It is possible that in special cases larger feeders (especially

if these consist of underground cables) may be advantageously fitted with reactance coils, but the question of regulation has always to be borne in mind, and it is this which has to be taken into account when considering what limit shall be placed on the short-circuit currents. As an instance of the desirability of not increasing the reactance of feeders, I might mention that split circuits are used on some of the largest overhead lines in this district. I should like to ask the author if he knows of any form of resistance which has been successfully used for choking purposes. In regard to the operation of synchronizing machines, in my opinion the extra complication involved by the use of reactance is undesirable. It is found in everyday practice that ordinary synchronizing can be carried out quite well by anybody who has had a little experience, and also that there is very little danger.

Mr. A. M. PATON: The paper reminds me of a few sentences contained in the preface by Dr. Steinmetz to one of his latest books, to the effect that the future progress in electrical engineering is dependent upon the understanding and control of what he terms "transient electric phenomena"—some of which are discussed in this paper. Incidentally, I should have liked to see in the paper some reference to the genius that Dr. Steinmetz has shown in analysing the very complex transient phenomena which occur in practice. I was interested in the author's statement that on short-circuiting an alternator eddy-current effects have been recorded equal to 24 times the armature reaction. The larger the ratio of the armature reaction to the leakage reactance the higher is the instantaneous value of the short-circuit current; consequently, if I understand the author's statement correctly, the eddy currents may, after they have begun to take effect, reduce the short-circuit current to approximately one-half of its probable value if there were no eddy currents. Could the author indicate under what circumstances this phenomenon might be expected to occur, and in his opinion would there be any practical value in seeking to reproduce the conditions so as to bring the short-circuit current as rapidly as possible to its permanent value, in other words "damp" it? With reference to the external reactance sometimes found necessary for operating alternators in parallel, I believe that the leakage reactance of a modern turbo-alternator is of the order of from 2 to 3 per cent, and that the internal resistance is 1 per cent plus the resistance of the cables connecting the machine to the busbars. From these figures it is quite clear that in order to bring the ratio of the reactance to the resistance up to the 3 or 4 to 1 mentioned by the author, a considerable amount of reactance must be added. The figures mentioned for the additional reactance, namely, 15 per cent and 20 per cent, are considerably higher than those that I have noticed elsewhere, which I think are mostly of the order of from 5 to 10 per cent and which check with those mentioned later in the paper. The latter figures limit the short-circuit current to between 10 and 15 times its full-load value. Are these large reactances mentioned by the author used on many systems? With regard to the suggestion contained near the bottom of page 257, I should like to ask the author whether choke coils have not been successfully used for years to protect transformers from line disturbances of high frequency. I should also like to know whether the author believes that shunted induct-

Mr.
Marshall

Mr. Paton

ance will be necessary on transmission lines in this country. The conditions here are fundamentally different from those in the United States, for two reasons: First, the length of transmission lines in this country will not be such as to necessitate anything like the high voltages which are necessary in America; and secondly, in this North-East district, which is likely to continue to possess the most important electrical transmission system in this country, we are not troubled, or likely to be troubled, with very light loads and the excessive rises of pressure due to the effect of the charging currents at such times.

Mr. E. P. HOLLIS (*in reply*): While there have been in several quarters justifiable reservations, it is evident from the discussion that current-limiting reactances are accepted as offering a solution of a number of power-station problems.

Mr. Hunter has misconstrued one of my remarks with regard to recent developments in the amount of self-induction of generator armatures. That remark was intended to summarize the developments since the introduction of low-speed alternators. In the early 100-cycle machines the armature reaction was less than the self-induction, and the transient short-circuit current was little less than the steady short-circuit current. With the advent of 50-cycle systems it was possible to double the pole pitch, thereby allowing the armature reaction to be doubled, while the self-induction was reduced by subdividing the conductor in a number of slots per pole. In such machines the armature reaction and the self-induction were nearly equal, so that the transient short-circuit current was of the order of twice the steady value. Then came 25-cycle systems, and again the pole pitch and armature reaction were increased. The adoption of higher peripheral speeds in the steam turbo-alternator still further increased the pole pitch and with it the permissible armature reaction, whilst the self-induction remained the same. A large armature reaction necessitated higher field excitation and was followed by developments which made it imperative to design the turbine on more economical lines, with the result that deeper armature slots and higher flux densities were resorted to. The former resulted in an increase in the armature reaction and the latter in a decrease in the self-induction, with the results that have been noted in the paper. That designers have endeavoured to increase the self-induction of modern machines, as Mr. Hunter remarks, is quite true, and is a phase of the question, which is discussed throughout the paper, of a general increase of the self-induction. The voltage asked for by Mr. Hunter is 6,600. The figure for the current was given as an example of the heavy currents that may occur on short-circuit on a typical system.

Together with Mr. Beard, Mr. Gregory, and others, Mr. Hunter raises the question of the shunting of busbar sectioning reactances by the feeder system, and I agree that this is an important matter. Indeed, the introduction of busbar reactances makes it necessary completely to revise the usual methods of laying out busbars, quite apart from whether the reactance would or would not be shunted by the feeder system. The "substantial difference of pressure" to which Mr. Hunter refers would only occur across the terminals of the reactance on short-circuit or when one busbar section was so heavily over-

loaded that it became necessary to draw a supply from another section of the station to cope with the load. I think that Mr. Hunter's fears will not be realized in the majority of cases. Where a pair of feeders on different busbar sections were connected together just outside a power station it would of course be futile to insert busbar reactances. Where, however, the feeders are long and there is a considerable feeder reactance between the two sections of the busbars, the efficiency of the reactances would not materially be interfered with. I cannot agree with Mr. Hunter that the installation of reactances in the power station would largely increase the cost of the transmission system, as the additional lagging current in the cables would be very small indeed. Mr. Hunter says that he does not use special reactances, since he can obtain sufficient reactance in the transformers without additional expense. The reactance coils are, however, intended to protect the generator, and what would be the use of reactance in the transformer for protecting the generator in the event of a short-circuit on the primary of the transformer itself—quite a likely event?

The same purpose is served by insulating the end-turns of transformers as by the use of a special protecting coil, as Mr. Hunter remarks; but it is all a question of advisability, and many engineers are of opinion that the protection should be afforded to the transformer outside, where in the event of a breakdown on the protective device—which after all is the more likely part to fail during the surge—repairs can easily be effected.

The suggestion made by Mr. Hunter that the amount of costly synchronous plant that would have to be installed would prohibit the use of a constant-potential system, is not in my opinion justified. It is the increased expenditure on and the smaller capacity of the line due to reactance drop, which are referred to earlier in Mr. Hunter's remarks, that the constant-potential transmission system is intended to overcome. Transmission lines are very costly, and if the capacity of a transmission line can be increased from 20 to 30 per cent, as it often can be by the use of synchronous machinery, and, if necessary, more reactance, it is frequently possible to show that the installation of synchronous plant is a good paying proposition. I do not, as Mr. Hunter remarks, suggest that reactance coils should be used to protect the end-turns of high-tension induction motors. I merely recorded the fact that they are largely used, and, indeed, are demanded of consumers by some large supply authorities. Most people will agree with Mr. Hunter that the transformer and a low-tension induction motor is the better alternative; but I am sure that Mr. Hunter will know how difficult it is to persuade a customer to go in for the more expensive scheme.

Mr. Gregory deprecates the use of busbar reactances as an additional source of danger and complication. I think this is a matter at which one should be careful to look in its true perspective. In all modern power stations busbars are sectionalized through switches, and it cannot properly be called a complication to insert in the leads such a simple thing as a current-limiting reactance. I doubt whether Mr. Gregory would trouble himself much about the inclusion of another current transformer, which has a far lower factor of safety than a current-limiting reactance.

While objecting to external reactance Mr. Beard is

Mr. Hollis.

Mr. Hollis. quite willing to approve of internal reactance. To that I can only repeat what I said in the paper, that internal reactance does not protect the plant against internal short-circuit when there will be a large influx of power from external sources. This may irretrievably wreck the plant, otherwise, the breakdown being protected from a rush of current from the busbars might have far less serious consequences and the plant could easily be repaired. The amount of room taken up by current-limiting reactances depends entirely upon the type used. The open type certainly takes up considerable space, but the porcelain-clad type is very compact, and the increase in the amount of room which it is necessary to provide becomes negligible. In large power stations it has to be remembered that the switchgear is entirely removed from the engine-room, and that the designer is not so pressed for room as he was previously, so that it is beside the point to lay stress on the extra amount of room taken by reactances.

Mr. Beard inquires as to the effect of a large stray field on surrounding metal-work. It has been found that in a proper installation the effect is negligible. Naturally it is desirable to keep the coils as far away as possible from metal-work, and in practice it is not found difficult to do this satisfactorily.

Mr. Baxter mentions the use of resistance circuit-breakers. Resistance has, however, given place to reactance, owing to the fact that the resistance absorbed a large amount of power and was frequently burnt out.

Mr. Philipp refers to what he calls a new use for reactance coils. In his scheme, however, he is not using reactance coils but auto-transformers.

I am glad to find that the experiences of Mr. Vesey Brown and Mr. Schuil have led them to have confidence in reactance coils. Mr. Vesey Brown's remarks are very much to the point. Money spent on reactance coils is in the nature of insurance, and in these days of penalties a complete failure of supply or the inconvenience of one or two burnt-out generators is a thing to be avoided. I thoroughly agree with Mr. Brown that the number of terms which are used in connection with reactance is very confusing. Still, I do not think there is any chance of reducing the number. In fact I might have used many more. I have, for instance, avoided "capacitance" and others which find their way into technical literature in America. Inductance is of course the easiest thing to talk about, because one does know fairly well what is meant by and what is included in the term "inductance." Then the effect of inductance on a current varies with the frequency, and so we speak of "reactance"; but reactance includes quite a lot of things. The "synchronous reactance" of a generator includes eddy-current effects, armature reaction, the transformer action of the armature current upon the field winding during short-circuit, and so on; while if the resistance were increased due to transient effects it would be difficult to dissociate it from the general term "synchronous reactance." "Impedance" of course includes resistance and capacity effects and is a comprehensive term which includes the whole of the effects that tend to limit or increase the flow of current in a circuit.

In reply to Mr. Wright the disadvantages of adding reactance to transformers are worse regulation, increased losses (especially eddy-current losses), and reduced effi-

ciency. These disadvantages are of course not very serious and are entirely overshadowed by the advantages that are obtainable in certain instances by adding a reasonable amount of reactance. I disposed of the suggestion that fuses might be used in field-coil circuits to blow at about twice the full-load current by pointing out that the rise in pressure in the field due to the breaking of the current might be the cause of serious damage in the field coils. I cannot see that a non-inductive resistance will serve any useful purpose. If it were low it would be a source of considerable inefficiency owing to the amount of current that it shunts, and if it were made high it would not be of very much use.

As I pointed out in the paper, when the star points of all the generators running in the station are earthed, they share the short-circuit current between them, whereas if only one point is earthed, that machine is exposed to the full shock of a short-circuit to earth. Connecting all the neutral points to earth has the advantage that the shock per machine is less, but the aggregate flow of current into the short-circuit is greater.

Naturally, as Mr. Wright suggests, any reactances introduced into circuit-breakers would have to be strong, but all reactances can be made extremely strong and with a very high factor of safety indeed. He has misconstrued that part of the paper in which I recorded that reactance coils were used for synchronizing machines. Those coils are of course only inserted temporarily and are short-circuited after the two machines are paralleled.

Where the size of conductors near a sub-station is reduced in order to dispose of a pressure rise occasioned by the leading capacity current of the line flowing over the line reactance, the conductors are only reduced in size for a short distance near the sub-station. As I explained on the blackboard, although there are points of similarity, there is a material difference in the unbalancing of pressure in a two-phase three-wire system due to the reactance of the motor and the rise in pressure due to a leading current flowing over a reactance. In the two-phase three-wire system the reactance E.M.F. on phase A is 90 degrees out of phase with the impressed E.M.F. and therefore falls into step with the impressed E.M.F. on the second phase B. On the other hand, the reactance E.M.F. on the phase B is 90 degrees out of phase with its impressed E.M.F. and 180 degrees out of phase with the impressed E.M.F. on the first phase A. In consequence, the reactance E.M.F. of phase A is added to the impressed E.M.F. of phase B, but the reactance E.M.F. of phase B is subtracted from the impressed E.M.F. of phase A. There is therefore a difference in pressure between the two sides equal to about twice the reactance E.M.F. of one phase.

Together with several others, Mr. Wright does not appreciate my point that a reactance coil may be called upon to carry a current for several minutes, and, like the others, he directs attention to the fact that if the fault were on a cable protected by the Merz-Price system it would not last that time. This, of course, is quite true, but if the fault occurred in a sub-station, as it often does, and the overload relays failed to act—I could point out many cases in which they have failed to act—the reactance coil might be left in circuit many minutes. After a few seconds the load would decrease to the permanent short-

Hollis, circuit current, and the feeder could be switched out at leisure.

At Mr. Thompson's request I have prepared a diagram (Fig. A) showing how the reactance coils are arranged for a system with two power stations running in parallel. I have assumed that the conditions on such a system are remarkable; that it includes:—

- (a) short feeders for, say, an electrolytic works where the rushes of current are heavy ;
- (b) a transmission line so long that it becomes necessary to add shunted inductance to reduce the rise in pressure towards the end of the line, and also to increase the efficiency of the line ;
- (c) a line which, owing to the drop in pressure due to the reactance of the line, it has been thought advisable to convert to the constant-potential system ;
- (d) two power stations which are rather far apart and where it has been necessary to introduce reactance on underground cables in order to improve the parallel running of the two power stations in the method that I have described ;
- (e) a number of feeders on which the inherent reactance is adequate for current-limiting purposes in the event of a short-circuit in the sub-station. (No amount of inherent reactance in the feeder can protect the generator in the case of a short-circuit near the power station.)

It should be understood that no attempt has been made to include the internal connections in the power station, which need far more consideration than can be given here.

Mr. Thompson was surprised to see that it was immaterial whether steam was on the generators or not in the case of a short-circuit. I gather from his remarks that he has not quite followed what I said. Steam is only switched off as an experiment in order to ascertain what effect that condition had. Of course the speed of the turbine would decrease rapidly in the case of a short-circuit. Like several other speakers Mr. Thompson has not appreciated the difference between the regulation of a machine from the manufacturer's point of view and the regulation of a system with that same machine controlled by means of a voltage regulator and connected to busbars. The very worst regulating machine could be made to give a good regulation by means of the voltage regulator.

Mr. Lovell inquires whether electrostatic condensers have been used for increasing the power factor. Their use has been suggested, but unfortunately they are too costly, and the leading current which they take cannot be adjusted.

Mr. Longmire inquires as to reactance circuit-breakers. In these circuit-breakers the reactance forms part of the device. The amount of reactance that would be used with switches could of course be very high, as the coils are only in circuit for a few moments. How high depends on the rating of the switch, and a 15 per cent reactance could easily be used for this purpose. Beyond this the reduction in current strength is comparatively small. The same speaker compares the figure of 15 per cent suggested by

Durgin and Whitehead with the figure of 6 per cent Mr. Hoile, mentioned by Mr. Hadley ; but Mr. Hadley's figure was for external reactance, and had to be increased by the amount of internal leakage reactance to the machine and transformer. As that might easily have been 5 or 6 per cent for the generator and 3 per cent for the transformer it is quite clear that the total leakage reactance is brought up to 14 or 15 per cent, so that there is not such a difference between the figures as Mr. Longman suggests. Whether the parallel running of the stations of which Mr. Longman speaks can be improved by means of a reactance depends

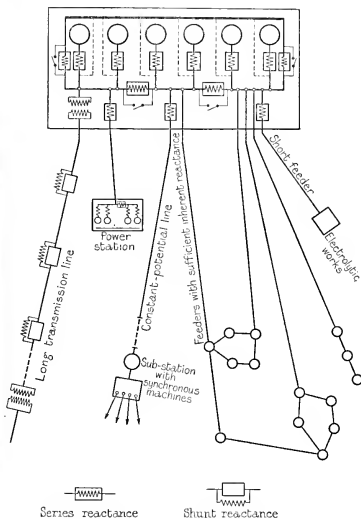

FIG. 4.

entirely upon the amount of resistance that is present between the stations. Of course, if the resistance is very high no amount of reactance can improve the parallel running; but if the resistance is fairly low, but still too high to permit of good parallel running, it would be possible to improve the parallel running by the insertion of reactance in the interconnectors.

The fact to which Mr. Longmuir draws attention, of the breakdown between the turns of regulators due to the charging of electrolytic arresters, is curious, since the electrolytic arrester itself is prescribed for the protection of induction regulators against high-frequency surges. If a generator were connected to a line through an induction regulator, that regulator would take the surges and be exposed to considerable dangers. If, however, it were

Mr. Hollis.

shunted by means of an electrolytic arrester, it would be protected from high-frequency discharges. In Mr. Longman's case the high-frequency currents are set up by the charging of the electrolytic arrester itself, and here reactance is the remedy, for a slight inductance in series with the arrester will have an enormous reactance owing to the high frequency of the currents, and it should entirely damp them out.

Mr. Longman inquires as to the advisability of inserting reactance coils to steady a rapidly fluctuating load. I doubt whether a reactance would be of very much use. A reactance coil would of course be limited in size, since it would not do to lower the power factor of the circuit too much, and I am afraid that the largest reactance permissible would only be sufficient to damp down very rapid kicks: such kicks have very little effect upon generators or overload relays with time limits.

Resistances for choking purposes, as mentioned by Mr. Marshall, could not of course be successfully used, as the drop of pressure across them would be large, and it might be that their effect would be to increase the short-circuit

power rather than to limit it, but not, of course, the Mr. Hollis current.*

In answer to Mr. Paton, it would not be possible to use the eddy-current effect in order to damp down the short-circuit. The effect is a product of the short-circuit current itself, but the time lag between the cause of eddy currents and the reaction that they have upon the armature is unfortunately large, and their full effect is felt too late.

In conclusion I should like to join issue with some of those speakers who have suggested that the question of reactance coils for transmission lines has little interest for us in this country owing to the fact that we have no very long transmission lines here. In my opinion such speakers are taking too parochial a view of the whole question. In this country we are supplying electrical machinery for all parts of the world, and it is our duty to investigate those questions which would enable us to add to our export trade.

TERMS AND DEFINITIONS PROVISIONALLY APPROVED BY THE BRITISH ELECTROTECHNICAL COMMITTEE.

REVISED MARCH, 1914.

Soon after the formation of the International Electrotechnical Commission, the British National Committee appointed a Nomenclature Committee. This Committee proceeded to consider and draft definitions of the electro-technical terms in current use in the English language. After the Committee had been at work for a short time the German National Committee circulated a list of terms in regard to which it was considered by them to be of importance that international agreement should be reached at as early a date as possible. This list formed the basis of discussion of the definitions which were internationally accepted at Berlin last year.

The list proposed for international agreement was very much shorter and less complete than the list which the British Committee was working upon, and in view of this fact the British Committee decided to complete its work on the nomenclature of electrotechnical terms as used in this country, the object being, as far as possible, to record the present usage in this country in regard to terms used in electrotechnical work. The Committee has admitted certain obsolete and obsolescent terms which are met with in electrical literature, but it has not attempted to include neologisms which are not generally recognized. Slight differences of usage in the United States have been recorded.

In many instances the Committee has been guided and assisted by the definitions of the Danish, French, and German committees and by the list of terms and definitions adopted at the Berlin meeting in 1913 of the Nomenclature Committee of the International Electrotechnical Commission.

It is to be noted that the exact wording of some of the definitions does not coincide with that in the Berlin list. This is due to the fact that the intention is to put on record the usage in this country and not to set out what might be agreed upon internationally. It is hoped that the next revision will bring the two lists more nearly into line.

The present list must not be taken as final. The Committee is aware that there is considerable difference of opinion on the exact meaning and interpretation of some of the words, and it is hoped that by circulating the list, suggestions (which should be addressed to the Secretary of the Institution) may be received which will tend to eliminate any errors that may be present and to set up standard definitions which may be definitely accepted in this country.

Absolute. A system of magnitudes is said to be absolute when all the magnitudes of the system can be defined in terms of units adopted as fundamental.

An instrument for absolute measurements is one which can be standardized by means of measurements which involve only the fundamental units.

Accumulator. A reversible electrolytic cell of such a character that the electrical energy supplied to it is converted into chemical energy (a process called Charging).

The chemical energy can be reconverted into electrical energy (a process called Discharging). Sometimes called a storage cell or a secondary cell. Several accumulators connected together in one circuit are sometimes called a storage battery or a secondary battery.

Active Current. Component of the current in phase with the voltage.

Admittance. The reciprocal of impedance. The quotient obtained by dividing the current in a conductor by the electromotive force which produces it.

Air-gap. See Gap.

Alternating Current. An electrical current which alternately reverses its direction around a circuit in a periodic manner. The time occupied by each pair of half-waves is called a Period or Cycle. Abbreviated A.C.

Alteration (A term not recommended). A half period. See Period, Frequency.

Alternator. A generator producing alternating electromotive forces and currents, either single phase or polyphase. An alternator may be described as a single-phase alternator, a two-phase alternator, a three-phase alternator, etc. The exciting current is generally supplied by a separate machine called an exciter. (The word Dynamo is usually reserved for a continuous-current generator.)

Ammeter or Amperemeter. An instrument with a scale graduated in amperes for measuring the value of an electric current.

Ampere. The practical unit of electric current. It is one-tenth of the centimetre-gramme-second (C.G.S.) unit.

Ampere-hour. A practical unit of quantity of electricity. One ampere for one hour, or its equivalent, such as four amperes for fifteen minutes, etc. One ampere-hour is 3,600 coulombs.

Ampere-turn. A practical unit of magnetomotive force. The number of turns or windings of a coil multiplied by the current in amperes which flows through it.

Anion. The ion which is carried to the anode.

Annunciator. An apparatus consisting of a series of devices for indicating which of several circuits is making a call.

Anode. (a) In an electrolytic cell. The conductor through the surface of which the current enters the liquid.

(b) In a primary cell. The metal (usually zinc) through which the current enters the electrolyte.

(c) The terminal by which the current enters a cell or other apparatus such as a vacuum tube, etc.

Antenna. A conductor or system of conductors for the emission or reception of Hertzian waves.

Antikathode. A target hit by the cathode rays in a vacuum tube.

Aperiodic. In an electrical instrument, the motion of the moving part is said to be aperiodic when it does not overshoot the mark on taking up a new position. Must not be confused with Dead Beat. See also Damped.

Apparent Power. In an alternating-current circuit the product of volts and amperes.

Arc. A luminous discharge of electricity through a gas in which the material of one or both the electrodes is volatilized and takes part in the conduction of the current whether continuous or alternating.

Armature (a) of a generator or motor. That part of the machine which consists of active windings, core, and supports, and which is acted upon inductively by the magnetic flux. In the case of a generator it supplies the main current to the terminals; in the case of a motor it receives the main current from the terminals.

Note to (a). In continuous-current machinery the armature usually rotates; in alternating-current machinery it is usually stationary. See Stator, Rotor.

(b) of a permanent magnet. An iron bar for completing the magnetic circuit; sometimes called a keeper. (Originally the pole-pieces attached to a lodestone.)

(c) of a simple electromagnetic mechanism. The movable iron part of the magnetic circuit which is not covered with wire; it is generally set in motion by an electromagnet.

Armouring of a cable. A protective metallic covering of wires or tapes, usually of iron or steel. (Verb: to armour.)

Arrester. An abbreviation. See Lightning Arrester.

Astatic. A system of magnets or coils is said to be astatic when the polarities of its parts are so adjusted that no directive effect is exerted on the system by a uniform magnetic field.

Asynchronous. A term applied to an alternating-current generator or motor the speed of which has no fixed relation to the frequency of the supply.

Auto-transformer. A transformer in which part of the winding is common to both the primary and the secondary circuits; sometimes called a Compensator.

Back Electromotive Force. See Counter Electromotive Force.

Balancer. A motor generator or accumulator used to equalize differences of potential between the different wires of a multiple-wire system.

Ballistic. An instrument in which the period of the moving part is long compared with the time of the duration of the transient force which the instrument is intended to measure.

Bank. A number of similar pieces of apparatus grouped and connected to act together is sometimes called a bank. Thus lamps are banked in parallel or in series, to form a resistance; and several transformers are banked to act as a single transformer.

Barreter. An instrument in which the current to be measured, generally alternating, flows through and heats a fine wire strip or filament, and causes a change in its resistance, from which change the current may be deduced.

Battery. Two or more cells or condensers electrically connected in one circuit.

Bifilar Suspension. The suspension of the moving part of an instrument by two threads, so arranged that the restoring force is mainly produced by gravity.

Bifurcating Box. A box containing the joints between a two-core and two single-core cables.

Blow (verb). When a fuse melts it is sometimes said to

blow, a term suggested, probably, from the result of the melting of a fusible plug in a steam boiler.

Board of Trade. A British Government Department charged with the administration, *inter alia*, of the Electric Lighting and Power Acts, Railway and Tramway Acts, and of regulations made thereunder for the safety of the public, etc.

Board of Trade Unit. One kilowatt-hour. The expression Unit is officially used in Great Britain and not the expression Board of Trade Unit. See Kelvin.

Bolometer. An instrument in which the radiant energy is measured by the alteration of the resistance of a fine wire strip or filament.

Bond for tramway and railway rails. A connector, usually of copper, used for electrically connecting the rails to each other or to a return conductor in order to ensure good conductivity. (Verb: to bond.)

Boom. See Trolley. (U.S. equivalent, Pole.)

Booster. A dynamo, alternator, or transformer, interposed in a circuit for the purpose of increasing or decreasing the electromotive force acting in the circuit.

Bow. A bow-shaped appliance for effecting a sliding electrical connexion between an overhead conductor and an electrically-propelled vehicle.

Braiding. A plaited covering of fibrous material or wire. (Verb: to braid.)

Branch Circuit. A circuit which derives its supply of current from points on another circuit.

B.T.U., B.o.T.U. Abbreviation (not recommended) for Board of Trade Unit.

British Thermal Unit. The quantity of heat required to raise the temperature of one pound of water one degree from 60° F. to 61° F. Abbreviated B.Th.U. (U.S. abbreviation, B.t.u.) See Calorie.

Brush. A conductor for collecting or delivering current from commutators, slip-rings, or other contacts. Originally made of copper wires, afterwards of copper strips, gauze, or carbon blocks.

Brush Discharge. A discharge having a feathery form and consisting of an intermittent partial discharge which takes place from a conductor when the potential difference exceeds a certain limit, but is not high enough to cause the formation of a true spark. It is always accompanied by a hissing or crackling sound.

Brush-holder. The apparatus which holds the brushes.

Brush-rocker. The apparatus which enables the position of all the brushes carried by it to be altered simultaneously in either direction. (U.S. equivalent, Brush-rocker arm.)

B. & S. Abbreviation for Brown and Sharp's wire gauge.

Buckling of accumulator plates. The distortion caused by uneven expansion.

Bus-bar. Abbreviation for omnibus-bar. Conductors (generally on a switchboard and of comparatively large size) to which several mains or feeders or circuits are connected.

Busy-back. An electrical signal transmitted from one telephone exchange to another to indicate that the line wanted is in use. (U.S. equivalent, Busy signal.)

B.W.G. Abbreviation for Birmingham wire gauge.

C.G.S. Abbreviation for Centimetre-gramme-second.

Cable for electrical purposes. A stranded conductor with or without protective covering.

Calibrate. To mark the scale of an instrument, or to adjust the instrument to conform with the scale. (Sometimes used as the equivalent of to verify. Not recommended.)

Calorie. (a) The calorie or gramme calorie (also called the Small Calorie). The quantity of heat required to raise the temperature of one gramme of water one degree Centigrade. Equivalent to 4.2 joules.

(b) The kilo-calorie (also called the Great Calorie) is one thousand calories and is the quantity of heat required to raise the temperature of one kilogram of water one degree Centigrade.

Note.—The value of the calorie depends to some extent on the temperature at which the water is taken, and on the scale of the thermometer employed. The hydrogen thermometer is usually adopted as the standard, and the temperature selected is generally 15° C. or 20° C., or the mean 0° C.–100° C.

Candle-foot. A term not recommended. *See* Foot-candle.

Candle-power. A measure of the luminous intensity of a source of light in a given direction.

Capacity (a) of an accumulator. The quantity of electricity in ampere-hours which may be taken from a cell at a given rate of discharge.

(b) of a condenser. 1. Electrostatic. The capacity of a conductor at an infinite distance from other conductors is the quantity of electricity that must be imparted to it in order to raise its potential from zero to unity, e.g. the capacity of a sphere equals its radius.

2. The self-capacity of an insulated conductor is the charge on the conductor when its potential is unity, all the other conductors in the field being at zero potential. If the position of any of the other conductors is altered, the self-capacity will generally be altered also. Maxwell called this the capacity of the conductor and also the coefficient of self-induction of the conductor for electrostatic charges.

3. The mutual capacity between two insulated conductors when all neighbouring conductors are at zero potential is the induced charge on either of them when connected with the earth, the other being maintained at unit potential.

2 and 3 are also called the capacity coefficients.

4. The capacity between two insulated conductors when all neighbouring conductors are at zero potential is numerically equal to the charge on either of them when the potential between them is unity and they are given equal and opposite charges. This is the capacity in general use by electrical engineers; e.g. the capacity of a concentric main, the capacity between two overhead wires, between two cores of a multicore cable, etc. Many useful formulae for this capacity are known.

(c) of a machine or of a generating station. This use of the word capacity is not recommended. The term Rating should be used.

Carcase of a dynamo, alternator, or motor. The assembled pole-cores, pole-pieces, and yoke or frame. (U.S. equivalent, Body.)

Carcel. The name of a standard oil-lamp, the official standard of ten candle-power used in France.

Cascade. (a) A series connexion of two or more condensers.

(b) A method of electrically connecting induction motors, whereby the secondary of one motor is connected electrically with the primary of the other. Also called Concatenation or Tandem.

Catenary. In railway work. A wire or cable from which electric wires or cables are hung. *See* Messenger.

Cathode. *See* Kathode.

Cell. (a) A source of electrical energy dependent on chemical action; complete in itself.

(b) A receptacle in which electrolysis takes place.

(c) A compartment of a high-pressure cellular switch-board.

(d) A combustion chamber of a dust or refuse destructor.

Characteristic. A curve or graph representing the relation between two magnitudes, which characterizes the behaviour of an apparatus; e.g. the exciting current of a dynamo and the electromotive force generated.

Charge (a) of a conductor. The total quantity of electricity on it.

(b) of an accumulator. *See* Accumulator.

(c) of a condenser. *See* Condenser.

Verb; to charge. The operation by which any apparatus receives a quantity of electricity, part or the whole of which it returns on discharge.

Choking Coil. A coil with so great a self-induction that its impedance depends chiefly on the self-induction rather than upon the resistance. (U.S. generally, Reactance coil.)

Circuit. The conductors connected with a source of electrical supply are collectively called a circuit. When they form a closed path through which a current circulates there is a closed circuit. When the path is not closed and no current circulates there is an open circuit.

Circuit Breaker. A switch which is opened automatically when the current or the pressure exceeds (or falls below) a certain limit, or which can be tripped by hand.

Closed Circuit. *See* Circuit.

Coercive Force. The magnetic force required to annul the residual magnetism of a substance.

Coherer. In wireless telegraphy. A device employed at the receiving end consisting essentially of an imperfect contact, or system of contacts, such that its resistance is altered on the reception of a signal.

Coil. One or more turns of a conductor wound side by side in one or more layers.

Collecting Rail. *See* Conductor rail.

Collector. A sliding piece which makes contact and collects the current from a fixed part of an electrical apparatus or vice versa.

Collector Ring. A ring used for making a sliding connexion between a fixed and a revolving part of an apparatus such as an alternator. *See* Slip-ring.

Commutator. (a) An apparatus for reversing the direction of a current in any circuit.

(b) In a dynamo or motor. A system of conducting bars insulated one from another on which the brushes press and collect or deliver the current.

Compensator. *See* Auto-transformer.

Compound Wound. A generator or motor is said to be compound wound when the magnetic field is excited

- partly by series and partly by shunt coils, or by independently excited coils.
- Concatenation.** See Cascade.
- Concentric Cable.** A cable consisting of two or more separate conductors arranged concentrically with insulation between them. Three conductors so arranged form a triple concentric cable. The external conductor should be called External and not Outer in order to avoid confusion with the outer conductors of a three-wire system.
- Condenser.** An apparatus consisting of two conducting surfaces at a very small distance apart, separated by a dielectric.
- Conductance.** The conductance of a conductor is the quotient of the current by the potential difference between the terminals of the conductor.
- Conductivity.** The conductivity (specific conductance) of a substance is measured by the current which flows parallel to an edge through a unit cube of the substance, when unit difference of potential is maintained between the two faces perpendicular to that edge. The reciprocal is Resistivity.
- Conductor.** A body or substance which permits the passage of electricity.
- Conductor rail.** (Positive or Negative.) A rail employed on electric railways for conducting current to or from the train. The terms Live Rail, Third Rail, Fourth Rail, Collecting Rail, and Working Conductor are not recommended. (U.S., Third Rail almost always used.)
- Conduit System** (a) for electric light and power distribution. A system of bare conductors carried on insulators in a conduit or culvert, generally of concrete.
(b) for wiring. A system of metal or other pipes into which wires are drawn.
(c) for traction. A system of bare conductors carried in a conduit, having an open slot through which a plough makes contact between the conductor rails and the electrical equipment of the car.
(d) for telegraphs and telephones. A group or collection of ways or passages called Ducts into which cables are drawn.
- Consumers' Load Factor.** The number obtained by dividing the actual consumption during a given period by what that consumption would have been had the maximum load reached during that period continued in use throughout the whole of that period.
- Contact.** An electromagnetic, electro-pneumatic, or automatic switch used for controlling heavy current circuits to motors, and which is itself controlled by a master or pilot controller.
- Contact Resistance.** A quality acting like a resistance which appears at the surface of contact between two conductors (e.g. as between brushes and commutator or slip-rings).
- Contact Ring.** A conducting ring for effecting a connexion between a revolving conductor and a fixed conductor as in a crane, a searchlight, a ship's turret.
- Continuous Current.** An electric current in one direction and sensibly steady or free from pulsation. Abbreviated C.C. The term Direct Current is not recommended. (The term Direct Current is much used in U.S.)
- Continuous Running.** Running for such a time, under specified conditions, that the final state is sensibly attained.
- Controller.** A compound or multiple switch containing the means for introducing resistances, or for connecting motors in series or in parallel. It has several steps or positions called Notches, and is intended for use on any notch for an appreciable period of time. It is to be distinguished in this respect from a starting-switch or starter. It is used for varying the speed or power of, as well as for starting, traction or other motors. A master controller, sometimes called a pilot or multiple-unit controller, does not act directly on the current supplied to the motors, but works contactors.
- Converter.** A machine having an armature with a commutator and slip-rings revolving in a magnetic field for converting single or polyphase alternating current into continuous current or vice versa; sometimes called a Rotary Converter. To be distinguished from a transformer, rectifier, or motor generator. (U.S. equivalent, Synchronous converter.)
- Copper-loss.** The total losses in the copper windings.
- Core** (a) of a magnetic circuit. That part which is within the winding. The part outside the winding, if any, is called the Yoke.
(b) of a transformer. The whole of the iron forming the magnetic circuit.
(c) of a cable. The conductor with its insulation or dielectric, not including the mechanically protecting covering. Two, three, or more cores may be laid together to form a twin, three-core, or multi-core cable.
(d) of an arc lamp carbon. The longitudinal filling.
- Corona.** The luminous discharge which appears round a conductor when its potential exceeds a certain value, depending on barometric pressure, the diameter of the conductor, etc.
- Coulomb.** The practical unit of electrical quantity. One coulomb is equivalent to one ampere flowing for one second; 3,600 coulombs equal one ampere-hour. The term Ampere-hour is almost universally adopted; the coulomb is seldom used.
- Counter Electromotive Force** or back electromotive force. An electromotive force which opposes the flow of the current in the circuit.
- Cut-out.** An automatic device for protecting apparatus from damage by overload. The term comprises all the separate parts which, together with their mountings and base, form the complete device, and it includes fuses and circuit breakers.
- Cycle.** A term not recommended as a synonym for period. See Period, Alternating Current. (Used in U.S.)
- Damped.** The motion of a piece of mechanism is said to be damped when any oscillations which may be started rapidly die away. If no oscillations can be produced it is said to be Aperiodic. See Dead Beat.
- Damper.** A special short-circuited winding on the poles of a generator or converter to diminish oscillations.
- Dash-pot.** An appliance for preventing sudden or oscillatory motion of any portion of an apparatus by the friction of air or of a liquid.
- Dead Beat.** An instrument or other mechanism is said

to be dead heat when the oscillatory movement rapidly dies away. To be distinguished from Aperiodic.

Decohere. To restore a coherer to its original state of resistance.

Delta. A mode of connexion in three-phase alternating-current working, in which three windings or pieces of apparatus are so connected that they may be diagrammatically represented by a triangle. A particular form of mesh.

Derived Unit. See Practical Unit.

Diamagnetic. A substance of which the magnetic permeability is less than that of a vacuum (unity).

Dielectric. Any material which offers high resistance to the passage of an electric current.

Dielectric Rigidity or Dielectric Strength. The property of a dielectric to resist the passage of sparks. (In practice, measured in volts per centimetre under specified conditions.)

Direct Current. A term not recommended. See Continuous Current.

Discharge (a) of a condenser. An operation which tends to bring the two conducting surfaces of a condenser to the same potential.

(b) of an accumulator. An operation which tends to bring the two plates of an accumulator to the same potential and which permits the chemical energy to be reconverted into electrical energy and utilized in an outside circuit.

Discriminating Cut-out. A cut-out, usually on a switch-board, for interrupting the circuit when the normal direction of the flow of energy is reversed. (U.S. equivalent, Reverse circuit breaker.)

Disruptive Discharge. The breaking down of a dielectric under electric stress, accompanied by sparking.

Disruptive Voltage. Difference of potential producing a spark discharge.

Distributing Board. A board carrying small bus-bars, used for connecting a number of circuits to a pair of mains. Sometimes called a Distribution Board.

Distributing Mains or Distributor. The conductors which intervene between the feeders and the service lines and which are collectively called the Distributing Network or Low-pressure Network, or the Network.

Diversity Factor. The number obtained by dividing the sum of the maximum load of the individual consumers supplied from any works during a given period by the maximum load delivered from the works during the same period.

Draw-in Box. A box used in connexion with a draw-in system of mains. When complete it contains no links, fuses, or switches, but in some cases permanent joints.

Draw-in System. A system of laying mains in which the cables or wires are drawn into pipes or ducts after the latter have been laid or fixed in position, in such a manner that the cables or wires can be withdrawn at any time without disturbing the pipes or ducts. Draw-in boxes, manholes, or junction boxes are usually provided through which the cables or wires may be drawn in or withdrawn.

Drop (in pressure). Synonym for Fall of Potential.

Drop Signal. See Annunciator.

Ducts. Pipes or blocks perforated with holes through which cables are drawn. Usually non-metallic and set

in concrete. The holes themselves are sometimes called ducts.

Dynamo. A continuous-current generator.

Dynamometer. (a) An instrument for measuring forces. (b) An apparatus for measuring the torque exerted by a prime mover or motor.

(c) An instrument for measuring electric currents depending on the measurement of the electromagnetic forces between two or more coils. (Abbreviation for Electro-dynamometer.)

Ear. In overhead tramway work. A grooved metal fitting riveted over, soldered, or otherwise attached, to a trolley wire for the purpose of—

(a) supporting the wire.

(b) altering the horizontal direction of a trolley wire, then termed a Pull-off Ear.

(c) anchoring a trolley wire.

Earth. (a) An electrical connexion with the earth, intentional or unintentional, is called an Earth. (U.S. equivalent, Ground.)

(b) (Verb : to earth.) To connect any conductor with the general mass of the earth in such a manner as will ensure at all times an immediate and safe discharge of electrical energy. (Board of Trade definition of Efficiently connected with Earth.)

(c) Earth circuit. A circuit of which the earth forms a part.

Earthed Circuit. A circuit one pole of which is earthed at one or more points. (U.S. equivalent, Grounded.)

Earth Rail. See Conductor Rail.

Earth Current. A current induced in a conducting body either by a varying magnetic field or by the body moving relatively to a fixed magnetic field.

Effective Volts. A term not recommended. See Virtual Volts.

Efficiency. 1. In the case of generators, motors, converters, or transformers. The ratio of the total output to the total input; e.g. in the case of a separately excited synchronous generator the excitation power should be added to the power received at the shaft.

2. In the case of accumulators—

(a) The ratio of the amount of energy available during the discharge to the amount of energy required during the charge (Watt-hours).

(b) The ratio of the quantity of electricity available during the discharge to the quantity of electricity required during the charge (Ampere-hours).

E.H.P. Abbreviation for Electrical Horse-power.

Electrocution. A form of capital punishment for criminals by electric shock.

Electrode. A conductor by which an electric current passes into or out of an electrolyte or other substance.

Electro-dynamometer. See Dynamometer.

Electrolysis. The decomposition which takes place when an electric current passes through a chemical compound.

Electrolyte. Any substance which undergoes chemical decomposition by the direct action of an electric current passing through it.

Electrometer. An instrument which utilizes electrostatic forces for the measurement or comparison of differences of potential.

Electromotive Force. That which causes or tends to

cause an electric current. Abbreviated, E.M.F. See Potential, Pressure, Tension, Voltage.

Excitation. (a) Production of the magnetic flux in an electro-magnet by means of an exciting current.

(b) Number of ampere-turns producing the flux.

Note: The excitation may be produced by several windings traversed by different currents.

Exciter. A dynamo used for producing the excitation of the field magnets of another machine. See also Alternator.

Extra Current. An obsolete term. The current during the variable period on closing or opening an inductive circuit.

Extra High Pressure. See Pressure.

Factor of Safety. In mechanics, the ratio of the ultimate breaking stress to the maximum normal working stress.

Farad. In the practical system of units the farad is the unit of electrical capacity. It is inconveniently large, and therefore capacities are usually expressed in microfarads.

Fault. Any local defect in the insulation or continuity of a conductor which may interfere with its use.

Feeder. A conductor for conveying electrical energy from the place where it is generated or transformed to feeding-points or sub-stations. Feeders are not used for supplying consumers directly, owing to the varying pressure along their length.

Feeder Box or Pillar. A box or pillar which may contain switches, links, or fuses for connecting feeders with distributing mains. (U.S. equivalent, Junction box.)

Feeder, Negative. See Return Feeder.

Feeding Point. The junction of a feeder with a network.

Ferro-magnetic. A substance of which the permeability is greater than that of a vacuum (unity). See Paramagnetic.

Field, Electromagnetic. See Field, Magnetic.

Field, Electrostatic. Any region in which there are electric lines of force, as in the space between a positively charged and negatively charged surface.

Field Magnet. Any permanent magnet or electro-magnet employed for the purpose of providing a magnetic field. (It is incorrect to speak of the field magnets of a dynamo or motor as its fields: they should be called its Magnets, if the term field magnets is too long.)

Field, Magnetic. Any region in which there are magnetic lines of force, as in the space between or surrounding the poles of a magnet or within a magnetizing coil. The strength of the field is usually expressed in C.G.S. measure as the number of lines per square centimetre. One line per square centimetre is called a Gauss. See Line and Maxwell.

Figure of Merit. (1) of a galvanometer. (a) The deflexion in millimetres per micro-ampere at a scale distance of one metre when reduced to a period of 10 seconds and a resistance of one ohm.

(b) The current in amperes required to produce a deflexion of one millimetre at a scale distance of one metre. Sometimes expressed as the number of megohms through which one volt will give that deflexion.

(2) of a telegraph instrument. The minimum current necessary to work the instrument with absolute certainty.

Flame Arc. An arc in which the major portion of the

light is given by the flame instead of by the electrodes. (U.S. equivalent, Flaming arc.)

Flashing. (a) Any process of manufacture involving the temporary electrical overheating of a glow lamp filament.

(b) The coating of a glow lamp filament with a layer of carbon by heating it electrically in a hydrocarbon vapour.

Flashing Over. The temporary formation of an arc from brush to brush on a commutator.

Flash Test. The momentary application of a high electrical pressure between two conductors insulated from each other.

Flux. (a) Magnetic. The number of lines of magnetic induction which pass round a magnetic circuit. See Induction.

(b) Photometric. The whole luminous radiation of a beam of light, or the candle-power multiplied by the solid angle of the beam.

(c) Chemical. Material used for reducing or dissolving the oxides of molten metals in casting, soldering, brazing, etc.

Foot-candle. The illumination received from a source of one candle-power falling perpendicularly on a surface at a distance of one foot from the source.

Form Factor. The ratio of the virtual value to the mean value of a periodic function.

Fourth Rail. See Conductor Rail.

Frequency. Reciprocal of the time for a complete period of a periodic quantity. In practice, the Number of Periods per second.

Friction Loss. Loss due to mechanical friction exclusive of windage.

Frog. In tramway overhead work. A fitting uniting two diverging trolley wires with a single wire, (a) provided with a spring tongue, or (b) of the fixed type.

Fuse. The actual wire or strip of metal in a cut-out which is fused by an excessive current.

Galvanometer. An instrument for measuring small electric currents.

Gap, Magnetic Air-. Any gap in a magnetic circuit filled with air or other diamagnetic substance.

Gap, Spark-. Any break in the continuity of a metallic conductor so arranged as to permit of an electric discharge across the break.

Gauge. (a) A general term applied to various kinds of measuring instruments.

(b) The thickness of a plate, or the diameter of a wire, on the inch, millimetre, or on any arbitrary scale.

(c) The distance between the rails of a railway or of a tramway. In the case of a railway it is the distance between the inner sides of the heads of the rails. In the case of a tramway it is the distance between the inside edges of the tread of the rails, i.e. over and including the grooves.

Gauss. A name given to the absolute electromagnetic unit of magnetic force in the C.G.S. system. See Field, Magnetic, and Line.

Generating Set. A combination of a generator and a prime mover.

Generator. A machine for converting mechanical energy into electrical energy. A term including Dynamo and Alternator.

Glow Discharge. A silent discharge of electricity through a gas which causes the gas to have a uniformly luminous appearance or glow, and which does not volatilize the electrodes.

Glow Lamp. A lamp in which the filament or wire is caused by the current to glow or incandescence. A term recommended instead of Incandescent Lamp in order to avoid confusion with the incandescent gas mantle.

Gramme Calorie. See Calorie.

Great Calorie. See Calorie.

Grid. (a) In an accumulator. The framework supporting the active material.

(b) A form of cast or stamped resistance.

Ground. A term used in America having the same meaning as Earth.

Henry. The practical unit of the coefficient of self-induction or of mutual induction in the electromagnetic system.

High Pressure. See Pressure.

High Tension. Term sometimes used for High Pressure.

Homopolar Dynamo or Motor. A dynamo or motor in which the inductive action takes place in a magnetic field or a series of magnetic fields, without change of sign.

Homopolar Induction. A term sometimes applied to the induction which occurs when a conductor is moved through a magnetic field, so as to cut the lines of force in the same direction continuously. Sometimes called Unipolar.

Horse-power. The industrial unit of power. The British horse-power is equivalent to 33,000 foot-pounds per minute or (approximately) 746 watts.

Hot Wire Instrument. An instrument the indication of which depends on the expansion of a wire or wires through which an electric current flows.

Hysteresis. The lagging of the strain behind the stress, which when the material is taken round a complete cycle and brought back to the initial state, involves a dissipation of energy.

Hysteresis Loss. Power dissipated in iron by reason of magnetic hysteresis.

Hysteresis, Magnetic. The tendency by which changes of magnetism lag behind the changes of magnetic force which cause them.

Impedance. The ratio of the electromotive force to the current which is produced by it in a conductor. The term is used with varying or alternating currents.

Incandescent Lamp. See Glow Lamp.

I.H.P. Abbreviation for Indicated Horse-power.

Inductance. (a) Synonym for Coefficient of Self-induction.

(b) The reactance due to self-induction. See Reactance. (Not used in U.S.)

Induction. When an electric or a magnetic force acts, through the ether, upon a body so as to alter its electric or magnetic state, that alteration of state is said to be induced in it, as distinguished from alterations of state communicated to it by conduction or contact. The operation of inducing alteration of state is called Induction. The three chief induced actions are (a) Induced Electrostatic Charge, (b) Induced Magnetism, (c) Induced Electromotive Force.

Induction, Electrostatic. When a body is brought into an electric field, thereby causing an electric charge

or charges to appear on the body, these charges are called Induced Charges, and the operation is called Electrostatic Induction.

Induction, Magnetic. (a) When a mass of iron, etc., is brought into a magnetic field, thereby causing magnetic poles to appear on the mass, these poles are called Induced Poles, and the magnetism so acquired is called Induced Magnetism; and the operation is termed Magnetic Induction.

(b) When a uniform magnetizing force H acts on a medium it produces a flux of induction the density of which is B . Flux of induction is also called Magnetic Flux. The ratio B/H gives the permeability of the medium for the value H . The unit line of magnetic induction (the Maxwell) is called a Magnetic Line.

Induction, Magneto-electric. When a body is subjected to the action of a varying magnetic field, thereby causing electromotive force to be generated in the body, these electromotive forces are called Induced Electromotive Forces, any currents that result in the body are called Induced Currents, and the operation of thus inducing electromotive forces and currents is called Magneto-electric Induction.

Induction Motor. An alternating-current motor in which the secondary part receives its current by magneto-electric induction and not by conduction.

Induction, Mutual. The (magneto-electric) induction exercised between two circuits, whereby the variations of the current in one circuit generate electromotive forces in the other circuit is called Mutual Induction. This mutual relation may be quantitatively expressed by means of a Coefficient of Mutual Induction.

Induction, Mutual, the Coefficient of, is the sum of the effective linkages of the turns of one circuit (the secondary) with the flux due to unit current in the other circuit (the primary). Symbol, M .

Induction, Self. The (magneto-electric) induction exercised upon the turns of a circuit by the current in itself is called Self-induction. It may be quantitatively expressed by means of a Coefficient of Self-induction.

Induction, Self-, the Coefficient of, is the sum of the linkages of flux and current when the current in the coil is unity. The (total) Self-induction of any coil is the product of its Coefficient of Self-induction and the current it is carrying. Symbol, L .

Induction, Unipolar. See Homopolar.

Inductive Capacity, Specific. See Capacity.

Inductive Circuit. A circuit in which the reactive effect of self-induction at the working frequency or at make or break is appreciable compared with its resistance.

Inductive Load. See also Lagging Load. An output at a power factor which by reason of self-induction is less than unity.

Inductive Resistance. A resistance having appreciable self-induction.

Inductor Generator. A generator with stationary field and stationary armature coils and in which masses of iron or inductors by moving past the coils alter the magnetic flux through them.

Inductors. In inductor generators. The masses of iron employed to effect variations of the magnetic flux passing through the armature coils.

Input. The total power received at the shaft or terminals of a machine or apparatus.

(a) Power supplied to a generator or transformer.

(b) Power supplied to the terminals of a motor.

Insulation. A term proposed in place of the expression *Insulation Resistance*.

Insulate (verb). To surround or support a conductor by non-conducting bodies or materials so as to restrict the flow of electricity to the desired path.

Insulation. (a) Process of insulating.

(b) Material employed to insulate.

(c) Quality resulting from the process.

Insulation Resistance. The resistance of the insulation between two conductors or systems of conductors, or between a system of conductors and earth. (Usually expressed in megohms.)

Insulator. (a) Any material which does not appreciably conduct electricity.

(b) An appliance used to insulate and usually to support a conductor.

Integrating Meter. A meter which sums up or integrates the quantity to be measured, with reference to time. See *Watt-hour Meter*.

Intensity. There is an increasing disposition to restrict the use of the word *Intensity* in English physical science to a ratio, the denominator being an area. The older meaning was synonymous with *Strength*.

Intensity of Current. An obsolete expression. It has been replaced by *Strength of Current*.

Intensity of Field, Magnetic. See *Field, Magnetic*.

Intensity of Light. The illuminating power or candle-power of a source of light.

Intensity of Magnetization. The magnetic moment per cubic centimetre.

Intermediate, The. The intermediate or neutral or middle wire or wires of a three-wire or multiple-wire system. (U.S. equivalent, *Neutral*.)

Interpole. An intermediary pole placed between the principal poles of a machine to assist commutation.

Interrupter. Sometimes called *Break*. A mechanism or device used to break the primary circuit of an induction coil.

Ion. An ion is a charged atom or molecule, or a group of atoms or molecules carrying a charge.

Isolating Link. A link used for disconnecting a circuit.

Joule. A unit of heat equivalent to 0.24 calorie, or one watt-second.

Joule Effect. The heating in a conductor by the passage of an electric current through it, and due to the resistance of the conductor.

Kathion. The ion which is carried to the kathode.

Kathode. (a) In an electrolytic cell. The conductor through the surface of which the current leaves the electrolyte.

(b) In a primary cell. The conductor (generally carbon) through which the current leaves the electrolyte.

(c) The electrode by which the current leaves a cell or other apparatus such as a vacuum tube.

Keeper, of a Magnet. An iron bar for completing the magnetic circuit (usually of a permanent magnet). See *Armature*.

Kelvin. A term officially proposed and authorized by the

Board of Trade, May, 1892, but which has not come into common use, for a Kilowatt-hour.

Key. An appliance consisting essentially of a lever carrying a contact or contacts, generally used in signalling and in testing.

Kicking Coil. Name given in U.S. to a Choking Coil used in conjunction with lightning arresters.

Kilowatt. A unit of power. One thousand watts. Equivalent to 1.34 British horse-power (approximately).

K.V.A. Abbreviation for Kilo-volt-ampere, or one thousand volt-amperes.

K.W. Abbreviation for Kilowatt.

Lag. The interval of time or angle by which one event follows another. See *Phase Difference*.

Lagging Current. An alternating current, the phase of which is retarded in time relatively to the impressed electromotive force.

Lagging Load. Any load on a machine or apparatus in which the phase of the current lags behind that of the voltage at the terminals.

Lamination. The division of a mass of material into thin sheets either to prevent eddy currents or to give flexibility. The thin sheets or stampings of iron forming part of a magnetic circuit are often called the laminations.

Lay, in a cable. The pitch or length parallel to the axis of one complete turn in the spiral arrangement of a stranded cable may be expressed (a) as a multiple of the diameter of the layer considered; or (b) as the increase in length of a strand above the length of the cable, expressed as a percentage of the length.

Lead. (a) Of a conductor or pipe. Its direction or run.

(b) Sometimes used as a synonym for a Conductor.

(c) Of an alternating quantity. The interval of time or angle by which one event precedes another. See *Phase Difference*.

Leading Current. An alternating current the phase of which is in advance in time relatively to the impressed electromotive force.

Leakage. (a) The passage of electricity from one conductor to another or to earth, caused by want of perfect insulation.

(b) Magnetic. That part of the magnetic flux which does not follow the path provided for it.

Leakance. The reciprocal of *Insulation*.

Leyden Jar. A condenser in its original form of a jar, generally of glass, having a conducting surface inside and out.

Lightning Arrester. An appliance for protecting electrical apparatus by providing an alternative discharge path.

Limit. A device for giving warning when a predetermined current is exceeded.

Line, Telegraphic. That part of a telegraph, telephone, or railway signalling circuit, whether aerial, underground, or submarine, which does not include the controlling or operating apparatus and the source of power. Used also, collectively, for a group of wires including poles, pipes, junction boxes, etc.

Lines of Force. (a) Magnetic. A line such that the tangent to it at any point represents the direction of the magnetic force at that point.

By convention the magnitude of the magnetic force

at any point is represented by supposing as many magnetic lines of force to be drawn through one square centimetre (situated around the point) as there would be dynes exerted on unit pole if placed at that point. Unit intensity, *i.e.* one dyne per unit pole, or one line per square centimetre is called one Gauss. See Magnetic Flux.

(*b*) **Electrostatic.** A line such that the tangent to it at any point represents the direction of the electric force at that point.

By convention the magnitude of the electric force at any point is represented by supposing as many electrostatic lines of force to be drawn through one square centimetre (situated around the point) as there would be dynes exerted on one unit of positive electricity placed at that point.

Link. A readily removable conductor forming part of a circuit, generally in the form of a flat bar. See Isolating Link.

Linked Switches. Switches linked together mechanically so as to operate simultaneously.

Load. (*a*) Synonym for Output.

(*b*) Synonym for Weight.

Loaded. Telegraph line or cable. A line or cable the self-induction of which has been intentionally increased.

Load Factor. The number obtained by dividing the actual output of a generator or of a whole generating station during a given period by the output if the maximum had been maintained during that period.

Looping-in. Bringing a wire as a loop to and from a terminal to avoid making a T joint.

Loop Test. A method of testing employed to locate a fault in a telegraph or other conductor when it can be arranged to form part of a closed circuit.

Loss, Total. The difference between input and output.

Low Tension. Term sometimes used for Low Voltage.

Magnet Coil, Magnetizing Coil. The winding used to magnetize an electromagnet, such as the field magnet of a dynamo. Sometimes called Field Coil.

Magnet, Permanent. A body which having been magnetized retains a substantial portion of its magnetization.

Magnet Winding. A set of magnet coils.

Magnetic Blow-out. An apparatus so arranged as to produce a magnetic field which breaks the arc formed on opening the circuit.

Magnetic Field. See Field, Magnetic.

Magnetic Flux. The number of magnetic lines which pass through any area is called the Flux through that area. In the case of a magnetic circuit, the number obtained by dividing magnetomotive force by reluctance. Unit, One Line or Maxwell.

Magnetic Flux Density. The number of magnetic lines per square centimetre. The number obtained by multiplying magnetic force by permeability. See Induction, Magnetic.

Magnetic Force. The force at any point in a magnetic field experienced by a unit pole placed at that point, divided by the permeability of the medium; sometimes called Field Intensity or Strength of Field.

Magnetic Line. The unit (*a*) of magnetic flux **B**, or (*b*) magnetic induction **B**. The rate at which the

number of magnetic lines linked with a circuit alters equals the electromotive force induced in the circuit.

Magnetic Permeability. Magnetic conductivity or specific permeance compared with unity (vacuum). The number obtained by dividing magnetic flux-density in a substance by magnetic force.

Magnetic Permeance. Sometimes called Magnetic Conductance. The number obtained by dividing magnetic flux by magnetomotive force.

Magnetic Reluctance. The reciprocal of magnetic permeance (sometimes called Magnetic Resistance, a term not recommended).

Magnetic Reluctivity. Specific magnetic reluctance. The reciprocal of the permeability of a substance.

Magnetic Remanence. Residual flux-density after the magnetizing force has been removed.

Magnetic Resistance. A term not recommended. See Magnetic Reluctance.

Magnetic Susceptibility, or Magnetizability. The number obtained by dividing the intensity of magnetization by the magnetic force producing it.

Magnetizability. See Magnetic Susceptibility.

Magnetization. The process or result of communicating magnetism to a body.

Magnetize. To give a body the properties of a magnet.

Magneto. Contraction for magneto-electric generator. A generator whose field magnets are permanent magnets.

Magnetometer. An instrument for measuring the magnitude and direction of magnetic force.

Magnetomotive Force. That which causes or tends to cause a magnetic flux. The unit is $4\pi/10$ ampere-turns. The industrial unit is the ampere-turn.

Main. Any conductor forming part of a distributing network. The principal conductors are collectively called the Mains. See Feeder and Trunk Main.

Master Controller or Pilot Controller. A controller used in the multiple-unit system of electrification and for the distant control of electric motors. It does not act directly on the current supplied to the motors, but works electromagnetically or other switches called Contactors. These contactors control the motors.

Maximum Demand System. A system for assessing the payment to be made for a supply of electrical energy, composed of two parts, (1) a sum depending on the maximum power supplied during a certain period; and (2) a sum proportional to the energy supplied during that period.

Maxwell. The name given to the magnetic line of force or (*a*) unit of magnetic flux, (*b*) unit of magnetic induction.

Meg-, Mega-. A prefix signifying one million times, *e.g.* megohm, one million ohms; megavolt, one million volts.

Mesh. A mode of connexion in polyphase alternating-current working, in which windings or apparatus are so connected that they may be diagrammatically represented by a closed figure.

Messenger. A name used in America for a wire or cable from which electric wires or cables are hung. Called in railway work a Catenary, in telephone and telegraph work a Suspending Wire.

Mho. A term proposed for the unit of conductance. The reciprocal of the ohm. The conductance of a circuit the resistance of which is one ohm.

Micro-. A prefix signifying one-millionth part; e.g. micro-ampere, one-millionth of an ampere; microfarad, one-millionth of a farad.

Micron. One-millionth of a metre; one-thousandth of a millimetre. Symbol, μ .

Microphone. A device employed at the transmitting end of a telephone circuit, consisting of a contact or system of contacts such that the resistance is altered by the impact of the sound waves.

Midline Wire. The conductor of a three-wire system of supply the potential of which is intermediate between those of the other two. Sometimes called the Intermediate or Neutral.

Mil. One-thousandth of an inch.

Mil, circular. A unit used in America. The area of a circle of which the diameter is one-thousandth of an inch.

Milli-. A prefix signifying one-thousandth part; e.g. milliamper, one-thousandth of an ampere.

Milker. A dynamo used for charging individual cells forming a portion of a battery of accumulators. Sometimes called milking booster.

Mirror Galvanometer. A galvanometer having a mirror attached to the moving part. A beam of light reflected from the mirror is used as a pointer, or the image of a scale is observed in the mirror by means of a telescope.

Moment (a) of a force. The tendency of a force to produce rotation about a point. The product of the magnitude of the force and the length of the perpendicular let fall on its line of action from the point.

(b) of a couple. The product of the magnitude of one of the two equal forces and the arm or perpendicular distance between them.

(c) of a magnet. The product of the strength of either of the poles of a magnet and the distance between them.

Morse Alphabet. A signalling code in which two different signals arranged in groups of one or more, are used to represent a letter, figure, or symbol.

Motor. A machine for converting electrical energy into mechanical energy.

Motor Generator. A machine consisting of a dynamo or alternator driven by an electric motor, either in the form of two distinct parts coupled together, or having the armature windings on a common core and revolving in a common field. In U.S., where the two component armatures are placed in one and the same field, the machine is called a Dynamotor.

Motor Transformer. A term not recommended. See Transformer.

Mouse Mill. A special continuous-current motor used for running paper strip through a siphon recorder.

Moving-Coil Instrument. A measuring instrument, the indication of which depends on the torque exerted by a magnetic field on a coil through which an electric current passes.

Multicellular voltmeter or electrometer. An instrument in which several pairs of quadrants act on several needles mounted on one axis.

Multiple Phase. Synonym for Polyphase.

Multiple Arc. Synonym for connexion in Parallel. A term not recommended.

Multiple Board. A form of telephone switchboard.

Multiple-Unit System. A system of electric traction in which two or more cars are units in themselves and have their own motors, controlled by electromagnetic or other switches called Contactors. When the cars are coupled together as a train, the contactors can all be worked from a single Master Controller.

Multiplex Telegraphy. A telegraphic system in which several messages generally more than two in both directions can be transmitted on one circuit at the same time.

Multipolar Generator or Motor. A dynamo, alternator, or motor, having more than one pair of magnetic poles.

Mutual Induction. See Induction, Mutual.

Needle. A name originally applied to the moving magnet of a mariner's compass, later to the similar magnet of a galvanometer, and to the paddle-shaped moving conductor of a quadrant electrometer.

Needle Astatic. See Astatic.

Negative. Of the two poles of any source of electricity that one is called Negative which corresponds as far as the direction of the current in the external circuit is concerned to the zinc plate of a Daniell cell.

Network. A system of conductors consisting of mains, feeders, and distributors interconnected for the distribution of electrical energy in a supply system.

Neutral Points on a dynamo commutator. Those points between which there is a maximum electromotive force when the dynamo is running on open circuit.

Nominal Horse-power. An obsolete mode of describing the output of a steam engine in terms of certain of its dimensions.

Non-inductive. (a) **Circuit**. A circuit so arranged that its self-induction is practically negligible.

(b) **Winding**. Two identical insulated conductors laid side by side or twisted together and so connected that a current traversing them in opposite directions generates no sensible magnetic field.

(c) **Load**. Any load on a machine or apparatus in which the current is in phase with the voltage at the terminals.

Ohm. (a) **True**. The unit of resistance in the Practical System of units. The value in the C.G.S. system is equal to 10^9 electromagnetic units.

(b) **International**. The resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.521 grammes in mass, of a constant cross-sectional area and of a length of 106.300 centimetres. (International Conference, 1908, and British Order in Council, 10th January, 1910.)

Ohmmeter. An instrument for measuring electrical resistance by the deflection of a pointer over a scale.

Oil Transformer. A transformer immersed in oil.

Omnibus-bar. See Bus-bar.

Oscillation Circuit. A circuit in which electrical oscillations can freely take place.

Oscillation, Electric. When a system or circuit possessing capacity and self-induction is disturbed from its condition of electrical equilibrium, electric oscillations occur flowing alternately in opposite directions with decreasing amplitude during the return to equilibrium.

Oscillator. A conductor having effectively both self-induction and capacity in which electric oscillations can be set up.

Oscillograph. An apparatus for observing or recording quickly varying currents or potential differences.

Outer. The two conductors of a three-wire system between which there is a maximum voltage are called the outers. A term not recommended as a synonym for the external conductor of a concentric cable.

Output. The power given out—

(a) At the terminals of a generator, converter, or transformer. A synonym for Load.

(b) At the shaft of a motor.

See Rated output.

Over-compounded. A compound-wound generator or motor is said to be over-compounded (a) when the potential difference between its terminals increases with the load, (b) when the speed increases with the load.

Over-load. A load greater than the rated load.

Over-load Circuit Breaker. An automatic switch which opens when a predetermined load is exceeded.

Parallel. (a) Two or more systems of conductors are said to be in parallel in a circuit when the current flowing in the circuit is divided between the two systems.

(b) Two or more systems of conductors, generators, or motors are said to be connected in parallel when the terminals of the same sign are electrically connected together.

Paramagnetic. A substance of which the magnetic permeability is greater than unity (vacuum).

Paste of an accumulator. The active material of the plates or grids of an accumulator. So called as it is sometimes applied as a moist composition or paste.

Peltier Effect. The liberation or absorption of heat which takes place in a heterogeneous circuit at the joint where an electric current passes from one material to another.

Period, Periodic Time. Any varying quantity which repeats its values regularly at equal time-intervals is said to be periodic, and the time interval of one repetition is called the periodic time or period.

Permanent Magnet. A body which having been magnetized retains a substantial portion of its magnetism.

Permeability. See Magnetic Permeability.

Pernance. See Magnetic Pernance.

Phase. (a) In an operation which recurs harmonically, the stage or state to which the operation has proceeded.

(b) In an operation which recurs harmonically, the fraction of the whole period which has elapsed, measured from some fixed origin.

(c) **Phase difference.** The difference of phase (usually reckoned in time or in angle) between two periodic quantities which vary harmonically and have the same frequency. See Lag.

(d) Each of the circuits of a polyphase apparatus is sometimes called a phase.

(e) **Single-phase.** A supply is said to be single-phase when it consists of a single alternating current.

(f) **Two-phase.** A supply is said to be two-phase when it consists of two alternating currents which are displaced with regard to one another by one-quarter of

a period. In U.S. Quarter-phase is often used in place of Two-phase.

(g) **Three-phase.** A supply is said to be three-phase when it consists of three alternating currents displaced with regard to one another by one-third of a period.

(h) **Polyphase.** A supply is said to be polyphase when it consists of alternating currents displaced in phase with regard to one another by equal portions of a period.

Phase-angle. The angle between two vectors representing two simple harmonic periodic quantities having the same frequency but differing in phase from one another, e.g. the vectors representing alternating voltage and the current produced by it.

Extended meaning. The angle between any two vectors which represent quantities having the same fundamental frequency.

Phasemeter. Apparatus for measuring the difference of phase between two periodic electric quantities of the same frequency.

Photoelectric Effects. Any changes in the electrical properties of a body produced by the action of light, e.g. generation of electromotive force, change of resistance, or loss of charge.

Piezoelectric Effect. The production of electrification by mechanical pressure.

Pile. (a) **Thermo-electric.** A source of electrical energy due to the direct transformation of heat into electrical energy, generally consisting of a series of thermo-junctions.

(b) **Voltaic.** An obsolete synonym for a Battery of Cells.

Pilot Wire. (a) A wire used for measuring the voltage at a distant part of a network.

(b) In a multiple-unit system, a wire used between the master controller and a contactor.

Plant. A collective term including various machines, equipment, and apparatus used together for any purpose.

Plated Plates. Accumulator plates prepared by electrolytic action on lead in acid.

Plough. An appliance for effecting a sliding electrical connexion between the conductors of a conduit system and the electric equipment of a car.

Plug Contact. A slightly conical or screwed metal plug for making electrical contact between two conductors, conducting bars or blocks, or between the bars or blocks and the plug.

Point. In wiring. The termination of the wiring for attachment to the fitting for one or more lamps or other consuming devices.

Polarity. A quality of a body in virtue of which certain characteristic properties are manifested at points called Poles.

Polarization. A condition set up in a battery or electrolytic cell as a result of the passage of a current and which manifests itself by a counter electromotive force.

Pole (a) of a cell. Synonym for the Terminal or the accessible part of an electrode.

(b) of a magnet. Points towards which lines of force converge, or at which the resultant magnetic force may be considered to act.

- (c) of an arc. The extremity of each of the electrodes between which the arc burns.
- Pole-piece.** Any specially shaped piece of magnetic material forming a polar extension, and in the case of a generator or motor, facing the armature.
- Polyphase.** See Phase.
- Positive.** Of the two poles of any source of electricity, that one is called Positive which corresponds as far as the direction of the current in the external circuit is concerned to the copper plate of a Daniell cell.
- Potential, Difference of (a) Electric.** A difference of potential exists between any two points if energy is expended or acquired in moving a unit of electricity from one point to the other. In practice measured by a voltmeter.
- (b) **Magnetic.** A difference of potential exists between any two points if energy is expended or acquired in moving a unit magnetic pole from one point to the other.
- Potentiometer.** An instrument for measuring electrical quantities depending in principle on balancing an unknown difference of potential against a known fall of potential obtained by the passage of a current through an adjustable resistance.
- Power.** The rate of doing work. Units, the Watt, Kilowatt, and Horse-power. See Watt.
- Power Factor.** The ratio of the watts to the volt-amperes. In the case of voltage and current of sine form the power factor is $\cos \phi$.
- Practical Units.** Some of the units of the centimetre-gramme-second or C.G.S. system are inconveniently large or small for practical purposes, and therefore certain practical units have been chosen, which are made some decimal multiple or sub-multiple of the corresponding units. Thus, the ampere is one-tenth and the volt is one hundred million times the C.G.S. unit (electromagnetic) of current and the C.G.S. unit of electromotive force respectively.
- Pressure.** Often used as a synonym for Voltage, Electromotive Force, Difference of Potential.
- Primary (a) Cell or Battery.** See Cell, in contradistinction to a secondary battery or an accumulator.
- (b) of a transformer. That winding of a transformer to which electrical energy is supplied.
- Pull-off.** See Ear.
- Pulsating Current or Pulsatory Current.** A unidirectional current which varies in some periodic or quasi-periodic manner.
- Pyrometer.** An instrument for measuring temperatures higher than those measurable by an ordinary thermometer.
- Quadrant Electrometer.** A measuring instrument consisting of a moving vane or needle placed within or near four quadrants, the electrostatic forces between the fixed quadrants and the moving needle producing the deflexion.
- Quadruplex Telegraphy.** The method in telegraphy in which four messages are sent simultaneously, two in each direction.
- Quantity (a) of electricity.** The product of current and time. Units, Coulomb and Ampere-hour.
- (b) Obsolete term for the strength of a current as distinguished from the intensity of the battery which furnishes the current.
- R.M.S.** Abbreviation for root-mean-square.
- Rail, Live, Third, Fourth.** See Conductor Rail.
- Rated Load or Output (of generators and motors).** The output which generators or motors are intended to produce under specified conditions.
- Rating of generators, motors, accumulators, etc.** The designation of the proposed output under the specified conditions, such as continuous working or intermittent working.
- Ratio of Transformer, Ratio of Transformation.** The number obtained by dividing the primary volts or amperes by the secondary volts or amperes in voltage and in current transformers respectively. The number is not quite constant, and depends to some extent on the conditions.
- Reactance.** That component of impedance which is not caused by resistance.
- Reactive Current.** The component of the current in quadrature with the voltage.
- Reactive Power.** In an alternating-current circuit, the product obtained by multiplying the volt-amperes into the sine of the angle of phase-difference between the current and the potential difference.
- Reactive Voltage.** The product of reactance and current.
- Receiver, Telephone.** That part of the telephone apparatus which reproduces the sounds.
- Recorder.** Any apparatus which makes a permanent record.
- Rectifier.** An apparatus which converts an alternating current into a unidirectional current.
- Rectify, To.** To convert an alternating current into a unidirectional current approaching more or less to a continuous current.
- Regulation (a) of a generator.** The variation (up or down) of pressure between no load and full load under specified conditions.
- Special meaning.* The percentage rise in pressure when full load is removed from a generator, the speed and excitation being kept constant.
- (b) of a motor. The variation (up or down) of the speed between no load and full load under specified conditions, usually constant supply voltage.
- (c) Telegraph and overhead wire-work. The equilibrium of wires on a span.
- Relay.** An apparatus for opening or closing a circuit, controlled by the current in another circuit.
- Reluctance.** See Magnetic Reluctance.
- Reluctivity.** See Magnetic Reluctivity.
- Remanence.** See Magnetic Remanence.
- Remote Control.** The controlling of apparatus and plant from a distance, e.g. the operation of the main switches from a switchboard at a distance from them.
- Residual Magnetism.** The magnetism remaining after the magnetizing force has been removed.
- Resistance. (a)** That property of a substance or body which causes in it a dissipation of electrical energy as heat when a current flows through it.
- (b) The resistance of a conductor is the quotient of the potential difference between the terminals of the conductor by the current, usually expressed in ohms.

Resistance, Magnetic. See Magnetic Reluctance.

Resistance, Specific. See Resistivity.

Resistivity. The resistivity (specific resistance) of a substance is the reciprocal of the Conductivity.

Resonance. A circuit is said to be in resonance when the oscillations produced in it have the frequency of the natural oscillations in the circuit.

Retentivity. A synonym for Coercive Force.

Return Feeder. In electric traction. The conductor conveying electric current from the rails to sub-stations or to the generating station.

Reverse Current Breaker. A circuit breaker which is opened automatically when the direction of the current is reversed.

Reverse Current Relay. A relay which is only operated by a current in one direction.

Rheostat. A readily adjustable resistance.

Rotary Converter. See Converter.

Rotor. That part of an alternating-current generator or motor, whether armature or field magnet, which rotates.

Ruhmkorff Coil. A kind of transformer used for producing high electromotive forces, consisting of a primary and a secondary winding on a straight core. The primary is supplied with a continuous current which is periodically interrupted.

Running Light (of a generator, converter, or transformer). Running when no appreciable current is delivered to the external circuit.

(of a motor). Running when no power is delivered at the shaft.

Safety, Factor of. See Factor.

Sag of a wire. The maximum vertical distance between a wire and the straight line joining the points from which it is suspended.

Secondary of a transformer. See Secondary Winding.

Secondary Battery. See Accumulator.

Secondary Winding of a transformer. The winding in which the electromotive force is generated by electromagnetic induction and from which electrical energy is supplied to the external circuit.

Section Insulator. An insulator by means of which a conductor is divided electrically into sections while maintaining mechanical continuity.

Section Switch. A switch for electrical disconnection of a circuit into sections.

Selector Switch. A switch for connecting a circuit to any one of a number of other circuits.

Self-induction, Coefficient of. See Induction, Self.

Sensibility or Sensitivity. See Figure of Merit.

Series. Two or more conductors are said to be in series when they are so connected that they are traversed by the same current.

Series Dynamo. A dynamo in which the field magnet coils are in series with the armature.

Series Parallel. (a) A number of pieces of apparatus are connected in Parallel and the groups so formed are connected in Series.

(b) A number of pieces of apparatus are connected in Series and the groups so formed are connected in Parallel. In U.S. it is common to call (b) Parallel Series in order to distinguish it from (a).

Series-Parallel Connection. Pieces of apparatus are connected either in series or parallel with arrangements

for changing over from one set of connexions to the other.

Series-Parallel Controller. A device for making Series-Parallel Connexion.

Short. A colloquial abbreviation for a Short-circuit or for the act of making a Short-circuit.

Short-circuit. A connexion, whether accidental or intentional, between two points in a circuit, by means of a path having a low resistance.

Short-circuited Rotor. A rotor which is short-circuited in itself. See Squirrel-cage.

Shoe. An appliance for effecting a sliding connexion between a conductor rail of an electric railway and the electrical equipment of a car.

Shunt. (a) Circuits are said to be in shunt or in parallel one to the other when a current is divided between them.

(b) A by-path for an electric current.

(c) Shunt circuit is a term applied to the pressure circuit of measuring instruments such as electricity energy meters, wattmeters, etc.

(d) A current shunt is a term applied to a low resistance used for the measurement of currents by means of a potentiometer; or by an ammeter through which only a fraction of the current passes.

Shunt Coil or Winding. A coil or winding which is connected in shunt or parallel to some part of the circuit.

In a generator or motor. The field magnet coils of a shunt dynamo or motor, these coils being excited by a current practically proportional to the pressure.

Shunt Dynamo. A dynamo in which the field magnet coils are connected to the terminals in shunt.

Shunt Instrument. An instrument in which all but a fraction of the current to be measured is passed through a resistance connected in parallel with the measuring instrument.

Shunt Motor. A motor in which the field magnet coils are connected to the terminals in shunt.

Shuttle or Siemens Armature. An early form of armature for a generator or motor, resembling a shuttle, and having a single coil and two core faces. Sometimes called an H armature.

Siemens Dynamometer. An instrument for measuring currents, either continuous or alternating, consisting of a fixed coil and a suspended coil controlled by a spring, the torsion of the spring being proportional to the square of the current when the coils are brought back to their initial relative positions.

Siemens Unit of Resistance. The resistance of a column of mercury of a sectional area of one square millimetre and of a length of one metre, at 0°C.

Silver Voltmeter. An apparatus for measuring a quantity of electricity by the weight of silver deposited on a platinum cathode from a solution of silver nitrate.

Simplex. A method of telegraphic working in which only a single message is transmitted at one time.

Single-phase. See Phase.

Single-Pole Switch. A switch which opens a circuit at one point only.

Siphon Recorder. An apparatus used in submarine telegraphy consisting of a magnetic field in which a

moving coil makes a record of the signals by means of a siphon acting as a pen.

Skate. An appliance for effecting a sliding electrical connexion between the studs of a surface contact system and the electrical equipment of a car.

Slide Wire. In a measuring instrument a wire of uniform resistance on which a sliding contact makes connexion at any desired point.

Slip. In an induction motor the angular velocity of the rotor is less than that of the rotating magnetic field of the stator, and this difference expressed as a fraction of percentage of the angular velocity of the rotating magnetic field is called the slip. The use of the word Slip to express the mere difference of angular velocities is not recommended.

Slipper Brake. A brake in which a block or slipper is pressed against the rails of a tramway. Also called a Track Brake.

Slip-ring. A conducting ring for effecting, by means of a brush, a sliding connexion between a revolving conductor and a fixed conductor. See Collector ring.

Slot System. See Conduit System for traction.

Slotted Core. An armature core of a generator or motor having slots in the iron in which conductors are placed.

Smooth Core. An armature core of a generator or motor on the surface of which conductors are laid.

Socket, Lamp-. Synonym for Lampholder.

Solenoid. A coil of tubular form for producing a magnetic field.

Sole Plate (tramway). A plate or piece of rail fastened below a rail joint for strengthening and anchoring it.

Sounder. A telegraphic receiving instrument producing audible signals.

Spacing Current. In telegraphy a current used to produce the space between the signals, flowing generally in the reverse direction to the signalling currents.

Span Wire Construction. A mode of supporting a trolley wire by transverse span wires stretched between poles or buildings.

Spark (electrical). A disruptive discharge of electricity through a dielectric.

Spark-gap. Any break in the continuity of a conductor so arranged as to permit of a disruptive discharge across the break.

Specific. Pertaining to or characteristic of a substance; e.g. the specific resistance of a given material is the resistance between the opposite faces of a cube of that material whose edge is one centimetre.

Squirrel-cage. A winding used on induction motors which consists of a number of bars, the ends of which are short-circuited.

Standard (noun). A thing serving as a basis of comparison. Such as a weight or measure to which others conform or by which the accuracy of other weights or measures is judged. See also Unit.

Standard Candle. Formerly used in photometry. A sperm candle weighing one-sixth of a pound, intended to burn 120 grains per hour.

Standard Candle (International). Unit of light. One-tenth of the light given horizontally by the Standard Ten-candle Pentane lamp under specified conditions.

In U.S. the Standard is maintained through the

medium of a group of selected incandescent lamps at the Bureau of Standards in Washington.

Standards, Electrical. British Board of Trade. See also Units, International. Resistance, the one-ohm coil of wire. Current, the one-ampere balance. Potential difference, the 100-volt electrometer.

Standard Lamp (electrical fittings). A lamp to stand on a table or floor. Lamp-standard, a pillar supporting a street lamp.

Star. A mode of connexion in polyphase alternating-current working, in which three or more conductors meet at a common junction called the neutral point. When there are only three conductors, also called a Y connexion.

Static. (1) Pertaining to electricity at rest. Abbreviation for Electrostatic. (2) Sometimes applied to a transformer, to distinguish it from a converter. Not recommended.

Stator. In an alternating-current generator or motor, the winding and associated iron, whether acting as armature or as field magnet, which does not rotate.

Storage Battery. See Accumulator.

Striae. In an electric discharge through a gas, alternate dark and luminous transverse bands.

Stud (tramway). A piece of metal or apparatus from which the current is collected, laid down in the street between the rails of a surface-contact system of traction.

Sub-station. Officially defined in Great Britain as premises in which electrical energy is transformed or converted for the purpose of supply to consumers, if such premises are large enough to admit the entrance of a person after the transforming or converting apparatus is in position. (Thus distinguishing it from a Transformer Box or Chamber.)

Sulphate. of an accumulator. In a lead accumulator the formation on the plates of a sulphate of lead which is inactive and hinders the action of the Cell.

Surface Contact System. A tramway system in which studs normally dead, placed between the rails, become connected to a main only when a car passes over them.

Surge. An abnormal rush of electricity along a conductor.

Surge-impedance. The natural impedance of any long conductor to transmit electric currents or surges, $= \sqrt{L/C}$.

Susceptibility. See Magnetic Susceptibility.

Suspension Wire (Telegraph). Synonym for Messenger Wire.

Switchboard. An assemblage of switches, fuses, conductors, measuring instruments, and other apparatus for the control of electrical machinery and circuits.

Switch Hook (Telephone). The hook on which a receiver is hung. When the receiver is placed on the hook its weight performs certain switching operations.

Synchronism. Two machines are said to be in synchronism when they are running on one system with identical frequency and a definite phase relation.

Synchronize, To. To cause two or more machines or pieces of apparatus to have the same periodic time or frequency and a definite phase relation.

Synchronous Motor. An alternating-current motor which normally runs at the speed corresponding to synchronism with the supply.

Synchroscope. An apparatus intended to indicate

when two alternating potential differences are in synchronism and in phase.

Syn-tonize. To adjust to the same periodic time or frequency. In wireless telegraphy called to **Tune**.

Syphon Recorder. See Siphon Recorder.

Tandem. See Cascade.

Tapper (Wireless). An apparatus which taps a coherer and automatically decoheres it after the receipt of a signal.

Telegraph. An apparatus for transmitting messages to a distance by means of signals.

Telegraph Line. See Line.

Telephone. An apparatus for transmitting sound to a distance.

Telpherage. A system for the electrical transport of goods or materials in self-contained motor-driven receptacles suspended from, and running on, stretched wires.

Temperature Coefficient. The change in the magnitude of any property of a substance caused by a rise of one degree Centigrade in the temperature, expressed as a fraction of the magnitude at some definite temperature adopted as a standard.

Temperature Rise. Of electrical machinery. The increase of temperature of any part of an electrical machine above the temperature of the surrounding atmosphere.

Tension. A synonym for Electromotive Force or Difference of Potential. Obsolete term when used alone.

Tension, High. Synonym sometimes used for High Voltage, or High Pressure. Abbreviation H.T. (Board of Trade limits, 650 to 3,000 volts, whether continuous or alternating.)

Tension, Extra High. Synonym sometimes used for Extra High Voltage or Pressure. Abbreviation E.H.T. (Board of Trade limit, above 3,000 volts, whether continuous or alternating.)

Terminal. That part of an apparatus or circuit to which conductors are intended to be joined in order to connect it electrically to another apparatus or circuit.

Terminal Voltage. See Difference of Potential at the Terminals.

Thermo-couple. A pair of conductors joined to produce a Thermo-electric Effect.

Thermo-electric Effect. The electrical effect due to a difference of temperature between two junctions. Sometimes called Seebeck Effect.

Thermo-pile. Apparatus consisting of thermo-couples suitably arranged.

Third Rail. See Conductor Rail.

Thomson Effect. (a) The electrical effect due to a difference of temperature between two parts of one and the same conductor; (b) the liberation (or absorption) of heat which takes place when current flows from a hotter to a colder portion of the same metal.

Three-phase. See Phase.

Three-phase Transformer. A transformer in which three magnetic circuits have parts in common with one another.

Three-wire System. A system of supply through three wires, in which the potential of the middle wire is intermediate between those of the outer conductors.

Time-constant. When the rate at which a function is diminishing equals the function multiplied by a constant

quantity, the reciprocal of this quantity is called the time-constant. It is equal to the time taken by the function to fall to $1/e$, that is, 36.8 per cent of its initial value.

Total Loss. The difference between input and output.

Transformer. An apparatus without moving parts which by means of electromagnetic induction transforms alternating voltages into alternating voltages of the same frequency, but generally of different magnitude.

Transformer Box or Chamber. A box or chamber containing a transformer and not large enough to admit the entrance of a person after the transformer is in position. (Thus distinguishing it from a Sub-station.)

Transformer, Core Type. A transformer with a closed magnetic circuit in which the copper windings completely or almost completely enclose the iron core.

Transformer, Primary of. See Primary.

Transformer, Secondary of. See Secondary.

Transformer, Shell Type. A transformer with a closed magnetic circuit in which the magnetic circuit completely or almost completely encloses the copper windings.

Translator. A form of telegraphic relay. Also called a Repeater.

Transmitter. That part of a telegraphic or telephonic apparatus by which signals are sent.

Trolley System. A traction system employing cars on each of which is mounted a standard carrying a boom. At the end of the boom is fixed a swivelling trolley head containing a trolley wheel which runs on the trolley wire. When the car is single-decked or has a roof over the upper deck the boom is carried on a base.

Trunk Main (a) in electrical supply. A main used as a feeder between a generating station and a sub-station or between two generating stations.

(b) in telegraphy and telephony. A line consisting of numerous circuits connecting two or more towns or exchange areas.

Tube of Force (Electrostatic Faraday Tube). The unit tube of force is bounded laterally by lines of force which enclose unit charges at its ends. It therefore contains 4π lines of flux.

Tune, To (wireless telegraphy). To adjust to a given periodic time of frequency.

Turns, Ampere-. See Ampere-turn.

Two-phase System. See Phase.

Two-phase Transformer. A transformer for two-phase currents, in which two magnetic circuits have parts in common with one another.

Unifilar Suspension. The suspension of the moving part of an instrument by a single thread or wire or strip, the restoring force being produced by its torsion.

Unipolar. See Homopolar.

Unit (physical). A selected definite physical quantity in terms of which the magnitudes of other physical quantities of a like kind may be reckoned or expressed.

C.G.S. system of units. A system employing the centimetre, the gramme, and the second as the fundamental units.

Electromagnetic primary Units. 1. Unit of Resistance. 2. Unit of Current. 3. Unit of Difference of Potential.

Derived Units. Quantity, Capacity, Self-induction.

Practical Units. See Practical Units.

International Units. The Ohm, Ampere, Volt, and Watt.

Board of Trade Unit. One Kilowatt-hour or Kelvin.

Virtual Ampere. The alternating current which produces the same heating effect as one ampere continuous current. The root-mean-square of the current, sometimes called Effective Ampere. A term not recommended.

Virtual Volt. The alternating electrical pressure which when applied to a non-inductive resistance of one ohm produces one virtual ampere. The root-mean-square of the volts. Sometimes called an Effective Volt. A term not recommended.

Volt. (a) The electrical pressure which when applied steadily to a conductor the resistance of which is one ohm, produces a current of one ampere.

(b) 10^8 C.G.S. electromagnetic units of Electromotive Force.

Voltage. Synonym for Electromotive Force, Difference of Potential and Pressure. Generally used descriptively.

Voltaic Current. An electric current produced by chemical action.

Voltameter. An electrolytic cell arranged for the purpose of measuring an electric current by determining the amount of chemical action produced.

Voltmeter. A measuring instrument with its scale graduated in volts for measuring electromotive force.

Wall Plug. An appliance containing both of the terminals of a twin flexible conductor, generally in the form of two pins (two-pin plug) or a pin and a concentric ring (concentric plug) which, when it is inserted in a wall socket, makes connexion between the flexible conductors and the fixed leads.

Wall Socket or Shoe. An appliance fixed to the wall into which are brought both the leads or conductors connected to a source of supply so that connexion may be made by inserting a wall plug.

Watt. Unit of Power. The energy expended per second by an unvarying current of one ampere under an electric pressure of one volt. With alternating current, the product of the instantaneous amperes into the instantaneous volts gives the instantaneous value of the power. The mean value of this over a whole period is the power in watts. It is equal to 10^7 ergs per second or 1 joule per second. See Kilowatt.

Watt-hour. The total energy expended when electrical energy is expended at the rate of one watt for one hour, or its equivalent, such as 4 watts for 15 minutes. Equal to 3,600 joules.

Watt-hour Meter. An integrating meter for measuring watt-hours. Also called an Energy Meter. The use of the term wattmeter in this connexion is strongly discouraged.

Wattless. When the phase difference between the current and the applied voltage is 90 degrees, the current is said to be Wattless or Reactive. In U.S. a term used by some, but strongly disapproved of by many.

Wattmeter. An instrument with a scale graduated in watts for measuring electrical power.

Weston Cell. A mercury, cadmium-sulphate, cadmium amalgam cell, prepared according to a certain specification, used as a standard of potential difference.

Wheatstone Bridge. A particular arrangement of resistance, galvanometer, and battery as an instrument for the comparison of resistances.

Wheel Base (railway or tramway). The distance between the points of contact of successive wheels of a vehicle with the rails.

Windage. The friction of the air on moving parts of machinery and vehicles.

Winding. All the conductors, turns, or coils belonging to one system.

Yoke. The iron connecting piece between the ends of the core or cores of an electromagnet, which is outside the windings.

No. 234.

ELECTRIFICATION OF RAILWAYS AS AFFECTED BY TRAFFIC CONSIDERATIONS.

By H. W. FIRTH, Member.

(Paper received 19th March, and read before THE INSTITUTION 23rd April, 1914.)

The application of electric traction to any extensive section of any of the large trunk lines of this country is a problem of great complexity. The technical aspects of electric traction from the electrical engineer's point of view have been considered fairly fully both by this Institution and by other engineering societies, but the consideration of traffic questions has not had the attention that it merits.

The electrification of a tube line, or similar property where the whole of the business is of one character, is comparatively simple; but the traffic problems which have to be considered in the case of trunk lines—problems almost, if not entirely, independent of the system of electric traction adopted—are complex and not easy to solve.

The main difficulty arises from the fact that traffics of widely varying character have to be handled over the same rails. The business of a great railway does not consist merely in passenger transportation, but comprises numerous services all of which must be performed as economically and expeditiously as possible, and some of which are more or less conflicting.

There is not only the working of goods trains involving shunting and marshalling, and requiring to be handled over the same roads as passenger services, but there is a very great diversity in passenger business alone. There are:—

1. Ordinary suburban trains, mostly consisting of trains running backwards and forwards on one particular trip regularly.
2. Less-frequent local trains performing journeys to the outer suburban area distant up to, say, 50 miles from the terminus.
3. Main-line express trains making long non-stop runs.
4. Main-line slow trains handling a large amount of parcels and milk traffic in addition to passengers.
5. Special horse-box trains and empty carriage trains.
6. Other varieties of traffic.

All these various classes of trains have to be accommodated on the same line in many cases, and the matter is still further complicated by the fact that in most instances there are branch lines, more or less numerous, having to be served as regards goods, passenger, parcels, horse-box, and other traffic.

The working is rendered more difficult in some cases by being largely seasonal. In the summer-time the seaside or other holiday expresses are more numerous. In some instances the time of maximum pressure of this traffic occurs at or about the same time as that of maximum pressure of suburban business. For London termini, at any rate, it is an important point, and the conjunction of the two maxima, notably about 12.30 p.m. to 1.30 p.m. or 2 p.m. on Saturdays, considerably increases the difficulties.

There are few termini—in London at all events—where sufficient room is available for carriage storage to any large extent, and consequently carriage stock has to be kept at sidings some way out, so that for these holiday expresses (and for other passenger services also) an empty-carriage train has to be run from or to sidings, to or from the terminus as the case may be.

A main-line train also requires more time than others for loading luggage, mails, bicycles, etc., and therefore occupies the platform for a greater length of time than a suburban train.

OPERATION OF TRAINS ON DIFFERENT SERVICES.

A difficulty experienced in the case of local traffic is the fact that rolling stock cannot always be reserved for one service only. A train may have to operate on one trip as a slow train, calling at stations the average distance apart of which is less than one mile, and it may be desirable on other trips to run the same train at a higher maximum speed for considerable non-stop runs.

The widely varying speed characteristics of these ser-

vices render it necessary to give very careful consideration to the motor characteristics and gear ratio, and the author would suggest that the attainment of a more flexible speed characteristic of the motor, either by partially shunting the series field of the ordinary series motor as has been suggested, or by some other means such as separate field control, is very desirable. The former method has been to some extent used, but the latter does not appear to have received the attention from designers which in the opinion of the author it deserves. Mr. R. T. Smith in his recent paper to this Institution² has also drawn attention to this matter as affecting electric locomotive design.

This question of the use of rolling stock in different services is a very important matter for lines having both a heavy suburban business and also a heavy seaside excursion traffic. On summer Sundays and Bank Holidays when the suburban business is greatly reduced, the seaside excursion trains are largely formed by suburban stock, in the first place in order to economize stock generally, and secondly because the great seating capacity of suburban stock lends itself to the satisfactory carrying of such traffic. On some railways the mileage thus run by suburban stock in non-suburban trips is as large as 80,000 or 100,000 miles per annum. Under steam conditions this flexibility in the user of rolling stock is of course easily attained, and any kind of carriage can be handled by any kind of locomotive.

To electrify the whole of the suburban trains may therefore necessitate the provision of spare stock for such trips as those mentioned above, unless the more important sections of the seaside traffic nearest to London are themselves electrified.

The nearer seaside resorts—those 50 or 60 miles from London—are becoming increasingly popular as residential neighbourhoods for London business men, and a large residential traffic is being built up. The conditions mentioned above may in the author's opinion have some weight in causing the electrification of such seaside traffic to be considered.

There are consequently very considerable difficulties owing to the above-mentioned conditions—which are of course merely the routine of railway working—in the provision of adequate accommodation for all classes of traffic at the "rush hours," and the problem is very different from that of handling urban or suburban passenger traffic pure and simple.

The general electrification of long-distance main-line passenger and goods trains has not yet been seriously considered in this country, and in the author's opinion the problem is not at the moment pressing. Under present conditions as to cost of steam and electric working for these particular services, the advantages to be gained by general electrification are apparently not commensurate with the capital expenditure necessary.

It may well be in certain special cases that the electric working of heavy mineral or other traffic over severe gradients will be economically justified, and the electrification of the Shildon section of the North-Eastern Railway where a very heavy mineral traffic is handled may be the forerunner of many similar instances, although, as Mr.

Aspinall and Mr. R. T. Smith have pointed out, the possibility of handling heavier goods trains in this country is considerably limited by the strength of the couplings of traders' wagons.

Whatever the future may bring in this way, the heavy inner suburban and outer suburban passenger traffic in the neighbourhood of London, and the suburban and inter-urban business round other great towns, are at present the main subjects for consideration of those now studying the electrification of steam lines.

DEFINITION OF "INNER SUBURBAN," "OUTER SUBURBAN," AND "MAIN LINE" PASSENGER SERVICES.

There is no hard and fast line of demarcation between these services. A "slow main-line" train may, in the course of a journey of, say, 100 miles, deal with all three kinds of traffic. It is, however, desirable to obtain some basis of description which may be generally used. The term "main-line services" has been used by different authors and speakers for totally different things. The present author is of opinion that the term "main-line traffic" or "main-line service" should be strictly limited to those services serving widely scattered communities quite distinct from each other and having no regular, all-the-year-round, residential, social, or amusement, traffic.

To speak of such services as London-Brighton, London-Clacton, London-Southend as "main-line" is not in the author's opinion correct. They are all services which have—or can be made to have—the characteristics of suburban traffic, *i.e.* a large season-ticket residential business with a flow of traffic largely "up" in the morning and "down" in the evening.

Such services, as has been proved by the three examples given, can even under steam conditions be made to attract large numbers of people, the present tendency being to live further away from town, and particularly so when seaside resorts can be reached comfortably in a journey of, say, under two hours. On the other hand, no augmentation of train service or reduction of fares will induce daily residential travel as between London and, say, Liverpool or York. Mere distance, although an important factor, does not necessarily make any particular service a main-line service from the traffic character point of view. The point that the author would emphasize is that it is the *character* of the traffic which is of importance, not merely the distance.

The author considers that the true main-line business, as above defined, cannot be profitably electrified at present except under exceptional circumstances, but the outer suburban traffic must be carefully considered whatever its length of run, because in many cases there may be great possibilities of obtaining by electrical means a considerably increased revenue, apart from the residential regular daily business, at comparatively small extra cost, especially in the case of seaside resorts with considerable traffic "down" in the morning and "up" in the evening.

It may be of use to state again the outstanding characteristics of steam as against electric operation of trains generally.

Steam traction can handle efficiently and at reasonably low costs, both for operation and fixed charges, a train service of heavy trains even at fairly short headway with stops not very close together. With few stops and an irre-

* R. T. SMITH. Some railway conditions governing electrification. *Journal I.E.E.*, vol. 52, p. 293, 1914.

gular and infrequent train service electric traction cannot show much superiority in operating characteristics; but if the stops are at short distances apart or the service demands great flexibility in seating capacity to meet widely varying passenger numbers, the operating conditions then demand two features which electric traction can give:—

- (1) High acceleration.
- (2) Multiple-unit train formation.

Where the operating conditions, *i.e.* the requirements of traffic, are such as to make these demands, electric traction is the proper means of adequately meeting these requirements, and it then remains to investigate the financial aspects of the change.

FORMATION OF TRAINS AND THE EFFECT ON ELECTRIC WORKING.

Under present conditions not only do the trains on one branch or portion of a system differ in make-up from those on another, but frequently almost every individual train will have a particular formation. Some trains must have dining-car sets, and some must have more than the usual number of brake vans as they deal with special traffic such as mails or milk. The result is that the particular vehicles forming an "up" train due in a terminus at say 4 p.m., most likely cannot form, as might be thought, the 4.30 p.m. "down" train to some other point, even if up to time, as its formation is not suited to the particular requirements. Consequently it has to run out to the car sidings as empty cars, and return to the terminus also as empty cars at some other time for a "down" journey suitable to its formation, or else it has to be split up and re-formed at the car sidings.

There are three results from this:—

1. Low mileage of vehicles in profitable work.
2. Considerable light (unprofitable) mileage and cost of haulage.
3. In congested terminal districts very serious occupation of the limited line accommodation by non-paying car trains to the exclusion of paying passenger trains.

If electrification of this class of traffic takes place, the situation is—financially—more serious. While it is obviously undesirable not to obtain the fullest possible mileage from every car even now, it is impossible to consider installing expensive electric equipment on cars so utilized for only a fraction of the possible time. The use of electric locomotives instead of multiple-unit equipments may be suggested as a remedy for this, but many of the extra suburban services—to places 40 or 50 miles distant—really call for multiple-unit working if the full operating advantages of the electrification of these services—particularly at crowded termini—are to be reaped.

The requirements of different trains, the provision on certain trains of through carriages to different branches, and other similar train-formation problems, are responsible not only for a very low mileage of rolling stock, which implies a very costly equipment of rolling stock for a given seat mileage per annum, but also—and perhaps more important still—for congesting the terminal area with carriage trains which not only cost money to haul backwards and forwards but also prevent the running of paying trains.

The problem of improving this feature of working is not easy of solution, but it is in the author's opinion worth a great deal of study even under present steam conditions, and in some electrification projects may be of almost vital importance. The number of car trains between the terminus and the car sidings compared with the number of passenger main-line trains may be some 80 per cent, *i.e.* if all carriage-train working could be eliminated this section of line could handle 80 per cent more passenger-carrying trains. The solution, if one be possible, must be looked for in two directions:—

1. Standardizing the trains on different services as much as possible.
2. A bold re-timing of trains to eliminate a good proportion of carriage-train working.

Re-timing of suburban trains (using the term "suburban" in its broadest sense of daily season-ticket travel irrespective of distance) is not easy, as the exigencies of business demand the arrival in town of large numbers of people at a more or less fixed time. More flexibility of timing of purely main-line trains can be allowed, but any alteration affects branch services and connections all down the line; although the use of train diagrams enables the whole service to be viewed quickly, the re-timing of the general traffic of an important line is not one to be lightly undertaken.

BUNCHING OF TRAINS.

When once a clear track has been arranged all down the run for an express train leaving a terminus or starting-point at a given time, it is far easier to let two or three more similar expresses follow at a few minutes' interval than to arrange for a similar clear track some time later. There is therefore a tendency—largely for good and sufficient reasons—to run main-line trains in bunches, *i.e.* four or five trains at a few minutes' interval and then none for some time. This leaves the required intervals for pick-up passenger and slow goods trains. Under steam conditions this involves no operating drawbacks as far as the main-line run is concerned, but under electric conditions it would be very bad. Even under steam conditions, however, when we come to terminal working the practice results in giving a bad platform load factor. The re-timing of such bunches of trains would not only relieve the terminal working, but give an improved service of greater regularity to main-line points.

The possibility of such re-timing depends largely on the lay-out of sidings and avoiding tracks where goods or slow passenger trains can be shunted to enable expresses to pass. In the ordinary way a lay-by siding is arranged as a trailing-point connection to the running line. To slow up and then stop a long, heavy, goods train, and then shunt it back into the siding until the engine is clear of the trap points may take as much as 8 or 10 minutes. To enable main-line traffic to be re-timed, many such sidings may have to be converted to facing point sidings, an alteration which it is not always possible to carry out.

USER OF PLATFORMS.

A suburban train can arrive at and depart from any one of a number of platforms, and no difficulty therefore

arises in making an incoming train serve as an outgoing train from the same platform; but with main-line trains the conditions are different. As far as possible important main-line trains must arrive at one of a number of special arrival platforms, alongside, or very near to, cab roads, and cannot easily again be dispatched from the same platform as a "down" passenger train as it is necessary to deal with various requirements, such as the cleaning of the train, the re-stocking and cleaning of dining-cars, and the filling of gas and water tanks. Unless, therefore, the number of platforms is large, compared with the number of entrance roads, so that a considerable time can be allowed in platforms, a considerable mileage of carriage-train working is necessary.

LIMIT OF ELECTRIC ZONE.

The fixing of the limit of the zone in which electric working is to supplant steam traction involves both technical electrical questions and traffic considerations. From the latter standpoint—which is the one that the author is more particularly dealing with in the present paper—it includes the further question of what classes of traffic shall be electrically worked, as well as the distance over which electric working is to take place.

If any satisfactory results from a traffic point of view are to be obtained by electric traction, it appears imperative to electrify at any rate all suburban and local passenger traffic (with the possible exception of some "rush hour" steam trains as mentioned below) within a certain zone in order to standardize the acceleration and schedule speed of these classes of traffic and thus get by uniformity the greatest capacity out of a given line, although it may appear in studying a complicated suburban electrification scheme that some of the smaller services are not sufficiently important or remunerative to warrant electrification from the point of view of the increased revenue possible.

Provided some satisfactory system can be adopted of so sectionalizing the traffic as to ensure at any rate at "rush hours" that traffic on a given line is almost, if not quite, all of the same character as regards acceleration and schedule speed, there seems no good reason at the moment to anticipate the electrification of the main-line business in the congested area. Where, however, it is impossible to prevent a general intermingling of traffic of varying speed characteristics in the densely crowded area, it may be necessary to consider what may be termed terminal electrification, *i.e.* the electric handling of all traffic, whether goods, main-line passenger, or suburban passenger, within a certain zone.

Such a case is very well illustrated by the New York Central Railroad, who have adopted the policy of electrifying all traffic in the congested terminal area.

SIGNALLING.

On a line where all the traffic is of much the same character, where the rates of acceleration and braking are of the same order, and the length of the train unit is fairly regular, a service of trains at very close intervals can be maintained and the block signalling can be designed very closely for the conditions. On stretches of line, however, which have to accommodate at various times high-speed expresses of perhaps 450 tons at 60 or 70 miles per hour, long heavy goods trains 380 or 400 yards in

length, or light suburban or local trains of only a few coaches, the block sections must be so proportioned as to give ample distance, having regard to gradients, curves, junctions, and other features, for the pulling up of the longest and heaviest trains.

As a paper on Electric Signalling has recently been read before the Institution by Mr. H. G. Brown² it is here proposed only to draw attention to some of the more general points in this connection.

Although in parts of the more densely crowded systems the lines are usually doubled or trebled it is a matter of the greatest difficulty to sectionalize the traffic, and although it is possible to some extent to allocate certain lines to certain traffic—some lines for suburban or slow passenger trains, some for fast passenger trains, and some for goods—it is necessary that any line may be capable at any time of receiving the traffic of another line which may be temporarily blocked. Again, the suburban business of at any rate some of the biggest suburban traffic-carrying lines entering London has a comparatively bad load factor. The suburban traffic on the steam lines entering London is very largely a dormitory traffic, heavy "up" traffic for two or three hours in the morning and heavy "down" traffic for two or three hours in the evening, with the worst rush for a very short time on Saturdays between 1 p.m. and 2.30 p.m. or 3 p.m., and consequently suburban traffic overflows to other adjacent main or local lines.

In this connection it may be remarked that the recent Shop Hours Act has added quite appreciably to the troubles of some railway companies by causing a much more general closing of business premises at 1 p.m. on Saturdays, and thus accentuating a peak load with which it was already not easy to deal.

This being so, it is obviously not possible in general to allocate a given line to suburban working pure and simple, and to signal it so that this type of traffic alone shall be accommodated; consequently, even if the lines can be sectionalized so as to keep the varying traffics more or less apart, the lines allocated to suburban business must still be so signalled as to be capable of accommodating other trains.

The shortening of sections is, however, not always so important as the elimination of flat junctions and complicated crossings, and if something can be done in this latter respect a very considerable suburban service can be run (especially where long suburban trains are required for the traffic) while still having signalling capable of passing other kinds of traffic when the suburban rush is over.

The minimum length of block sections is primarily dependent on the distance required for braking, plus a constant (equal to the length of the train), and assuming a length of line not complicated by curves, junctions, etc., the length of block sections will vary as the square of the speed of the trains. Comparing speeds of say 60 miles per hour and 30 miles per hour, in the latter case it is possible to cut up the line into four times as many block sections as in the former case, subject to the constant for the length of train, while the running time for each section is one half. It therefore follows that the frequency of trains is doubled. So that if one can restrict the speed to 30 miles per hour instead of 60 miles per hour, one can

² *Journal I.E.E.*, vol. 52, p. 545, 1914.

nearly double the carrying capacity of a line per unit time at a corresponding sacrifice of the schedule speed.

This may operate in an important way in the case of electrification of a railway where the main-line and suburban passenger trains have to run over the same metals for part of the journey. In many cases such lines near the terminal area are signalled for express speeds, while such speeds cannot be consistently maintained by the main-line trains at busy times owing to the intermingling of suburban trains of lower speed characteristics. The average speed of these main-line trains is therefore in practice not as high as the signalling is capable of allowing for, and the block sections are therefore unnecessarily long.

In the author's opinion there are many lines carrying a dense service of trains of varying speed characteristics over sections originally signalled for high speeds where a speed limit of say 30 or 40 miles per hour on main-line trains would enable a much greater frequency of trains to be operated without reducing the average speed of these main-line trains by more than a small amount.

The same question of the proper adjustment of the length of the block section and the speed of trains applies in cases where two lines converge into one. If properly signalled and graded as to speeds, one line in the busy section where speeds cannot be high may adequately feed two branching sections of line in the outlying area where speeds can be high.

Although these principles are to some extent applied on existing lines, the important benefits of careful and scientific grading of speed have not, so far as the author is aware, been utilized to the full extent, and could in many cases be applied so as materially to increase the capacity of the present lines whether electrically or steam operated.

EFFECT OF CROSSINGS AND FLAT JUNCTIONS ON FREQUENCY OF SERVICE.

One of the most usual difficulties in a general suburban service over a complicated line is the delay of a train at a junction or cross-over from one line to another, and the length of time taken on re-starting to clear the junction or cross-over points. The effect which the high acceleration of an electric train has on shortening the time of crossing, and thus facilitating the clearance of roads for other conflicting trains, is important, but the delay to traffic even in this case is serious.

If the traffic characteristics of any of our big suburban systems be investigated, it will be found that a very large part of the difficulty in getting the trains through, or in getting more trains through, lies in the number of complex junctions and cross-over roads over which the trains serving widely branching systems have usually to run, thus conflicting with other trains.

The number of trains which can be worked over a flat junction depends on many variables, on the speed and length of trains, on the curves and gradients of the converging lines, and on the proportion of the total trains which diverge and therefore cut other trains. As it is difficult to find two junctions where the conditions are the same, every junction must be studied separately in order to arrive at the "junction factor," which is the relation

between the number of trains per hour that can be run over the flat junction and the number possible on a plain road. The fewer the number of trains diverging at the junction in proportion to the total number, the higher the junction factor; but it may be taken that this factor with a fair proportion of splitting of train services on to the two legs of the junction is very rarely as high as 0.8, and in general is more of the order of 0.75. Although a greater service can be worked electrically over such junctions than is possible with steam, the introduction of even one such junction may reduce the capacity of the line, while if many such junctions are present close together the reduction of capacity is almost certain to be serious. In serious cases of complication it will be found that the additional number of trains which can be run even electrically is reduced greatly as compared with the number possible on the plain portions of the line, and often so reduced as to prevent the attainment of an improved service commensurate with the outlay on electrification.

Some lines, like the Great Northern and the London & South-Western, are fortunate in having many flying junctions by which much conflict of trains is avoided, and in these cases the increased train frequency possible with electric traction, owing to superior acceleration, can be taken full advantage of as the "junction factor" of a flying junction is unity, and what is equally important the length of train can therefore be kept within reasonable limits. Where mixed traffic has to be worked over flat junctions it is not possible to have so high a frequency, hence the size of train unit must be increased.

Unfortunately the majority of big terminal systems have grown up gradually, and have developed in ways somewhat unexpected when the lines were originally designed. Additional branches have been connected to the lines, and these connections have in a great number—in fact, in the majority—of cases been laid out as flat junctions where the trains must conflict.

It is futile to spend large sums of money on electrification unless a proportionate increase in service capacity is attained, and in the author's opinion there are numerous cases where electric traction can only be introduced to give its best advantages and to be an economic success if steps be taken to simplify some of these conflicting junctions by means of fly-over lines.

This is particularly the case where trains of different speed characteristics conflict, as where main-line and suburban services have to be intermingled. As a case in point, the electrification of the London & North-Western line has led to the introduction of a burrowing line at Chalk Farm in order to avoid the crossing of Broad-street-Watford trains with Euston main-line services. The amount of work carried out by the District Railway at Earl's Court and elsewhere is also well known. It has also recently been reported in the Press that the London & South-Western Railway is considering the provision of a fly-over between Vauxhall and Waterloo in order to prevent the suburban electric trains intermingling with main-line trains.

In the author's opinion there are many cases where it will be found that the introduction of flying junctions and the consequent simplification of working will enable electric traction to give a satisfactory and paying increase in facilities, where at the present time with flat junctions

the expenditure of capital for electrification would not give a reasonable return.

As the capital cost of electrification (as regards cables, sub-stations, and the contact conductors at any rate) does not vary proportionally to the train frequency, and is broadly speaking of the same order for train frequencies of say 25 or 30 trains per hour, it follows that it is worth while to spend considerable sums of money on any improvements that will enable the train service to be increased, and consequently to enhance the return from a given expenditure on electrical equipment. More especially is this the case where by some increase in the frequency a decrease in the size and weight of the train can be secured, as an increase in the weight of the train is usually of more importance as affecting capital cost than an increase in frequency of lighter trains.

FREQUENCY OF SERVICE AND SIZE OF TRAIN UNIT.

It is axiomatic that a service of electric trains should be as frequent as possible and that the train should be as short (and therefore light) as possible consistent with giving adequate seating accommodation. Assuming of course the same acceleration and retardation in all cases (the retardation of longer trains is usually slightly lower than that of short ones owing to time lag in brake operation, unless electric operation of the air brake be made use of), the shorter the train the shorter the block section can be made; but although this will give great frequency of trains it does not give the greatest seating capacity per hour. For any given schedule speed there is a definite point where an increase in frequency will actually decrease the seating capacity per hour, owing to the increased frequency necessitating shorter block sections and therefore shorter trains in order to give adequate cover between.

With regard to the maximum possible capacity of suburban lines, a number of very interesting German papers have recently been published in which investigations are made into the limits of the carrying capacity of such lines. The following may be referred to as the more important of a large number:—

- PFELL, *Elektrische Kraftbetriebe und Bahnen*, vol. 5, p. 601, 1907.
 BRECHT, *Elektrische Kraftbetriebe und Bahnen*, vol. 6, p. 101, 1908.
 BRECHT, *Elektrische Kraftbetriebe und Bahnen*, vol. 11, p. 220, 1913.
 BRECHT, *Annalen für Gewerbe und Bauwesen*, vol. 65, pp. 93 and 111, 1909.
 BETHGE, *Elektrische Kraftbetriebe und Bahnen*, vol. 11, p. 217, 1913.
 BRUGSCH and BRISKE, *Elektrische Kraftbetriebe und Bahnen*, vol. 11, p. 553, 1913.

On the through sections, i.e. not at junctions or termini, the frequency of trains is governed by the time required for one train to brake, stop at a station, and accelerate clear of the station so as to free the signal, allowing the next train to follow.

Brecht has studied the relation between train length and frequency in respect to carrying capacity, and shows that the longer the train the greater is the capacity per hour, because although longer trains require more time to clear

sections and can therefore not be operated at such frequent intervals, the time required for one train to follow another does not increase in proportion to the length.

Bethge gives a series of curves showing the influence of train length on frequency, and also the influence of varying acceleration in combination with varying train lengths.

Brugsch and Briske show the influence of the speed of the train at the moment of braking on the distance and time required for bringing the train to a stop, and they give the following figures:—

Speed in km. per hr. at moment of braking	60	50	40	30	20	10
Distance required for braking, metres	174	121	77	43	19	5
Time required from passing train-stop of station home signal to bringing train to rest at platform, seconds	41	37	35	34	38	61

Assumed: Length of train, 150 metres;

Deceleration, 0.8 metre per sec. per sec.

This article brings out the influence of the speed of the train at the moment of applying the brakes on the time required for running into a station, and shows that a speed of 30 km. per hour is the most favourable under the conditions assumed. The article proceeds to discuss the possibility of automatically limiting the speed at the moment of applying the brakes, which the author believes was first suggested by Bion J. Arnold for the New York Subway, and shows that by so doing and by the greatest possible refinements of signalling it is theoretically possible to obtain the following results:—

Train length in metres	60	90	120	150
Time interval between trains in seconds	49	55	60	65
Number of trains per hour in each direction, assuming a station stop of 20 seconds	73	65	60	55

Assuming a figure of 5 seats per metre run of train, this gives the following seating capacity per train and per hour:—

Seating capacity per train	300	450	600	750
Seating capacity per hour	21,900	29,250	36,000	41,250

These figures show that the hourly seating capacity of the larger train is greater than that of the smaller ones at the slightly increased frequency which shortening renders possible.

The hourly seating capacity figures given above are apparently the maxima theoretically possible, and are not likely to be attained in practice except perhaps on a new line built specially as a ring or otherwise so as to have no terminals or junctions. They must not be taken as possible figures on existing lines.

On existing lines with flat junctions and terminal stations, with in many cases curves restricting the speed possible, and with heavy gradients and other disabilities, it is not possible to attain such short headway.

With a length of train of about 150 metres the maximum number of trains possible on a line excluding flat junctions

and dead-end termini may safely be assumed as about 40 per hour, and this figure has been given as the possible attainment on the Berlin Stadtbahn in the 1913 paper by Brecht already mentioned, in which an investigation is given into the carrying capacity of terminal stations in relation to the capacity of the free stretches of line. He shows that for a terminus such as is shown in Fig. 1, consisting of two platform roads used alternately, the number of electric trains which it is possible to run at this terminus under working conditions is 33 per hour, compared with the 40 possible on the intermediate sections. The actual numbers will vary in different cases depending on grades, curves, etc., but broadly speaking the proportionate reduction of train numbers is not widely affected. The reduction shown above, viz. from 40 to 33, is the measure of the disability of the terminus. This ratio may be conveniently called the "terminal factor," and in this case is $33/40$ or 0.825.

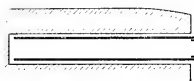

FIG. 1.

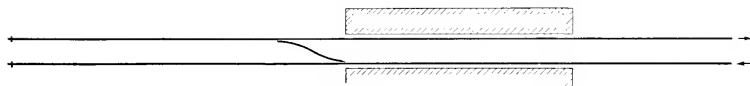

FIG. 2.

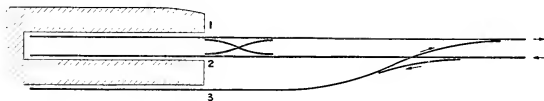

FIG. 3.

The same article compares the relative results with steam working and gives the following figures relating to the Stadtbahn. The possible number of steam trains on the basis of 140-metre trains and an acceleration of 0.22 metre per sec. per sec. on the through sections is given as 32, while the number which can be worked into a terminus such as Fig. 1, is given as 21. The "terminal factor" in this case is $21/32$, i.e. 0.656.

Comparing the numbers on the through sections, viz. 40 electric against 32 steam, the reduction by using steam is 8 in 40, or 1 in 5; but in the terminal working the reduction is from 33 to 21, i.e. 12 in 33, or 1 in 2.75, thus showing the great superiority of electric working over steam for terminal business. This comes about through the requirements of the locomotives. Not only has a locomotive to be attached to the train which has come in, to take it out, but the incoming locomotive has to be detached; and when the train has left, the points for the engine dock have to be operated and this locomotive put in the dock before another train can be accepted.

If the terminal arrangement shown in Fig. 2 can be

adopted, where the crossing takes place not at the entrance to the platforms but beyond them, theoretically the "terminal factor" for electric multiple-unit trains can be made unity, i.e. no limitation of frequency exists; but it requires one more train to perform the schedule, and the shunting increases the number of non-remunerative train-miles.

For an urban line carrying passengers only, the time during which the train is at rest at the platform in Fig. 1 (i.e. not more than the time interval between trains) is sufficient for station purposes, which only amount to unloading and loading passengers and the change of ends by the motorman; but with a trunk-line suburban service there is the requirement of dealing with milk, parcels, mails, etc., and the lay-over given is not always sufficient.

Apart from this the time required for emptying a platform of people arriving by a train governs to some extent the lay-over necessary if the same train is to operate as a passenger train in the reverse direction. In modern rapid-

transit projects separate entrance and exit platforms are sometimes provided, but in dealing with existing termini where the exits of the platforms must be in the majority of cases at the ends of the platforms and therefore limited to not more than the platform width, and dealing with two trains running simultaneously into the two sides of a platform, each train discharging anything up to 1,000 people, it will be found to take 3 or 4 minutes before all these passengers are clear of the barriers.

With a distributed service running through the city where a number of stations are available to serve the business area, the same problem does not arise.

With three platforms in use, as shown in Fig. 3, double the lay-over time is obtained, but this involves one extra train in traffic. In this case the conflicting trains are less frequent, but in the worst case of conflict as between a train leaving platform 3 and one entering platform 1 or 2, the time required to clear is greater, so that it will be usually found that the "terminal factor" for such a lay-out, with the usual allowable curves and platform widths, will be of the same order as that for Fig. 1.

MAXIMUM CAPACITY OF A LINE WITH FLAT JUNCTIONS AND TERMINAL DIFFICULTIES.

Bearing in mind what has been said above, the author is of opinion that with trains of 450 ft. length, 30 per hour in each direction on a double line is about the maximum possible over lines where flat junctions are introduced, and where all the trains at the busy end of the system have to be dealt with in a terminus where it is not possible to extend the platform lines as shown in Fig. 2 beyond the platforms and thus do away with the "terminal factor." In the majority of our big stations this is practically impossible.

Under steam conditions and with the same junction and terminal factors limiting the capacity of the line, it is not economically possible to run on a double road more than 10 trains per hour each way. The size of these trains is, however, in many cases very large, and the number of seats in some cases exceeds 1,000 per train. In the case of Liverpool-street Station (which handles probably the biggest steam suburban passenger business in the world), in one hour, on one pair of roads, 15 trains, having a total seating capacity for one direction of over 13,000 seats, are working in each direction into and out of the terminus.

In considering the replacement by electric trains of a steam service giving a seating rate of 13,000 per hour by 15 trains (an average seating of say 870 per train), it is evident that the size of the train must in any case be considerable.

The maximum frequency of electric trains at the present time is about 42 per hour on the District Railway, with 50 mentioned as a possible development when the Earl's Court flying junctions are fully in use. Assuming 50 per hour, the seating capacity of each train must be 260 in order to obtain a total of 13,000 per hour. The seating capacity of a District or Metropolitan train of usual size (6 cars) is approximately 300 seats, so that on one pair of roads and in each direction 50 ordinary Metropolitan or District trains per hour will only give 15,000 seats per hour, as against 13,000 now provided by steam trains on the Great Eastern Railway and on other lines handling heavy suburban traffic. Thus, although 50 such trains per hour (could they be operated) would give an increased frequency of service to the various branches of the suburban system, only a small increase in the seating capacity would accrue, and as all the steam trains are well filled (the maximum number of people per hour on one line being about 13,000, or almost the same as the number of seats) the seating capacity must be increased in order to provide for the extra business which may be expected to be obtainable.

Over the roads and junctions now existing on any general trunk-line system 50 such trains could not be operated per hour, so that for the solution of problems of this nature a much greater seating capacity per train must be provided at "rush hours" than is usual for electric trains, and hence the capital cost of electrification is considerably increased, as an increase of the weight of the train has a greater effect on the capital cost than an increase of frequency of shorter trains.

Assuming that 30 trains per hour can be run on one line (which in the author's experience is about as high as can be dealt with continuously under the circumstances before-mentioned), the seating capacity per train must be about

435 in order to equal the existing facilities for passenger travel on the steam line quoted above. To give an increase of 33½ per cent in the seating capacity—a very reasonable requirement—a train having in round figures 580 seats must be provided. This means a train, allowing for luggage compartments and motormen's cabs, at least 325 ft. long, weighing, without electrical equipment or passengers, some 160 tons, giving about 3½ seats per ton weight, or 1·8 seats per foot-length of train. The seating capacity of the ordinary side-door compartment cars is higher than that of the end-door type. Various published figures for seating capacity of different trains are available (e.g. *Annalen für Gewerbe und Bauwesen*, vol. 62, p. 227, 1908), and one seat per foot-run of train may be taken as almost exactly the figure for end-door saloon cars such as are used on urban railways generally. The specially wide cross-seat corridor car of the Lancashire & Yorkshire Railway has a seating capacity of 1·62 seats per foot-run.

The side-door compartment cars can be filled and emptied more quickly than end-door cars, and to maintain a frequent service with a short station stop the time of loading and unloading is of very great importance.

The length of time taken by the station stop is one of the most important, if not the most important, of the many factors governing the maximum train frequency. If the station stop be excessive, say more than 30 seconds, the resulting reduction in frequency may be as much as, or more than, that due to a junction, in fact there must be for any given set of general conditions a limiting length of time of station stop, any increase of which nullifies the advantages of the improvements in junctions, etc. The time required for the station stop is affected by many apparently minor considerations. The use of lifts to transport passengers to the trains causes longer station stops than do escalators, as the latter distribute a more regular flow of people. The use of the last possible means to reduce the station stop is justified.

Such devices as train describers, which indicate to passengers exactly which is their train, help in avoiding unnecessary waste of time.

One point in the use of side-door compartment cars which does not appear to have been referred to, so far as the author recollects, is the question of shutting carriage doors of long trains. With the high acceleration of electric working this is no easy matter, a larger staff must therefore be provided to deal with the door shutting, or else longer station stops will have to be allowed.

There are compartment cars with side doors in use for electric trains on the Metropolitan Railway, and on the London, Brighton & South Coast Railway, although the trains are so short that the door-shutting difficulties are not serious. The author has noticed that when the train runs from platforms on the left-hand side of the direction of travel, owing to the high acceleration the doors tend to shut themselves as the train starts, or only require a small push; but where the doors are open in the reverse direction (as must happen with some platforms at terminal stations, or at an island platform on a double line) the difficulty is likely to be very considerable.

The train unit must be so chosen as to be capable of being split up into smaller units for times of lighter traffic, keeping a due proportion of luggage space and accommo-

dation for various classes in each section unit. The facility with which electric multiple-unit trains can be broken up into shorter units and the absence of any engine shunting in such operations is of course well known, but an incidental drawback to this advantage is the necessity of finding more siding accommodation at various points where the trains may require to be split up. This is not an easy or cheap matter in the majority of cases.

In the case of railway systems where some of the

a series of trains which arrive at the terminus before a given time in the morning and by which cheap fares are available. The last of these trains is certain to be overcrowded even if a frequent service be given immediately before.

The curve shows the bad load factor of London suburban traffic. It is the average daily business and does not in fact deal with what is the worst period, Saturday between 1 p.m. and 2.30 p.m. For example, Liverpool-street Station deals with in round figures 200,000 passengers

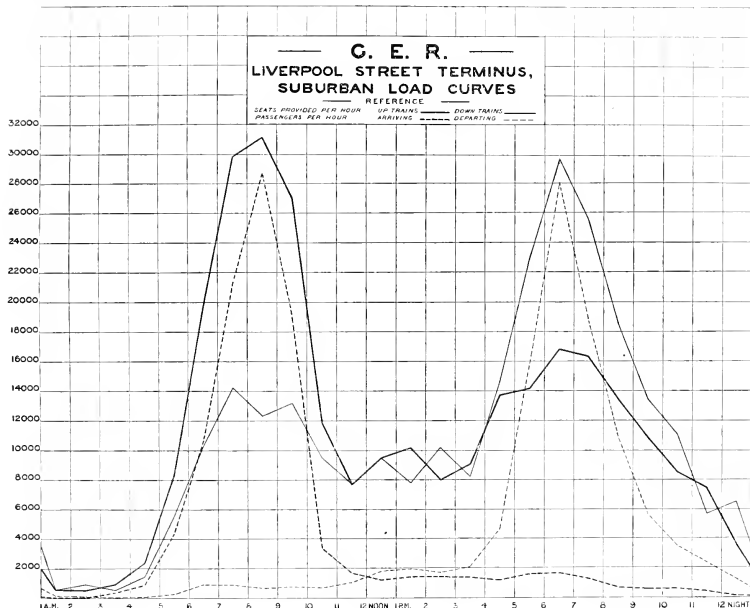

FIG. 4.

suburban stations are termini, the platform roads at such stations can be utilized for the storage of trains at night.

LOAD FACTOR OF LONDON SUBURBAN TRAFFIC.

Fig. 4 shows the week-day suburban passenger traffic of Liverpool-street Station and gives not only the number of passengers per hour but also the seats per hour. It shows incidentally that over a period of one hour a greater number of seats is provided than is required, but it must not be taken from this that there is not some overcrowding of individual trains. Whatever system of traction be employed there are almost certain to be some trains which are overcrowded. This is especially the case with the last of

per day on average week-days, approximately 100,000 arrivals and 100,000 departures, i.e. an average of say 4,150 per hour in one direction; but in the busiest hour, 1 p.m. to 2 p.m. on Saturdays, the number of outward suburban passengers is approximately 36,000, dealt with of course not on one line of rails but to some extent on three. The inward traffic at that time is small and the maximum number of passengers in one hour "up" and "down," main-line and suburban, is about 38,000. The "daily passenger load factor" of Liverpool-street Station is therefore:—

$$\frac{200000 \times 100}{38000 \times 24} = 22 \text{ per cent approximately.}$$

The load factors of other similar termini are of the same order, and in some cases lower.

The importance of load factor in any business is obvious to members of this Institution, a great part of whose difficulties in all branches of the supply of energy for power and lighting is due to poor load factor. Members may rightly claim that the scientific investigation of the subject and the recognition of its vital importance on the economics of any project are to the credit of electrical engineers.

The question of load factor in transportation is one therefore of peculiar interest to this Institution. It may here be mentioned, as showing the wisdom of those responsible for running the motor omnibuses, that the "rush hour" service is not much greater than the service during normal hours. This is excellently brought out in Plate 3 of the Report of the London Traffic Branch of the Board of Trade, 1912, in which a diagram is given comparing the normal and "rush hour" services on the Tubes and the motor omnibuses. The proportion between the number of seats operated by motor omnibuses at times of average traffic and those operated at "rush hours" is roughly 0.9, i.e. the number of seats run at average times is 90 per cent of the number run at peak time. Unfortunately the 1913 Report does not give a corresponding diagram, and the number of motor omnibuses has very largely increased since 1912. The author thinks, however, that the relation between the average and peak seating capacity operated remains much the same. Mere observation shows that the ratio is far higher than in the case of railways. The omnibuses evidently do not lay themselves out to cater for peak-load business.

Suburban passengers fall into two great classes:—

- (1) Season-ticket holders;
- (2) Ordinary passengers;

and the relationship between the numbers of each is an indication of the character of the traffic. Broadly speaking the season-ticket traffic is peak-load traffic, whilst the "non-rush hour" traffic is very largely ordinary ticket passengers. It is this latter traffic which has suffered most severely by road competition, for two reasons:—

1. The poor and infrequent steam service given on some lines at "non-rush hours."
2. The lack of through-running to shopping and amusement centres.

The latter point is of great importance to this class of passenger, but the season-ticket traffic does not feel it to the same degree because it is almost entirely business traffic, and this to a large extent chooses its residential suburb with regard to the convenience of the terminal station to its business centre. It is also of importance to arrive at business at a definite time, and a railway service is more reliable in this respect than road transport.

The "non-rush hour" business is mainly quite different in character, being more of the nature of shopping, theatre, and social traffic, which requires to be carried to various portions of the metropolis, and is not content to be landed at a terminus and have then to take an omnibus or tube when an omnibus can usually be found giving a through-service from the suburb to any portion of London. Further, this traffic is not tied rigidly, like business traffic, to arrival at a definite hour.

It is in this section of the suburban business where trunk railways have lost ground, while the season-ticket business tends steadily to increase.

Some interesting figures are given in the 1913 Report of the London Traffic Branch of the Board of Trade as to the growth of ordinary ticket receipts and season-ticket receipts on the larger railways entering London. These figures show that ordinary ticket receipts have increased from £10,824,897 in 1906 to £11,029,573 in 1912, an increase of 1.9 per cent. Season-ticket figures for the same period have increased from £1,604,198 to £1,865,832, an increase of practically 10 per cent. These figures include all travel on the railways dealt with, and are therefore only a rough guide to the situation.

It is well known, however, and has been referred to by several railway chairmen at company meetings, that the season-ticket receipts have grown while the ordinary ticket receipts from London suburban traffic have actually decreased in many cases.

The return on the investment necessary for electrification must be looked for in the increase of the "non-rush hour" traffic far more than in any further development of the peak, involving greater capital expenditure and worse operating conditions. If the railway traffic which is illustrated in Fig. 4 be electrified, its power demand will be represented by a similar curve and load factor (really rather worse, as car movements will increase the peaks).

Fig. 5 is a curve for Liverpool-street Station showing combined "up" and "down" passenger movements for suburban services, as well as the combined "up" and "down" seats run both in booked passenger trains and in car trains. It emphasizes the very large unremunerative peak of empty car movements which must of necessity be run at "rush hours," and shows how this dormitory business of London employs for two limited periods per day a seating capacity otherwise largely idle, and even during these peaks there is a large amount of light mileage, as the traffic is almost all in one direction and the trains therefore run empty in the other direction.

Let us consider how the electrical engineer would handle a similar load curve in the case of power supply. There is no question that if money is no object it is well to have the most efficient and modern plant for the whole load, but there are many supply businesses where the peak is dealt with by older plant, or older stations, not as efficient or modern as is to be desired for the continuously running plant.

The two methods available for dealing with an electric power-supply load of this nature are:—

1. To increase the load factor by obtaining cooking, heating, and other non-peak load business.
2. To supply the peak by existing plant of comparatively high running cost rather than to install new plant purely to deal with peaks.

The economical way to deal with a traffic problem of the nature shown in the curve appears to depend on precisely similar considerations.

1. THE IMPROVEMENT OF LOAD FACTOR.

The improvement of the load factor of suburban services depends, in the author's opinion, largely in the

possibility of developing through-running; and also on the provision of a frequent and quick service during "non-rush hours," which can be given economically only by electricity.

An interesting experiment in what electrical engineers would call "restricted-hour service" is the institution by the Metropolitan Railway of ladies' season tickets available only after 10.30 a.m. when the morning peak is over.

No doubt something may be done in this direction to improve the passenger load factor in the same way as

It must not be assumed that the excellent results as regards increased traffic that have been shown on some electrified lines can be reproduced in all cases, as in some of these cases the steam all-day service previously given was very irregular, infrequent, and slow. Where, however, efficient all-day steam facilities are given, the same proportionate increase by electrification cannot be looked for. This is balanced, however, by the fact that in those cases (and they are more numerous than some people think) where all day a good steam service is provided, it is only at a very

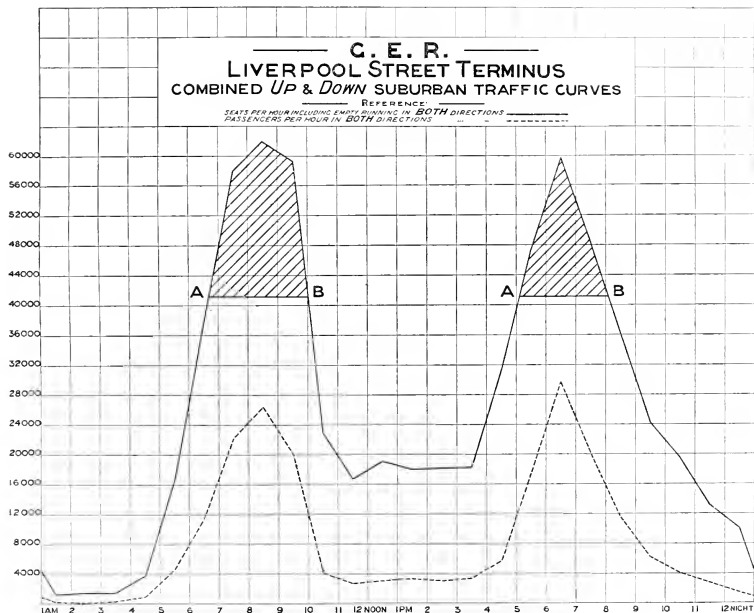

FIG. 5.

electric-supply load factors have been increased by encouraging cooking, heating, and power demands, although the nature of the locality served by the railway may affect the possibilities in this direction.

The author would like to point out that in considering the increased traffic obtainable by electrification, two factors must be considered:—

1. The frequency and convenience of the existing steam "non-rush hour" service.
2. The nature of the business, particularly whether urban or terminal.

high cost of working, and on the whole therefore electrification is likely to show better results, but in this case partly by an increase in the business and partly by a decrease in the operating cost, rather than by an increase of business only.

Where the business is urban in character, or where through-running on to an urban system can be achieved, the increase in all-day business can undoubtedly be made very great by adequate facilities; but where the service is terminal the increase of business obtainable even by an increase of frequency is unlikely to be of quite the same

magnitude. The nature of the district served has also to be very carefully considered in estimating the possibilities of increased traffic. Obviously in a case such as the Liverpool-Southport line, the possibilities of all-day traffic between a large business town and an important seaside residential and pleasure resort with a very eligible residential district throughout the entire route, are enormous and depend simply on an adequate service. The conditions for an electric line are in such cases at their best, and such districts can only be properly served electrically; but the results from a radial line serving a number of purely residential suburbs cannot be expected to be of quite the same order except in certain cases, as, for example, the traffic between London and Crystal Palace, where again there is important all-day traffic to be secured as well as an exceptionally rich residential neighbourhood to be served. In this respect, again, the situation is similar to that of electric power supply where the nature of the district supplied may considerably affect the possible development of off-peak supply.

2. HANDLING THE PEAK BUSINESS WITH CHEAP PLANT.

The broad distinction in operating features between steam and electric traction is that steam is expensive in running costs but cheap in capital charges, while electricity has the reverse characteristics. On heavy peak traffic the electric equipment required cannot save sufficient in operating expenses during the comparatively short user possible to meet the increased capital charges, in exactly the same way as many power stations cannot show a return on the investment required to provide modern plant of high operating efficiency for a peak which does not last long enough to enable these operating savings to offset the increased capital charges.

As steam can deal economically with rushes and electricity economically with steady high-load-factor traffic, the logical solution of a traffic problem such as is presented by the curve in Fig. 5 would appear to be to perform the lower solid part of the curve electrically leaving the peaks to be dealt with by steam.

This solution may at first sight appear impracticable and probably would be so in many cases, but the author is of the opinion that logically it seems to be sound and at any rate is certainly worth investigation in a number of cases. The difficulties are mainly:—

1. Terminal working of locomotives.
2. Combined working of steam "rush hour" trains superimposed on a regular electric service.

It may be stated at once that such a solution could only be considered in the case of a line operating a considerable steam business apart from its suburban traffic. In this case the cost of providing for repairs to the steam plant which might be used for suburban peak business would be small, and the organization of the working might be arranged to fit in with other steam services.

It might not be desirable to operate such a system for a purely suburban railway having no general trunk-line traffic. On a line, say 10 miles long, having only two tracks it would appear to be impossible to work a service like this, but on a radiating system running into a terminus with many platforms the author is of opinion that it appears worthy

of study, more especially in cases where the peak load of main-line business does not normally coincide with that of suburban business, and many of the steam "rush hour" trains might be accommodated on the relief or main lines as they are at present.

It must not be forgotten that "rush hour" suburban business is largely "non-stop"; for example, an "up" morning "rush hour" train often picks up its full load at two or three stations—in some cases only at one station—and then runs through to the terminus giving precisely the best conditions for steam working. In services such as this the superior acceleration of electric trains has not the opportunity of showing much advantage, and the schedule speed of steam trains on such runs not hampered by frequent stops is as good as can be made by electric trains, especially by such electrical equipments as are best fitted by gear-ratio considerations for performing frequent-stop services.

Although the difficulties of working the locomotives would be considerable, they would be no more than they are at present. The electric service being of a regular nature could be quite well worked at the terminus into a very small number of platforms, and the extra carrying capacity given by the electric trains might enable the "rush hour" steam trains to be slightly reduced in length and weight and thus to have better acceleration, or alternatively to be reduced in number. The terminal facilities for a mixed traffic of this nature would of course be greatly improved if the electric trains could be arranged to run through on to urban distributing systems and not to stop at the steam terminus. The handling of the two classes of trains through complicated junctions would be difficult if there were very frequent stoppages (due to signal checks) of the steam trains, as owing to their slow acceleration the latter require a long time to pick up speed again.

The provision of "run round" lines at some points to enable a steam non-stop train to pass an electric train at a station would enormously improve the flexibility of the service and might do a good deal to enable such a combined service to be operated. It would be equally valuable in all-electric services where any of the trains are run non-stop. This solution would seem to be particularly attractive in cases where physical connections with distributing urban lines already exist capable of taking a portion of the traffic large enough to deal with the all-day business.

A very interesting case in point (all steam worked, however, at present) is provided by the London traffic of the Great Northern Railway, which line has a very heavy suburban business. There is a physical connection from the Great Northern Railway just north of King's Cross terminus to the Metropolitan widened lines, which are used by the Great Northern and Midland Railways jointly to Moorgate-street. A study of the Great Northern suburban services will reveal the fact that a more or less steady through-connection between suburban points and Moorgate-street is given, but that the "rush hour" traffic is largely dealt with by trains terminating at King's Cross. The 1913 Report of the London Traffic Branch of the Board of Trade gives the following number of suburban trains arriving in London on to 10.30 a.m.: King's Cross 44, and Moorgate-street (G.N.) 33. The difference between

the two curves of traffic is well illustrated in Fig. 6, Curves 3 and 4.

Probably even under electrification conditions the "rush hour" traffic would be too large to be entirely dealt with to Moorgate-street, but a very attractive, yet cheap, solution in the case of the Great Northern Railway would

schedule on the longer runs as could be provided electrically.

As showing this discrimination between "terminal" and "through" trains even under steam working, the figures for the Great Northern Railway are interesting. In the Report of the London Traffic Branch of the Board

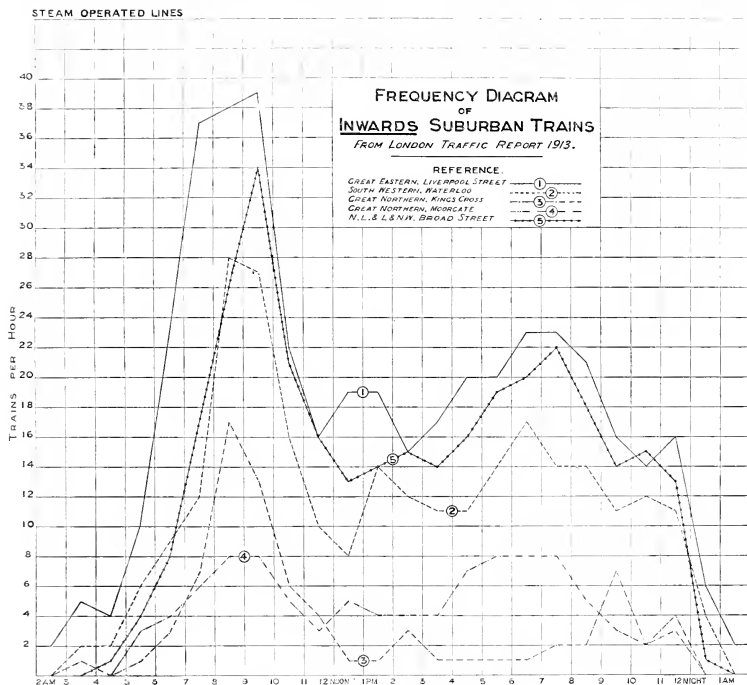

FIG. 6.

appear to be to electrify a steady regular service of reasonably small trains to Moorgate-street, leaving the steam trains to deal with the peak loads as at present. It may be urged that the tendency would be to overcrowd the electric trains and leave the steam trains less well filled; but the author does not think so, because obviously the electric trains would be used for the stopping traffic (for which they are so much more suitable than steam trains can possibly be), leaving the "rush hour" terminal steam trains to do a service which would give perhaps not such facilities in intermediate service, but still as good a

of Trade, 1913, Appendix B 15, the following information is given:

	No. of inward suburban trains between 8 a.m. and 9 a.m.	Average rate of speed
(G.N.R.) King's Cross	17	22.9 m.p.h.
(G.N.R.) Moorgate-street	8	17.2 "

These figures confirm the impression that the terminal business at King's Cross is composed of the more or less non-stop trains, while the Moorgate-street connection gives a more distributed service.

A table is given in Appendix B 18 to the 1913 Report of the London Traffic Branch of the Board of Trade showing the number of inward suburban trains at various points during the 24 hours. The author has had some of the more interesting of these figures put in diagrammatic form (see Figs. 6, 7, and 8), and the curves show very clearly

case; and in the other cases it may be assumed that the curves would be similarly affected. No information is given in the figures mentioned as to the size of train, but merely of train frequency, nor are any recent figures available as to the passenger load factor, *i.e.* the numbers travelling at various times.

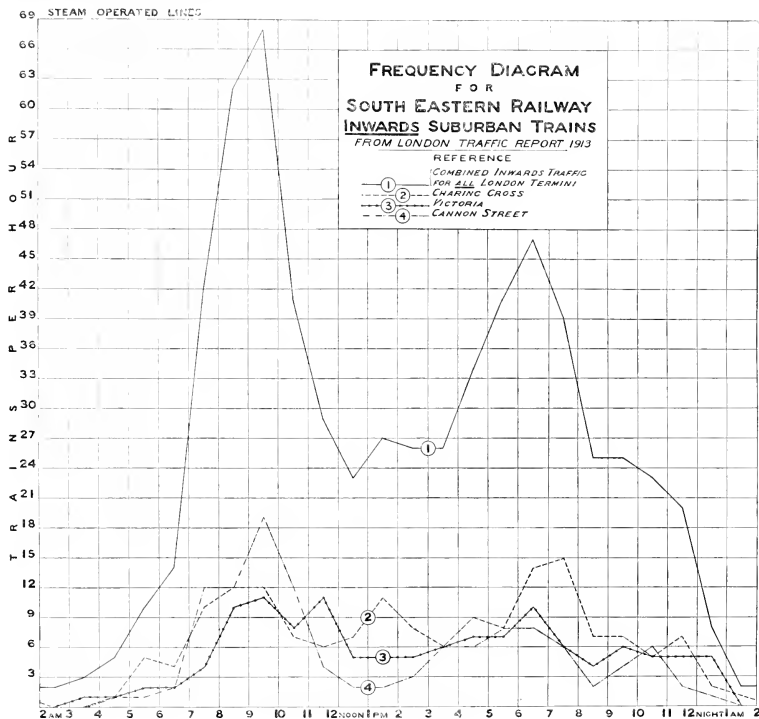

FIG. 7.

the difference in train frequency as between "rush hours" and "non-rush hours" in the case of heavy radial suburban business, and the much greater regularity of train frequency in the case of urban lines distributing their traffic over the central area.

The table unfortunately deals only with inward suburban trains, and this explains the relatively small evening peaks shown. In Figs. 4 and 5 the author gives the actual curves for both "up" and "down" traffic in one

A large number of diagrams of passenger movements at various termini were given in 1905 by the Advisory Board of Engineers to the Royal Commission on London Traffic. The developments and alterations in London traffic conditions since 1905 are such as to render these diagrams of little use. In the case of stations in the City of London some figures for a portion of the day are available in the report on the "City of London Day Census," 1911.

The following figures may be given :—

	Minimum Number of Passengers in One Hour	Maximum Number of Passengers in One Hour	Min. Max.
(G.E.) Liverpool-street ...	1,500	23,316	6.5
(S.E. & C.) Cannon-street	485	8,431	5.75
(Met.) Bishopsgate-street (now called Liverpool- street)	734	3,007	24.5
(Met. Dist.) Mansion House	500	3,020	16.6
(Central London) (Bank)*	800	2,600	30.6

* Extension to Liverpool-street not then open.

growth of motor omnibus traffic) have occurred since then. So far as they go, however, they show the great distinction between traffic on urban lines like the Metropolitan, Metropolitan District, and Central London Railway, and that on radial lines like the Great Eastern and South-Eastern and Chatham Railways.

In the case of steam lines it must be remembered that these figures include all passengers, whether suburban or long distance.

The figures for the departure traffic would show an almost exactly similar comparison.

In the case of urban lines there is a considerable flow in both directions all day, and the radial traffic is much more of a peak nature, all "up" in the morning and "down" at night."

The curves shown bring out the fundamental difference between "urban" and "radial suburban" traffic, and show

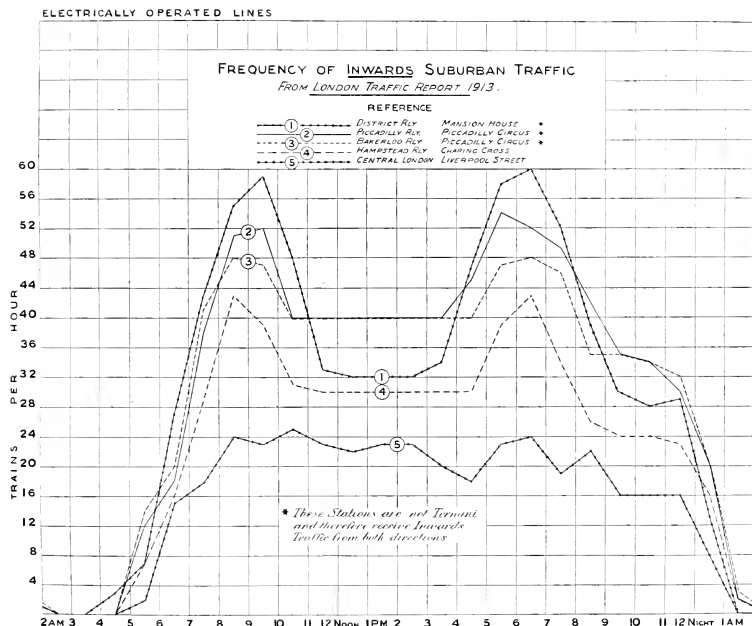

FIG. 8.

Unfortunately this census only lasts from 7 a.m. to 7 p.m., and neglects therefore a very considerable portion of suburban traffic, and even these figures are somewhat out of date as considerable alterations (particularly the

the very great importance in the latter case of the "rush hour" business. An investigation of the actual figures will be of interest. Referring to the curve shown in Fig. 5 the lines A B, A B, are drawn at an arbitrarily chosen point

two-thirds of the maximum height which represents the number of seats per hour. The two areas of the curve above A B, A B, represent about 87,000 seats, and the part below these lines about 615,000. The total is 702,000 seats, being the number of seats moved in both directions per day. The areas represent of course the number of seats per hour multiplied by the time, *i.e.* the total number of seats moved. The areas of the portions of the curve above the line represent $87,000/702,000$, or 12.4 per cent of the total number of seats moved per day, while the lower portion represents $615,000/702,000$, or 87.6 per cent of the whole; or, to put it another way, the two peaks are satisfied by running 87,000 seats above the 615,000 of the lower portion, or an increase of 14 per cent; but the maximum demand is increased from 42,000 seats per hour to 63,000 seats per hour, or by 50 per cent.

The maximum peak load above the line A B represents 21,000 seats per hour. Assuming an average train capacity of 780 seats per train, *i.e.* taking about the maximum train reasonably worked, *viz.* about 440 ft. long, 27 train-trips will be necessary per hour to deal with this business. Assuming a schedule speed of 22 miles per hour, a lay-over time at each end of the journey of 4 minutes, and an average distance of run of 10 miles, the time required for one train-trip is 31 minutes. The number of trains required in service at one time to carry out 27 trips per hour is therefore 14.

The area of the two peaks above the lines A B represents 87,000 seats. At an average train capacity of 780 passengers this represents 112 train-trips per day, or 1,120 train-miles per day, or, assuming that this peak occurs on 300 days per year, 336,000 train-miles per annum. With 14 trains required for performing this service, this gives 24,000 train-miles per train per annum.

If the trains at peak times could all be run non-stop through a number of stations the schedule speed might be more than 22 miles per hour. Assume it to be 28 miles per hour, which is not likely to be exceeded as a fair average figure for all the trains at peak time, the run of 10 miles will require 21.5 minutes, and with 4 minutes' lay-over at each end the trip time will be 25.5 minutes; therefore if 27 trips per hour were required, 12 trains would perform the service. The train mileage per train per annum in this case would be $336,000/12$, *i.e.* 28,000.

The height of the curve at the lines A B represents 42,000 seats per hour. On the same assumptions as before for average train capacity, schedule speed, and length of run, *viz.* 780 seats, 22 miles per hour, and 10 miles respectively, 53.5 train-trips per hour will be necessary, requiring 28 trains to deal with the traffic. The area under the lines A B represents 615,000 seats or 800 train-trips per day, or 8,000 train-miles per day. As a large proportion of this business will be handled on Sundays as well as on business days, the mean number of days per year will be about 340. The number of train-miles per year will be $2,720,000$ or 97,000 train-miles per train per annum.

These figures ignore questions of spare stock under repair, and undoubtedly more spare stock proportionately would be required for the latter portion of the service than for the former. Allowing for this consideration, however, the figures do show the very restricted user of rolling stock possible on such a traffic as that shown in these peaks compared with the user in general.

An 8-car bogie train of a length of about 450 ft. will

require, for a severe suburban schedule, three of the cars to be equipped as motor cars, each with an equipment of four motors each of over 200-h.p. output. The capital cost of such equipment, including trailer-car apparatus, will be at present prices about £10,000.

In the case of the 14 trains working the peak above A B making only 24,000 train-miles per annum (if restricted solely to suburban work as they might have to be, as already pointed out), the interest and depreciation (at 10 per cent) on electrical equipment alone will amount to 10d. per train-mile. If the train mileage can be increased to 28,000 the figure will be 8.6d. per train-mile.

As this peak-load traffic is to a large extent less severe in service characteristics than the average traffic (owing to some of the business consisting of non-stop running) it might be possible to handle it with trains equipped with less powerful and less costly electrical apparatus, and in some cases it might pay to do so, but that introduces the very undesirable feature that in addition to the trouble of the suburban stock being incapable of utilization for holiday business on non-suburban lines (unless the holiday lines are also electrified), the suburban stock itself would be of two kinds, and the lightly equipped suburban trains would be unable to perform heavy suburban schedules or to act as spare stock for such a service.

From an operating point of view this method of reducing the capital charges is not feasible, as it would be necessary to have all suburban trains of standard equipment suitable for the severest service conditions, and suitable for operating either "non-stop" or "all station" traffic as the circumstances might require. One round trip ("up" and "down") may demand both characteristics. Assuming that power be bought from outside sources, the price charged would unquestionably be decided by any commercial supply authority on the basis of the load factor of the demand. As the evening peak of traffic largely coincides with the winter lighting and power peak, the diversity factor cannot have much effect. If the railway should decide to generate its own electrical energy the capital cost of the plant necessary to supply the top 33.5 per cent of the load shown in Fig. 5 would be at least 25 per cent more than that of the plant required for the bottom 66.5 per cent. In addition, the cost per unit of generating the energy for the peak would be considerably higher than that of generating the bulk. Additional boilers worked up for a limited time, or alternatively the overloading of boilers regularly used, would cause an increase in the cost of coal per unit, extra staff would be required, and the conditions generally would be unfavourable to the most economical operation.

COST OF RUNNING "PEAK" SERVICE.

A train of 780 seats will weigh, with passengers and electrical equipment, some 320 tons. Such a train operating at a schedule speed of 22 miles per hour with station stops 0.9 mile apart, will result in an average load at the power house of 500 kw. The 28 trains necessary to run the bottom portion of the curve in Fig. 5 will therefore make an average demand of 14,000 kw. The momentary peak load will be say 17,500 kw.

With 12 additional trains running (assuming the lowest number required for the peak), *i.e.* a total of 40 trains, the figures will be:—

Average load at power station 20,000 kw.
 Momentary peak at power station, say ... 25,000 "

An increase in the number of trains from 28 to 40 necessitates an increase in the momentary peak of 7,500 kw., or 43 per cent. It may therefore be taken that additional plant of about 8,000 kw. capacity would be required, which would cost say £10 per kilowatt, or £80,000. Interest and depreciation at 10 per cent is £8,000 per annum. The number of train-miles run by these 12 trains during peak times is 336,000. The capital charges on the extra power station plant are therefore 57d. per train-mile.

The capital charges on the electrical equipment of the rolling stock have already been stated, on the basis of 28,000 miles per train per annum, as 86d. per train-mile. The total capital charges may therefore be stated as 143d. per train-mile.

As the service is assumed to be to some extent of a "non-stop" character, 80 watt-hours per ton-mile can be assumed as a reasonable figure (certainly not too high) for such a service. A 320-ton train will therefore require about 25 units of electrical energy per train-mile. Assuming the cost of energy to be 0.3d. per unit (excluding capital charges) the cost of energy per train-mile will amount to 7.5d. Adding the cost of the motormen's wages and the repairs and maintenance of the rolling-stock electrical equipment at say 4.5d. per train-mile, the operating cost per train-mile will be 11.5d. So that including the following:—

1. Rolling stock equipment capital charges ... 86d.
2. Power station equipment capital charges ... 57d.
3. Operating costs 11.5d.

the total cost per train-mile at peak times equals 25.8d., or approximately 26d. This figure is obtained without including any capital charges for sub-station plant or transmission cables, or for third rail or other contact conductor, or any operating cost for the maintenance of the third rail, etc., and it is therefore unduly low.

The cost of operating by steam such a peak service as that shown would not be more than 15d. per train-mile, so that electrical operation at peak time shows an increase of 11d. per train-mile without charging to it all the items that it should bear. On 336,000 train-miles per year the additional cost in round figures is £15,000 per annum.

These figures are not put forward as estimates of the actual costs to be expected in any given case, but for the purpose of comparing the conditions of steady load traffic as against peak load.

As regards the steady portion of the curve the position is obviously quite different. For example, the charges on rolling-stock equipment, assuming 60,000 train-miles per train per annum, are reduced to 4d. instead of 86d. Power station capital charges would be reduced in approximately the same proportion, while the cost (per unit) of generating the energy would be considerably lower than at peak time.

A reduction in the number of cars forming the train does

not reduce the cost of steam haulage proportionately to the reduction in weight, while with electric operation the operating cost varies more in proportion to the size of the train, so that if the size of the train be halved and the number of trains be doubled the cost will be of the same order except for motormen's and guards' wages, which are, per train-mile, practically the same whatever the length of train.

By electric operation during "non-rush hours" (so far assumed as performed by trains of the same length as those used at peak times) the cost of operation can be reduced by shortening the trains where possible while retaining the same frequency.

Such comparatively good-load-factor working as results from leaving the peaks to steam can therefore be made at small extra cost much more attractive by electric working, at any rate at an extra cost almost certain to be more than wiped out in any average conditions by the increase of revenue due to the more attractive transport. In this kind of work electric traction can make an unanswerable challenge to steam working from both the operating and the financial points of view; but on "rush hour" traffic of intense character for a short time the figures given show that the electrification of peaks of a traffic load curve such as is shown in the figure can scarcely be a financial success at present fares on the basis of providing a seat for every passenger at "rush hours."

POSSIBILITY OF REDUCING PEAK BY USE OF END-DOOR CARS.

As to whether the introduction of end-door saloon cars such as are used on the Tubes and similar lines, thereby providing plenty of standing room but a limited number of seats (handling, however, a large number of passengers per unit length and weight of train), would be accepted by passengers on trunk lines as cheerfully as they appear to have been on the Tubes, is a question that the author considers debatable.

The average distance travelled per passenger—at any rate at peak times—is greater in terminal suburban traffic than in urban transport.

It was mentioned by Mr. Bowden in the discussion on Mr. O'Brien's paper¹ that in the case of the Metropolitan Railway, on which line both side-door compartment cars and also end-door saloon type cars are used, many passengers seem to prefer the former.

Assuming the possibility of operating a mixed suburban service of steam "rush hour" trains superimposed on a regular electric service, the financial aspect of such a proposition in cases of abnormal peak traffic appears to be more favourable than in the case of total electrification.

In the author's opinion the figures given show that this method is worth investigating in such cases as may be found suitable for its use from an operating point of view. It has the merit of still leaving rolling stock available for Sunday and Bank Holiday excursion traffic.

¹ *Journal I.E.E.*, vol. 52, pp. 458-9, 1914.

DISCUSSION.

Mr. Smith.

Mr. ROGER T. SMITH: It is appropriate that this paper should be the last of the present series of papers on railway electrification, because of the paramount importance of the traffic side of the question. The electrical engineer has, it not the simplest, at least the most straightforward share in the electrification of a railway. Financial considerations are paramount, but traffic considerations come next, and it is right that at the end of such a series of papers as we have had, the great importance of the traffic problems which govern railway working of every sort should be emphasized as it has been in this paper. Mr. Aspinall is the author of more than one trite saying in connection with the electrification of railways, and one of his latest is that in order to be financially successful it is necessary to choose the right locality for electrification. I venture to think that the present paper is written practically on that text, and it is particularly expressed near the top of page 620. I should like to congratulate the author on the excellent analogy that he has made between the peak-load business of electricity supply and the peak-load business of moving seats for railway passengers, and also on the analogy between the load factor for electricity supply and the daily maximum demand load factor for passenger or seat loading. I must, however, issue a warning against importing what is a purely electrical term into railway working. As an electrical term "load factor" always means one of three or four things, and needs another word in front of or behind it in order to express which of those things it does mean. "Passenger load factor" or "weight-of-goods load factor" as a railway term is admissible and would always be understood by railway men, because the term loading, either of goods or passengers, is a commonly accepted railway term. Except, however, as an analogy happily illustrating the point that the author wished to impress upon us—that is, the cost of actually running the peak-load business, which is brought out in Figs. 5, 6, 7, and 8—I feel bound to object to the term "train load factor" or "seat load factor" as applied to the ratio of the average number of seats or the average number of trains per day or per year to the maximum number of seats or trains respectively. The term will undoubtedly be misunderstood by railway men. We ought, however, to have a term to represent those ratios, and tentatively I should like to suggest "utility factor," which although it has been suggested for use in electricity supply, has not yet been generally adopted. The author defines a suburban service, whatever be the length of the journey, as a service with a bi-daily peak, one peak "inwards" traffic, and the other peak "outwards" traffic, with a bi-daily season-ticket traffic which probably predominates over the other traffic. He further defines a "main-line service" as one serving widely scattered communities distinct from each other and without any well-defined bi-daily alternating peak or a large residential traffic. It is very important that we should have clear definitions for these services on a traffic basis rather than on an engineering basis, in order that electrical engineers may tackle their part of the problem; and we want if possible to have definitions covering all kinds of traffic, including goods traffic. In that respect

the author's preliminary contributions to these definitions Mr. S. are both important and suggestive.

The first five pages of the paper, up to and including the paragraph finishing with flying junctions on page 614, point to the ideal of a separate pair of tracks exclusively used for electric suburban service, confined to that and signalled for that. I am quite aware that the author does not directly advocate it, but he hints at it as an ideal. I would go further and say that it may be essential. Whether it is really necessary or not depends very much on the relative importance of the main-line and suburban traffics. On the Great Eastern Railway, for instance, I believe something like 70 or 80 per cent of the total number of passengers are suburban passengers, and in that instance it may become a case of trying to provide separate tracks for the main-line traffic. In the case of the North-Western Railway, however, where the main-line traffic is of the greater importance, they have thought it worth while to install separate lines for their suburban service as far as Watford; and that very well illustrates, I think, the two extreme cases. In order to decrease the headway the author proposes, on page 613, to fix a speed limit for main-line trains where main-line and suburban trains have to use the same tracks. Whether it is wise to do this or not depends, again, on the relative importance of the main-line traffic and the suburban traffic. The matter, however, is worthy of due consideration, for I think this is the first time it has ever been suggested. The advisability of the author's proposal to work the top of the peaks shown in Fig. 5 by steam, the remainder of the traffic being worked electrically, depends on the accuracy of the comparison that has been made between the cost of steam working and of electric working. In his Presidential Address to the Institution of Mechanical Engineers in 1909,* Mr. Aspinall showed that when electrical working was being introduced on the Liverpool-Southport line, and steam trains had to be sandwiched in between electric trains, the coal consumption of the steam locomotives on a service which to-day is running at a scheduled speed of 25 miles per hour for the stopping trains—I do not know what the speed was at that time—was 100 lb. per mile for stopping trains, and for non-stopping trains 80 lb. per mile. With coal at 12s. 6d. per ton this represents about 6½d. per train-mile for the stopping service. On page 625 the author gives 15d. per train-mile as the cost of running this peak service at a schedule speed of 22 miles per hour, which is probably not much below what it was in the case of the mixed service on the Southport line. I should like to ask whether that is a carefully prepared estimate, or whether the figures, which include a coal cost of probably something like 7½d. per train-mile at present coal prices, were obtained from actual experience. Railway people are ignorant about the relative steam costs of suburban working and main-line working. It is extremely difficult with steam working to separate the two, and I am rather anxious to know how far the above figure is a mere estimate and how far it corresponds with facts: my own belief is that 15d. per

* Institution of Mechanical Engineers, Proceedings, 1909, No. 2, p. 452.

train-mile is too low. In making the comparison the author has taken capital charges as 10 per cent. Surely that is too high: 7 per cent is more nearly the figure that should be taken. I also did not quite understand in the comparison why on page 625 the author has included the capital charges on the electrical equipment, but has excluded the capital charges on the locomotive. Surely the locomotive capital charges should be included on the other side. I am quite aware that his figures do not represent an accurate estimate, but only a tentative estimate to show the order of the comparison, but it is very important to railwaymen and others that we should have these figures as nearly correct as we can get them.

The author's proposals for the non-stop suburban service to be run by steam and for the stopping service to be run electrically are actually to be seen in operation to-day in one instance, and soon there will also be another instance in the London suburban railways. The existing steam service on the Great Central Railway between Marylebone and Aylesbury is by Statute not allowed to stop this side of Harrow. That means for $9\frac{1}{2}$ miles it is a non-stop service. The minimum fare, excluding workmen's fares in the morning and evening, is 8d., and the trains go out full with nobody paying less than 8d. This is a most important point indeed for the success of a suburban service. Beyond Harrow these steam trains are stopping trains. This line is paralleled by the Metropolitan Railway, with a stopping service of electric trains up to Harrow. Unfortunately two railways are concerned, but if the two are considered as one it would be an excellent illustration of the principle advocated by the author. The other case, which is somewhat similar, is represented by the work now being carried out by the Great Western Railway for a suburban service that joins the Central London Railway at Shepherd's Bush and goes out to Ealing. This line will be worked electrically, and will carry right into the City all those passengers from up the line who care to change trains at Ealing. The general suburban service of the Great Western line to Paddington is run by steam trains. There will shortly be a third instance; for when the London and North-Western suburban lines are electrified, electric trains will run via the Tubes all the way from the Elephant and Castle to Watford, thus missing Euston altogether and relieving that station of some of its terminal traffic. The suburban traffic between Euston and Watford will be hauled electrically over lines built and used exclusively for this electric service, as mentioned previously.

Mr. H. E. O'BRIEN: This paper deals so specifically with London conditions that it is only with considerable diffidence that those concerned with provincial railways may venture to discuss it. The main question dealt with is the working of the traffic peak load. This peak is inseparable from the nature of railway urban business, and it has two aspects—one, that of rolling stock and track, and the other, that of power-station plant. The discussion may be confined to conditions occurring between the hours of 5 a.m. and 11 p.m., for outside those hours traffic is and always will be negligible. The introduction of a frequent service of trains in itself tends to remove the peak and to increase the traffic in the "non-rush hours"; these hours are very insufficiently catered for at present both in train services and in attractive fares, and much can be done by the

traffic officials (who I regret are not here to-night to discuss this paper) to reduce the peaks in this way. When all that can be done has been done, a peak every morning and evening will still remain, and apparently the author suggests the use of steam locomotives to smooth the peak out for the power station and for the electric plant and rolling stock. The peak for the plant is best smoothed out by the use of batteries, which not only eliminate both momentary and hourly peaks, but also are a valuable insurance and stand-by. In conjunction with batteries the efficiency curves of modern turbines and boilers are so uniformly high over a large range in the neighbourhood of full load, that both the overload at the peak and the underload at the "non-rush hours" are efficiently dealt with when reduced to a moderate range by the batteries: further, the battery plant costs no more than the extra generating plant, and enables money to be saved in feeders and sub-station plant. The provision of peak rolling stock is a more difficult matter; the author correctly points out that it is impossible to introduce the steam trains to the same platforms as the electric ones, but he does not point out what should be done with the steam locomotives during the "non-rush" period of the day. It would seem preferable to meet "rush hour" work by the use of trains with a maximum number of trailer cars, the motor cars of which will be used to maintain the frequency of service during the day with fewer trailer cars. In this way the motor cars will be kept in service and the peak rolling stock motive power provided for in the cheapest possible way; extra peak staff are also eliminated by this method. There is a loss of weight efficiency in some of the light trains in the "non-rush hours" due to the preponderance of the motor cars, but a higher acceleration can be used, and more coasting done, which will partly eliminate the loss due to carrying about the extra weight. By designing the trailers with buffers suitable for engines, these trailers can be used for seaside holiday traffic if not wanted on the electrified lines as the author suggests, though this is not the experience in the North of England. Centre corridor cars are very popular on our seaside services both for local electric trains and for such traffic as that from Manchester to Southport and Blackpool; in fact, passengers complain if compartment stock is substituted. A single wide centre door such as is used on the Tubes may be useful in corridor electric stock; but, generally speaking, for work in open country—and it is essential to go out at least 20 miles from an urban centre to make electrification financially successful—side doors are undesirable. The author rightly draws attention to the large staff required for, and the difficulty experienced in, shutting side doors on high-acceleration trains; the frequent slamming of doors also causes heavy maintenance. Further, the public who get straight into a corridor train from points marked on the platforms waste time in looking for empty compartments in compartment stock. There is no doubt that there is still a field in London and elsewhere in some specialized cases for steam-hauled suburban services. The Belgians have designed some magnificent super-heater tank engines for such work, and it is not known or realized yet at how low a cost a high-speed suburban service could be worked with 2—8—2 four-cylinder tank engines with terminal facilities specially arranged for coal and water supply. Permission from the Board of Trade to work the train with the engine always at the same end

Mr. O'Brien. would be essential to the success of the scheme, and it would be quite possible to design a method of controlling the regulator from the brake van as is done on steam rail motors. The author suggests the use of semi-expresses and expresses passing stopping trains on emergency tracks; both these devices have long been in use on the Liverpool and Southport line with complete success. He is to be congratulated on a splendid and comprehensive paper on the complex subject of London urban traffic, but admirable as the paper is from a technical point of view he does not seem to have grasped the fact that it is the comparatively long-distance traffic which earns the dividend, and that the object of electrification should not be merely to fulfil the statutory obligation of conveying the people who present themselves, but rather to induce them to travel farther and more frequently. Money must be spent to make money, and empty trains may have to be run for a long time and yet pay handsomely for themselves in the long run. The author is incorrect in assuming that the length of a block section depends only on the factors which he has named; it also depends on the rate of acceleration attainable.

Mr. Bowden. Mr. J. BOWDEN: This paper is valuable and it presents many factors other than electrical which enter into electric railway operation. The freedom from electrical bias is particularly marked, but I consider that the case for electric traction is not as strongly put as it might be. The author's analysis is based upon providing seats for every passenger, a condition which does not obtain on steam suburban trains to-day and which in the comparisons of the paper is unfair to electrification. That condition may be most desirable, but it may seriously prejudice the financial aspects of an intense suburban proposition whether steam or electric. Passenger regulation is most difficult in "rush hours" and unless numbers are controlled at the barriers, passengers will stand if thereby they can travel by an earlier train. In such circumstances the public are better served by easier circulating ways and greater standing accommodation such as are found on suburban passenger cars in America. The peaks on the seats curve, Fig. 5, are responsible for heavy capital charges per train-mile in the estimate for electric working, and the author indicates still further capital charges to cover the cost of spare stock for shed and shop purposes. Shed work may be provided for during slack hours, say 10 a.m. to 4 p.m., by the stock shown to be idle in Fig. 5, and spares may thereby be reduced to those required for shop work. Steam does not lend itself to such an arrangement, which makes for lower capital and stand-by charges. In the comparison of the cost of steam working is assumed at 1s. 3d. per mile, which is too low for suburban steam services. The published accounts of several railways show an approximation to that figure when all expenses and mileage (including shunting and empty stock) are taken into account; but if figures for purely suburban working were taken separately, the cost per mile would show a higher figure. In two ways therefore the estimates appear to be unfair to electric traction. The paper emphasizes such limitations to intense suburban services as are imposed by flat junctions, terminal and platform accommodation, and signalling. On the inauguration of electric traction on the Metropolitan and Metropolitan District Railways similar limitations were encountered, but up to that time

they had not proved formidable owing to the restrictions imposed by the use of steam locomotives. On the removal of these restrictions by the use of electric motors extensive developments in the permanent way and stations became necessary to meet the growing traffic, and by their adoption these railways have in conjunction with electric working been enabled to give the intense service in operation to-day. A fairer case for electric traction would have been made by the author presuming such junction and station developments. Railways are under statutory obligations favourable to suburban passengers, and London terminals will have to deal with more traffic in the future. There are no transit facilities equivalent to those provided by railways, even allowing for the possibilities of the motor omnibus, and the increased speed and frequency of service necessary cannot be given by steam without widenings, the cost of which would render them impossible. Fig. 5 indicates a poor load factor in the generating and sub-station plant. Railways working a mixed traffic could do much to fill up load-curve hollows by including shunting and goods working in the zone of electric traction. The advantages appear to be many, and there have been considerable developments abroad in this direction.

Mr. H. BURGE: On page 616 the author discusses the question of side-door and end-door cars as affecting the time of stop. I should like his opinion on the corridor type of train combined with a certain number of side doors. The passengers instead of walking the length of the platform in order to find seats go in at the nearest door and look for their seats afterwards, which must facilitate rapid loading. Turning to the electrical side, the author lays great stress on the flexible speed characteristic and the necessity for low operating costs, so that any scheme using current more economically must be worth consideration. I have some figures of tests made on an underground railway on the Continent, where the ordinary traction motors were controlled by a Ward Leonard or booster set arranged on a multiple-unit system with automatic acceleration: it had evidently been adapted to the existing railway stock. For comparison two motor coaches were coupled together, No. 1 having the usual series-parallel control, and No. 2 the booster control. About 14 journeys were made, each coach doing the hauling on alternate journeys, so that the conditions were exactly similar. At the end of the tests the meters showed that the coach with series-parallel control had consumed 25 per cent more units per train-mile than the coach with booster control. It was estimated that if the booster control were used throughout the whole of that railway the saving would be over £40,000 per annum, assuming the low figure of 3d. per unit for current. Probably there would be a similar saving in the generating plant and in the feeders. The net increase in the total weight of the train so equipped was only about 3 per cent, but as the stored energy was returned on braking, the question of weight would not be important. I have a slide which gives a view of the ordinary traction motor and the Ward Leonard set alongside; the latter does not appear to take up any more space than the transformer always required for single-phase traction. The second slide shows a curve representing the number of kilowatts taken from the line. Starting on the left, the power is small, and gradually reaches about 360 kw.: then the braking commences, and

Burge. about 30 per cent of the energy used for acceleration is returned to the line. It has often been urged that the steam locomotive can fulfil conditions not yet possible with electric working, but I think it ought to be noted that this braking by returning energy to the line is something that the steam locomotive does not do.

Mr. W. M. MORLEY: I wish to follow up what I said* when Mr. Roger Smith read his paper a few weeks ago, as to the possibility of a more economical use by the train of the energy supplied to it, especially as bearing on the comparison given in the first column of page 625 of the present paper. The uncomfortable fact is brought home to us that according to the estimates electric traction under the conditions given means an additional annual cost over steam of £15,000 for a service of 336,000 train-miles, the cost per train-mile being 26d. as compared with 15d. for steam. I want the author to consider whether a large part of this difference cannot be removed. He assumes 80 watt-hours per ton-mile for a service "to some extent of a 'non-stop' character." If this can be reduced—on what is perhaps not an unreasonable assumption—to one-half, then the 26d. will come down to 17·4d. by halving items Nos. (2) and (3), namely, 57d. and 115d., in the estimate. My suggestion for this reduction is based on general considerations of attainable efficiency and is illustrated by Fig. 1 of Mr. Roger Smith's paper. He shows how the energy per ton-mile increases as the runs become shorter, rising from 40 watt-hours per ton-mile with stations one mile apart to 80 watt-hours with stations 0·4 mile apart. This was from actual results for London suburban motor-coach trains for a schedule speed of 17 miles per hour. If Mr. Firth had been dealing with a service with stations very close together in which the energy consumption under present conditions is large, I would then also ask him to consider whether a considerable reduction is not possible. Mr. Burge has just shown a diagram which bears on the point that I previously raised and to which I should like again to refer to-night. In short-run services a very large proportion of the energy is lost in the starting resistances or is stored up in the train and lost in braking. Whether these losses can be avoided or reduced, practically and commercially, is the question. These losses are inherent to the method of control adopted; they are not inherent to electrical driving even with continuous current. Mr. Burge's diagram illustrates this point. The Ward Leonard method or any similar method offers, however, no very great advantage for "non-stop" working, and therefore would not help the author for the case with which he deals, but for other cases one may still hope that some such method may come into use. Engineers cannot be permanently satisfied with efficiencies in the neighbourhood of 25 per cent, which is probably as much as is now reached on the average. I refer of course to the efficiency of propulsion calculated on the energy actually spent in directly overcoming train resistance, and bearing in mind that 1 lb. friction per ton needs at 100 per cent efficiency 2 watt-hours per ton-mile.

Mr. H. G. DRURY: There is no difficulty in carrying the traffic by steam at the hours of the day when there is no rush, but even with the additional attractions of electrical

working I think it is extremely doubtful whether at those hours of the day sufficient traffic could be withdrawn from the roads to warrant the expenditure of a large amount of capital. For suburban traffic and for such traffic as that on the Metropolitan and Metropolitan District Railways electric traction is the ideal motive power.

Mr. H. W. FIRTH (*in reply*): Mr. Smith emphasized one point which he attributes to Mr. Aspinall, viz. that for electrification to be successful it is necessary to choose the right locality. I have tried to emphasize that feature in the paper. I have pointed out that the results which can be obtained from electrification must be very carefully considered with regard to the kind of district that is being served. That also answers another point raised by Mr. O'Brien with regard to improving the load factor, in which he instanced the Liverpool-Southport traffic. With all due respect to Mr. O'Brien, however, although the traffic officers of the Lancashire & Yorkshire Railway are very able men, I think that the enormous increase of traffic on that line is not entirely due to the work of those officers. On page 620 of the paper I myself have mentioned that particular service as an instance. When there is a big town at one end of the line and a fine seaside resort at the other, with a number of golf links and seaside resorts between, as well as a big residential district, that is a service which is simply crying out for electrification. When a service of that kind is compared with a tapering London suburban service, starting at a terminus and going down to a little place in the suburbs, with perhaps two or three passengers for the train, and no all-day attractions, we are not comparing like with like. I fully agree with the remark of Mr. Aspinall, which I had not noticed before, that the right locality must be chosen, and that point is strongly emphasized in this paper.

Mr. Smith issues a warning against carrying the analogy of peak-load supply in power work too far; he also rather criticized the use of the term "load factor" as applied to railway traffic. I particularly used the term "load factor" because I wanted to make this analogy, and because "load factor" is a term which is so greatly used by all of us in our work. I thought, therefore, it would convey the best idea of what I wanted to discuss without attempting to introduce a new unit. The term "load factor" must of course be used with care, but used in the way that I have used it in the paper I think it conveys what I want it to convey.

Mr. Smith also mentioned, with regard to the first five pages of the paper, that the ideal appeared to be to have at least one separate pair of tracks confined to and signalled for suburban traffic alone. That is all very well; but, as I mentioned in the paper, with bad-load-factor traffic one is faced with the difficulty that if a separate pair of tracks is provided, so signalled as to provide specially for suburban services, one is then introducing a line which is not available, or at any rate not so available, to take other traffic. It is a very nice arrangement indeed, but very expensive, and I think that with bad-load-factor traffic, such as I have been particularly emphasizing, it would absolutely be put out of court on the question of expense. Mr. Smith mentioned as an instance that the London & North-Western Railway have separate lines; but as I am not very familiar with the latest developments on their new line, I should like to ask Mr. Smith whether he can tell me if these new

* *Journal I.E.E.*, vol. 52, p. 371, 1914.

† K. T. SMITH. Some railway conditions governing electrification. *Journal I.E.E.*, vol. 52, p. 293, 1914.

Mr. Firth. lines are to be signalled exclusively for suburban working, or whether they are being signalled so that they can be used, if required, for general traffic.

In regard to the question of costs, Mr. Smith asked whether the 15d. given in the paper was an estimate or whether it was based on actual working; he also said that it is too low, and that capital charges on locomotives should be included. As I say in the paper, the figures are not put forward as estimates of actual operating costs in any particular case, but have been taken as a fair average. I think that the published reports of the companies show that 15d. is a fairly good figure, taking main lines, goods working, suburban working, and everything else; and if one remembers that peak-load suburban traffic is to a large extent non-stop or semi-non-stop in character, I think it will be agreed that 15d. is a fairly reasonable figure. Anyway, perhaps it has not been borne in mind that in arriving at the 26d. which I have given for peak electric service I have not debited the electrical cost of operating that peak with all the figures that it ought to have set against it. To my mind those extra charges would certainly offset the locomotive capital charges, more especially as these are small, and it is assumed that the locomotives could be used to a considerable extent in other services as well as in the peak-load service, so that the proportion of capital charges of the locomotive to be charged to the suburban working is quite a small figure per train-mile. The instance which Mr. Smith mentioned of a mixed service is quite interesting. It is operated, as he pointed out, by two companies, one controlling the steam service and the other the electric; so that it is not quite on all fours with the suggestion that I made.

With regard to Mr. O'Brien's remarks, I have dealt above with his point about the possibility of improving the load factor. To amplify that slightly, it is greatly dependent on the type of district involved. Undoubtedly a great deal can be done, and has been done, by traffic officers to improve the load factor, but in my opinion the success of their efforts depends very largely indeed on the nature of the district. Mr. O'Brien also rather criticized the feasibility of working a mixed traffic of steam and electric trains into terminal stations. The last two paragraphs in the first column of page 620 of the paper, however, sufficiently deal with that point. I am assuming that these "rush-hour" steam trains would be dealt with more or less on the other spare main-line platforms. As to the use of trailer cars as a possible solution, surely one has to pay either in coal or in malt, as the lawyers say, for the transportation equipment. If all the apparatus is placed on a fewer number of motor cars it is still necessary to haul practically the same weights, and to perform the same schedule; and, as Mr. O'Brien himself mentioned, the equipment at the "non-rush hour" times would be less efficient and it may be that the train is not so capable of being split up into the right-sized smaller trains for "non-rush hours." Although it is worth consideration in some cases, I think that it would not entirely meet the case in respect to intense rushes.

With regard to the question of the use of superheat for steam suburban services, I was very interested to hear the remarks on that point from the representative of a railway which has done a very great deal in regard to superheating, as I have always understood that super-

heating for steam locomotives on suburban services with Mr. Firth many stops was an extremely difficult subject. Mr. O'Brien asked if the length of block section does not depend on the acceleration rate of the train. I think that that is not so. The time of clearing the section is dependent on the acceleration to some extent, but the length of block section depends on the length of the train. It is the length of train, not the time taken to cover the distance, which is the limiting factor as to the length of the block section; but the acceleration does largely influence the time it is in that block section. [Mr. O'Brien: The acceleration influences the length of the block section, because it influences the maximum speed. The higher the acceleration, the greater is the maximum speed that it is possible to obtain between one block section and another.] I had more in my mind the question of block section length at a station than that point. In a through run of course the acceleration does affect it, because it affects the maximum speed, but the limiting point is really the station block length, and there it is necessary to cover the length of the train.

Then Mr. O'Brien made the point that passengers can be taught to enter the car at the rear end and to go out by the head end. All I can say is that I believe that was tried on the London tubes: as to whether it has been successful, I will leave the audience to judge.

I was very interested in Mr. Burge's remarks on the question of utilizing the Ward Leonard control. If the figures that he put forward can be justified in practice, if the weight can be kept down, and if there are no other difficulties, the 25 per cent saving will certainly be a very great point indeed. I take it that Mr. Burge has assured himself that the characteristics of this arrangement would be suitable for the various classes of traffic that I have mentioned. I have not seen any curves or figures as to what this equipment actually does, but I am glad to see that it is a matter in which other people are taking an interest.

Then Mr. Bowden said that I did not make out a sufficiently strong case for electrification. I am sorry if that is so. I have tried to put down here some of the facts as they appeal to me, and I must leave them to be their own justification. As to the possibility of mitigating the bad load factor by using the spare time for shed purposes, the amount of time which can be utilized efficiently in that way is, I think, very small indeed.

Mr. Mordey's remarks were very much to the point. I quite agree with him that the energy is not utilized in the present equipments as it ought to be. As to the 80 watt-hours per ton-mile mentioned in the paper, I think that that is not much too high if one remembers that the "rush hour" business is only partially non-stop, and that at any rate a number of the trains at "rush hours" must be stopping trains. If one takes service conditions and not test conditions I think that 80 watt-hours per ton-mile is not too high.

On the question of capital charges Mr. Smith criticized my figure of 10 per cent and said that it ought to be 7 per cent. Of course, one can make a case anything that one wishes by taking appropriate figures, but I think that at any rate as regards rolling stock 10 per cent is not too much to allow for capital charges, including depreciation and obsolescence. I want to emphasize that these are not

Fifth.

to be taken as hard and fast figures for any particular case. They are not put down as absolute estimates, but merely as giving some fairly good idea of what this peak service means. If my figures are 50 per cent wrong I still maintain that that peak service, on the basis of present fares and on the basis of providing a seat for every passenger at "rush hours," does not appear to be a financially attractive proposition.

Mr. Bowden has criticized the suggestion of providing seats for every passenger during "rush hours," and has said that steam railway companies do not do it. They do not always do so, but at any rate they are certainly not behind the electric tube railways and other similar railways in that respect, and they certainly do try to provide a seat for each passenger. Perhaps one point in which we fail is that we do not provide straps in our cars for the people who cannot find a seat.

In conclusion, I am an enthusiast for electric traction whenever the load factor conditions or the utility factor conditions are satisfactory, or can be made satisfactory. It is no good ignoring facts, however, and the facts in relation to heavy-peak "rush hour" traffic are not easy to get over. If by reducing the energy consumption and also the capital cost, by improving the efficiency and by improving methods generally, we can reduce the cost of operating those peak services, nobody will be more delighted than I shall be; and if this discussion has emphasized the point sufficiently, so that competent people will take up the question, reduce the cost, and improve the mechanism for operating these peak-load services, I shall certainly not have written this paper in vain.

Communicated: I should like to deal with several of the points raised in the discussion which lack of time prevented my replying to verbally.

Mr. Roger Smith refers to Mr. Aspinall's remarks as to combined steam and electric working on the Liverpool-Southport line while the work of electrification was being carried out; but I would point out that this was the service in which the attempt was made—and necessarily made—during the transition period to carry out the same schedule with steam trains as was being worked by the electric trains. This is explained by Mr. Aspinall in the Address in which the figures quoted by Mr. Smith are given, and the remark is made that the excessive fuel consumption of the locomotives was due to the high accelera-

tion required. This is a type of service quite different from the combined working suggested in the paper, in which it is assumed that to a considerable extent at any rate the steam "rush hour" trains can be operated on main-line tracks, as is largely the case at present, so that the speed characteristics on any given track can be kept much the same. The paper has emphasized the difficulties of intermingling trains of widely varying speed characteristics on the same track.

The author agrees that the figure of 15d. per train-mile is too low for general heavy suburban service, but he is of opinion that it is a reasonable figure to assume for that peak-load portion of the suburban service which has been mentioned, a considerable proportion of which calls for fairly long runs with stops therefore comparatively far apart and conditions which are not particularly onerous.

With regard to Mr. O'Brien's remarks as to storage batteries, while these are undoubtedly valuable in smoothing the peaks at the power station, their efficiency is not high and the depreciation and maintenance costs are comparatively heavy. The author thinks that with widely divergent demands for power, such as would be made by traffic having the characteristics shown in Fig. 5, batteries would not be of great assistance, or at any rate that their use would not materially reduce the capital and operating costs taken together much below those assumed in arriving at the figure of 26d.

Mr. O'Brien makes a criticism that the author "does not seem to have grasped the fact that it is the comparatively long-distance traffic which earns the dividend, and that the object of electrification should not be merely to fulfil the statutory obligation of conveying the people who present themselves, but rather to induce them to travel farther and more frequently." In answer to this, the author would point out that he has specifically called attention on page 610 to such services as the London-Brighton, London-Clacton, London-Southend, and has emphasized the point that in considering the line of demarcation between the main-line and suburban services the character of the traffic is of importance and not merely the distance; and further he has stated that the outer-suburban traffic must be carefully considered, whatever its length of run, because of the great possibility of obtaining by electrical means a considerably increased revenue.

REPORT OF THE COUNCIL FOR PRESENTATION AT THE ANNUAL GENERAL MEETING OF 21st MAY, 1914.

At this, the Forty-second Annual General Meeting of The Institution of Electrical Engineers, the Council present to the members their Report for the year 1913-14.

MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since the 1st May, 1913, are shown in the following table:—

TOTALS AT	Hon. Mem.	Mem.	Assoc. Mem.	Assoc.	Grad.	Stu.	TOTALS
1st MAY, 1913	7	1,549	3,535	671	260	1,062	7,084
Additions during the year:—							
Elected ...	—	13	74	5	32	103	287
Reinstated...	—	4	6	1	2	2	15
Transferred to ...	1	22	50	2	33	—	108
Total ...	1	39	130	8	67	165	410

Deductions during the year:—

Deceased...	—	21	12	8	—	3	44
Resigned...	—	12	35	21	5	37	110
Lapsed ...	—	5	48	23	1	110	187
Transferred from ...	—	2	15	11	6	74	108
Total ...	—	40	110	63	12	224	449

NET DECREASE ... 39

TOTALS AT

1st MAY, 1914:—	8	1,548	3,555	616	315	1,003	7,045
-----------------	---	-------	-------	-----	-----	-------	-------

In addition, 112 candidates for Associate Membership have been approved by the Council for admission to that class on condition that they pass the Institution examination or otherwise satisfy the examination regulations. Of these, 2 are Associates, 29 Graduates, 11 Students, and 70 non-members.

MEMBERS DECEASED.

It is with deep regret that the Council have to record the death, on the 6th November, 1913, of Sir William Henry Preece, K.C.B., F.R.S. Sir William, who was one of the original members of the Institution, was at the time of his death the senior surviving Past President, having been first elected to that office in 1880, after serving successively as Member of Council and as Vice-President from the year 1873. He served a second year of office as President in 1893.

Among other well-known members who have died during the last twelve months are Mr. Charles Thomas

Fleetwood (Member of Council, 1879-80), Mr. Alfred S. Giles (Chairman of the Cape Town Local Section, 1906-7), Mr. John Gott, Mr. John Wykeham Jacomb-Hood (Member of Council, 1907-10), and Colonel Matthew Townsend Sale, R.E., C.M.G. (Member of Council, 1879-80 and 1888-9).

The complete list of those who have died during the past session is as follows:—

Members.

Alfred Apps.	Francis Valentine Toldervy
Thomas Blissett.	Lec.
Frederick Brown.	William Francis Melhuish.
James Herbert Cawthra.	Henri Menier.
Thomas Cushing.	Hatsune Nakano.
William Tregarthen	Walter Ambrose Pearson.
Douglass.	Sir William Henry Preece,
Robert Steuart Erskine.	K.C.B., F.R.S.
Stephen D. Field.	Colonel Matthew Townsend
Charles Thomas Fleetwood.	Sale, R.E., C.M.G.
Alfred S. Giles.	William Rowan Wilson.
John Gott.	George Alexander Zeden.
John Wykeham Jacomb-Hood.	

Associate Members.

James Russell Allport.	Lieut.-Colonel James Walker
William Walne Alston.	Ormonist, R.A.
Burdett Wyke Bayliss.	George Henry Phillips.
George Stratton Cross.	Tyson Sewell.
Henry Farmer.	Ernest Sykes.
Nigel Cuthbert Espir Hall.	Sydney Woodfield.
Reginald Choldmeley Campbell Yates.	

Associates.

Frederick E. Evans.	Walter Pethybridge.
Andrew L. Lind.	John Guy Pointon.
Johan Mygind.	Antolin Ruiz.
Joseph Giannusso Oliveri.	Alfred Smith.

Students.

Ronald Graham Hargraves.	Leslie Bromley Moulson.
William Arthur Adamson Page.	

MEETINGS AND PAPERS.

During the past twelve months 15 Ordinary Meetings and 17 Council Meetings have been held. The usual Standing Committees have met regularly, and there have also been meetings of other Committees appointed by the Council for the consideration of special matters, the total number of Committee Meetings held during the year being 127.

There have been 62 meetings of Local Sections, viz. Birmingham Local Section 11, Dublin Local Section 6, Manchester Local Section 12, Newcastle Local Section

12, Scottish Local Section 8, Western Local Section 5, and Yorkshire Local Section 5.

Meetings have also been held of the Calcutta and Cape Town Local Sections.

ANNUAL DINNER.

The Annual Dinner of the Institution took place at the Hotel Cecil, London, on the 5th February, 1914. A report of the proceedings will be found in the *Journal*, vol. 52, p. 378.

KELVIN LECTURE.

The fifth Kelvin Lecture was delivered by Sir Oliver Lodge, D.Sc., F.R.S., on the 22nd January last, the subject of the lecture being: "The Electrification of the Atmosphere, Natural and Artificial." (*Journal*, vol. 52, p. 333.)

JOINT MEETING IN PARIS WITH THE SOCIÉTÉ INTERNATIONALE DES ÉLECTRICIENS.

A very successful joint meeting with the Société Internationale des Electriciens was held in Paris from the 21st to the 24th May, 1913. A full account of the proceedings will be found in the *Journal* (vol. 51, p. 481).

PREMIUMS.

The following premiums for papers have been awarded by the Council this year. In accordance with precedent, in deciding upon these awards the Council have not taken into account papers contributed wholly or in part by Members of Council.

THE INSTITUTION PREMIUM, value £25,

to Mr. S. Evershed, for his paper, "The Characteristics of Insulation Resistance."

THE AYRTON PREMIUM, value £10,

to Mr. F. Lydall, for his paper, "Electric Locomotives."

THE FAHIE PREMIUM, value £10,

to Commandant G. A. Ferrière, for his paper, "Application of Wireless Telephony to Time Signals."

THE JOHN HOPKINSON PREMIUM, value £10,

to Mr. L. J. Hunt, for his paper, "The Cascade Induction Motor."

THE PARIS PREMIUM, value £10,

to Mr. B. Welbourn, for his paper, "British Practice in the Construction of High-Tension Overhead Transmission Lines."

AN EXTRA PREMIUM, value £10,

to Messrs. K. M. Faye-Hansen and J. S. Peck, for their paper, "Current-Limiting Reactances on Large Power Systems."

AN EXTRA PREMIUM, value £5,

to Mr. S. H. Holden, for his paper, "The British Standard Specification for Consumers' Electric Supply Meters."

AN EXTRA PREMIUM, value £5,

to Mr. F. J. Tingo, for his paper, "Experiments on Air-Blast Cooling of Transformers."

STUDENTS' PREMIUMS.

A STUDENTS' PREMIUM, value £10,

to Messrs. E. A. Richards and D. Dunham, for their paper, "Comparative Tests on Single-Phase A.C. Commutator Motors."

A STUDENTS' PREMIUM, value £7,

to Mr. H. S. Ripley, for his paper, "The Electrical Equipment of Collieries."

A STUDENTS' PREMIUM, value £5,

to Mr. J. Lindley Thompson, for his paper, "Discases and Troubles experienced with Transformers."

A STUDENTS' PREMIUM, value £5,

to Mr. J. L. Moffet, for his paper, "The Possibilities of Electric Traction on Railways."

A STUDENTS' PREMIUM, value £5,

to Mr. W. S. Flight, for his paper, "The Laws of Dielectrics."

A STUDENTS' PREMIUM, value £5,

to Messrs. A. Arnold and E. L. M. Entage, for their paper, "The Automatic Control of Electrical Generators by means of Automatic Pressure Regulators."

SCHOLARSHIPS.

The Council have awarded a Salomons Scholarship of the value of £50 to Mr. C. H. Stubbings, of King's College, London; and two David Hughes Scholarships of the value of £50 each, one to Mr. John G. Wellings, of the City and Guilds of London Technical College, Finsbury, and one to Mr. James Mould, of University College, London.

STUDENTS' SECTIONS.

Nine meetings of the Students' Section have been held, at which papers were read and discussed. At the opening meeting an address to the Students was delivered by Dr. C. V. Drysdale in the Lecture Theatre of the Institution (*Journal*, vol. 52, p. 286).

The Annual Dinner was held at the Trocadero Restaurant, London, on the 8th December, 1913.

The Manchester, Newcastle, and Scottish Students' Sections have each completed a successful session, having held ten, six, and five meetings respectively. Visits were made to various works by the kind permission of the firms concerned.

"SCIENCE ABSTRACTS."

In 1913, as in the previous year, the Physics Section shows a small increase in size: the volume comprises 2,022 Abstracts as compared with 1,916 in 1912. The Electrical Engineering Section, on the other hand, contains the same number of pages as in 1912.

Several additional transactions and periodicals have been added to those which are regularly reviewed. A list of these is given in the Index to the 1913 volume.

INTERNATIONAL ELECTROTECHNICAL COMMISSION.

A meeting of the International Electrotechnical Commission was held at Berlin from the 1st to the 6th Sep-

tember, 1913, at which the British Committee was represented by Mr. Alexander Siemens (President of the Committee), Colonel R. E. Crompton, C.B., Mr. W. Duddell, F.R.S., Mr. A. R. Everest, Mr. L. Gaster, Dr. Gilbert Kapp, Professor T. Mather, F.R.S., Mr. F. H. Nalder, Mr. G. Stoney, F.R.S., Dr. S. P. Thompson, F.R.S., and Mr. P. F. Rowell (Secretary).

The next plenary meeting of the Committee will take place at San Francisco in September, 1915.

The Council desire to draw the attention of members to the decisions of the Commission adopted at the Berlin meeting:—

Symbols.

The recommendations of various Special Committees by whom this subject had been dealt with from time to time were considered, and the final recommendations in the form adopted by the Commission will be found in Publication 27 issued in January, 1914, by the Central Office of the Commission.

Rating of Electrical Machinery and Apparatus.

The adoption of an upper limit for the cooling-air temperature was discussed, and further action was deferred until the next plenary meeting.

Nomenclature.

A list of some 80 terms and definitions was adopted, and it was decided to undertake the consideration of others applicable to electromotive forces and differences of potential in single or polyphase alternating-current systems.

Prime Movers.

A number of definitions were approved relating to hydro-electric installations.

INDUSTRIAL COMMITTEE.

The Council have to report that the Industrial Committee has been dissolved.

This Committee was constituted on the 28th March, 1912, and then consisted of six Members of Council, twelve members of the Institution not being necessarily Members of Council, and six other persons not being necessarily members of the Institution. On the 14th November, 1912, the members of the Committee not being members of the Institution were increased from 6 to 12 in number. Representatives of the Tramways and Light Railways Association, the Association of Electric Power Companies, the British Electrical and Allied Manufacturers' Association, the Incorporated Municipal Electrical Association, the Conference of Chief Officials of the London Electric Supply Companies, and the Association of Municipal Corporations, accepted seats on the Committee.

The work of the Parliamentary Committee of the Institution which had hitherto dealt with legislative and similar subjects was transferred to the Industrial Committee.

The constitution of the Committee was framed so as to secure the widest representation of the industry, and with a view to the accomplishment of effective work by utilizing the organization and influence of the Institution. The powers conferred upon the Committee were very

carefully considered with a view to the attainment of the maximum benefit from its operations, and the Council hoped for much good from the Committee's deliberations and recommendations. In common with other Committees of the Institution the Industrial Committee was required to report to the Council by whom such action would be taken as they might consider advisable. The constitution and powers of the Committee will be found in the Annual Report for 1911-12 (*Journal*, vol. 49, p. 664).

Fourteen meetings of the Committee have been held, at which the matters considered were the Electric Lighting Bill (1912), the National Insurance Act, the draft Census of Production Schedules, and the Sheffield Corporation Bill (1912).

On the 9th March last, the Committee reported to the Council as follows:—

"The Industrial Committee have carefully considered the constitution of the Committee and the powers conferred upon it by the Council of the Institution.

"They are unanimously of opinion that it is not only desirable, but of importance to the electrical industry, that an organization should exist which is capable of protecting and promoting the legislative and industrial interests of the industry, in so far as these interests are not already represented, protected, and promoted by the various existing Associations, and also for the purpose of co-ordinating and supporting the work of these sectional associations.

"They are of opinion that the present constitution and powers of the Industrial Committee are not such as to enable it to perform useful work. They are further of opinion that the views of the Council of the Institution should be ascertained as to whether it is advisable to enlarge the powers of the Industrial Committee and give it the necessary authority effectively to carry out the work referred to; or, alternatively, as to whether the Council be of the opinion that the consideration of these industrial questions is properly within the province of the Institution."

On the question of enlarging the powers of the Industrial Committee, the only additional powers would have been the granting of plenary authority to act independently of the Council, but no such extension of powers could be given, as the Council cannot wholly delegate to a Committee the powers or authority vested in them by the members of the Institution. Neither were the Council able to suggest any advantageous change in the constitution of the Committee, and in view of the opinion of the Committee as expressed in their Report there was no alternative but to dissolve the Committee.

The Council take this opportunity to point out the grave difficulties which arise if questions are dealt with which involve matters of a political character or in regard to which the interests of various sections of the membership may be in conflict.

With regard to the Council's attitude towards industrial questions, the Council will in future, as in the past, within the provisions of the Memorandum of Association, take such action in respect of legislative or industrial matters as may conduce to the general advancement of electricity and its applications, and will give full consideration to any representations made to them while preserving impartiality to all sections of the electrical industry.

MUNICIPAL LOANS.

The Council have recently appointed a Committee to consider and report on the question of the duration of municipal loans, and whether it is advisable to approach the Local Government Board in relation thereto.

MEETINGS FOR SPECIALIZED PAPERS.

In view of the development of electrical engineering and the consequent greater specialization among the members, the Council have had under consideration the question whether by some reorganization of the meetings interest in the different branches can be stimulated so as to encourage the members to take a more active part in discussions on the subjects which are of special interest to them.

It will be remembered that the Council had a similar object in view when it was decided to hold "Informal Meetings," but the only meetings held under that scheme were not of the kind indicated above and on the whole therefore did not fulfil their purpose.

The tendency to form new societies dealing with special branches shows that there is a real demand for meetings at which specialized subjects can be considered and discussed, and the excellence of the papers obtained by some of the smaller societies indicates that authors are willing to write papers for a specialized audience.

The proper body to organize meetings for all the branches of the electrical engineering profession is the Institution, and the Council have accordingly appointed a number of Sectional Committees, each of which will be intimately connected with some particular section of electrical engineering and whose duty will be to advise the Council as to the selection of papers and promotion of discussions of a specialized nature likely to be of interest to those engaged in that particular section.

LOCAL CENTRES ABROAD.

The Council are of opinion that it would be in the best interests of the Institution to extend its influence by the formation of Local Centres abroad for the purpose of reading papers and for discussions on electrical subjects. Local Centres already exist at Calcutta and at Cape Town, and recently the Council sanctioned the formation of a Centre at Hong Kong. The Council will accordingly be glad to hear on this subject from members residing abroad in places where such Centres might be established.

The Council are highly gratified at the successful meetings held at the Calcutta Centre.

RESEARCH.

The Council have placed a sum of £500 at the disposal of the Research Committee for the year 1914 for work in connection with Magnet Steels, the Heating of Buried Cables, and the Properties of Insulating Oils. An outline of the proposed investigation will be found in the *Journal* (vol. 52, p. 47).

KELVIN MEMORIAL FUND AND MEDAL.

The Memorial Window to Lord Kelvin, subscribed for by engineers of the British Empire and Dominions and of the United States of America, has been placed in Westminster Abbey and was dedicated there on the 15th July,

1913. The ceremony was attended by a large number of engineers, including representatives of all the Engineering Societies whose members had taken part in the provision of the Memorial, and by representatives of Glasgow University and Peterhouse College, Cambridge.

The receipts in connection with the Memorial amounted to £1,600 13s. 6d., and the disbursements were £1,222 19s. 7d., leaving a balance in hand of £377 13s. 11d. The Council have agreed to the suggestion of the Executive Committee of the Fund that this balance be disposed of in the following manner:—

- (a) A Kelvin Gold Medal to be established for award triennially as a mark of distinction achieved in engineering work of the kinds with which Lord Kelvin was especially identified.
- (b) The award to be made on each occasion after consideration of recommendations to be invited from the principal engineering societies in all parts of the world.
- (c) The award to be dealt with by a Committee in London, to consist of the Presidents for the time being of the Institution of Civil Engineers, the Institution of Mechanical Engineers, the Institution of Electrical Engineers, the Institution of Naval Architects, the Iron and Steel Institute, and the Institution of Mining and Metallurgy.
- (d) The Institution of Civil Engineers to be requested to accept the custody and trust of the Medal Fund.

INTERNATIONAL ILLUMINATION COMMISSION.

The Council have decided to take part in the International Illumination Commission by appointing delegates to the British National Committee and by contributing equally with the Institution of Gas Engineers and the Illuminating Engineering Society towards the expenses of this Committee.

The following delegates have been appointed by the Council to represent the Institution:—

Mr. W. Duddell, F.R.S.

Mr. F. Bailey.

Mr. Haydn T. Harrison.

Mr. K. Edgecombe.

Professor J. T. Morris.

INTERNATIONAL SCIENTIFIC RADIO-TELEGRAPHIC COMMISSION.

In October last the President reported to the Council that he had recently taken part in an international conference at Brussels with regard to the formation of an International Commission to carry out scientific experiments in wireless telegraphy, the intention being that the Commission should be on the lines of the International Electrotechnical Commission and that National Committees (one for each country taking part) would send delegates to the central body. The President also informed the Council that: owing to the generosity of Mr. Goldschmidt, of Brussels, the use of a large wireless station and the sum of 50,000 francs had been placed at the disposal of the Commission, and that it was proposed in the first place to make measurements of the strength of the signals sent out from Brussels. The National Committee would in each country organize the method of making the measurements and arrange with experimenters to carry them out.

It was resolved that the Institution undertake the responsibility of forming the National Committee for the United Kingdom, which has accordingly been constituted by the Council as follows:—

British National Committee (I.S.R.T.C.).

Mr. W. Duddell, F.R.S.

Dr. W. H. Eccles. Dr. E. W. Marchant.
Professor G. W. O. Howe. Sir Henry Norman, M.P.
Sir Oliver Lodge, D.Sc., F.R.S. Dr. S. P. Thompson, F.R.S.

The first meeting of the Commission was held in Brussels on the 6th April last, and the British National Committee was represented on this occasion by Mr. W. Duddell, F.R.S., Dr. W. H. Eccles, and Dr. E. W. Marchant.

ENGINEERING STANDARDS AND BRITISH ELECTROTECHNICAL COMMITTEES.

A re-organization of the Electrical Section of the Engineering Standards Committee and of the British Electrotechnical Committee on the following lines has been approved by the Council and the Engineering Standards Committee:—

(a) The number of representatives of the Institution on the Engineering Standards Committee to be increased from two to three.

(b) In place of the existing Electrical Plant Committee of the Engineering Standards Committee an Electrical Sectional Committee thereof to be formed, representative of every electrical interest and containing a predominating representation of the Institution.

(c) In future the Engineering Standards Committee, in consultation with the Institution, to appoint the British Electrotechnical Committee, with the understanding that the members of the Electrical Sectional Committee constitute in the first place the British Electrotechnical Committee as re-organized.

(d) The Engineering Standards Committee to be responsible for the funds necessary for conducting this work and for the expenses of the British Electrotechnical Committee.

The representatives of the Institution on the Engineering Standards Committee are Colonel R. E. Crompton, C.B., Mr. J. F. C. Snell, and Mr. C. P. Sparks.

MODEL GENERAL CONDITIONS FOR CONTRACTS.

The revised Model Conditions have been approved by the Council and were published on the 1st May, 1914.

BENEVOLENT FUNDS.

The Committee of Management report that the Benevolent Fund of the Institution shows a satisfactory increase for the past year. On 31st December, 1913, the capital account of the Fund stood at £4,642 3s. The donations and subscriptions to the Fund in 1913 amounted to £153 15s. 6d. The Council desire to acknowledge their indebtedness to the generosity of the donors and subscribers who have supported the Fund.

The Wilde Benevolent Trust Fund stands at £1,846 4s. 6d.

ANNUAL ACCOUNTS.

Excess of Income over Expenditure.—The margin to the good on the Revenue Account, £2,832 12s. 3d., carried to the credit of the General Fund, compares with £1,237 19s. 5d. in 1912.

Mortgages.

	£	s.	d.
In the Accounts for 1912 these stood at	35,621	18	2
Amount of repayment during the year	680	11	3
They now stand at	£34,941	6	11

Life Compositions Fund.—The amount received during 1913 was £86 6s., bringing the total of the Fund to £5,500 9s. Out of this the sum of £53 10s. has been transferred to the General Fund, in accordance with the Articles of Association, on account of Life Compositions of deceased members, leaving to the credit of the Fund £5,566 19s.

Of this amount, £5,332 2s. 10d. is invested in Stock Exchange securities.

Building Fund.—This has been augmented during the year by—

	£	s.	d.
Donations, Subscriptions, etc.	112	9	0
Contribution out of Institution			
Revenue	568	2	3
	£680	11	3

which amount was utilized in reduction of the Economic Life Assurance Society's mortgage.

Assets.—Taking the Tothill Street property and the Investments at cost, and the Institution Building and Lease, the Library and Furniture, etc., at the values standing in the books after writing off depreciation—

	£	s.	d.
the Assets amount to	114,001	1	4
against Liabilities	44,781	8	4
leaving a margin to the good of	£69,219	13	0

which is made up as follows:—

	£	s.	d.
Building Fund	42,495	14	11
Life Compositions Fund	5,506	19	0
Kelvin Lecture Fund	862	10	10
Reserve for Repairs	183	3	2
General Fund	20,171	5	1

This margin set against the margin to the good in 1912 of 65,217 9 10 shows an improvement for 1913 of £4,002 3 2

LIBRARY.

Seventy-two new books have been purchased since April, 1913, and 238 books and pamphlets have been presented by members, non-members, and publishers. The total number of readers during the past twelve months was 1,557, of whom 223 were non-members. The thanks of the Institution are again due to Mr. R. K. Gray, who

continued to pay the wages of a skilled book repairer engaged in repairing the old bindings in the Ronalds and the Institution Libraries.

The trustees of the Ronalds Library held their annual meeting, as provided for in the Trust Deed, in February last, and after inspecting the books stated that in their opinion the terms of the Trust Deed had been carried out by the Institution in a satisfactory manner.

In February last the catalogue of the Lending Library was issued to members. The catalogue contains 634 entries of works selected by the Library Committee for purchase, and during the two months which have elapsed since the formation of the Lending Library 306 issues of books to members have been made. These figures are gratifying to the Council, and it is hoped that members will continue to make use of this branch of the Library.

MUSEUM.

Numerous additions, among which are the following, have been made to the collection of historical apparatus:—

Articles presented	Donors
Specimens of early telegraph cables and miscellaneous electrical apparatus from the collection made by the late Sir William Preece.	Family of the late Sir William Preece
A collection of high candle-power carbon filament lamps and collars.	Edison and Swan United Electric Light Co., Ltd.
A telephone used in the winter quarters of the British Antarctic Expedition, 1910-12.	F. Gill
Sir William Fothergill Cooke's two original telegraph needles, electric alarm clock, and original specification and patent grant for the telegraphic apparatus patented by Sir William Fothergill Cooke and Sir Charles Wheatstone.	Grandchildren of the late Sir William Fothergill Cooke (Mrs. A. F. Grimley, Mrs. Jenkins, Major W. F. Cooke Taylor, and Mr. G. R. Taylor)
A collection of fuses patented by Sir William Thomson, and a Kapp and Crompton potential indicator.	K. Hedges
An early Wilde dynamo.	P. Huddleston
A reproduction of the original telephone invented by Alexander Graham Bell in 1875.	J. E. Kingsbury
A Dahl electric motor.	W. M. Mordey
An early telephone switchboard.	Norwegian Telegraphs Department

We beg to report that we have audited the Balance Sheet of the Institution of Electrical Engineers, dated 31st December, 1913, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct, and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

DISCUSSION ON

"SUGGESTED METHODS OF IMPROVING THE TELEPHONE SERVICE."

NEWCASTLE LOCAL SECTION, 9TH FEBRUARY, 1914.

Mr. J. R. M. ELLIOTT: With regard to the difficulties caused by subscribers themselves, it is unfortunately too true that difficulties of this nature are constantly arising. This is especially the case at private branch exchanges. After all, however, it is the duty of telephone engineers to design apparatus for use at the subscriber's end of the line to be as fool-proof as possible. Under the heading of "Automatic disconnection on manual switchboards" the author's suggestions are very ingenious, and although they may have advantages there are on the other hand certain disadvantages. For instance, if the receiver hook be inadvertently touched by the subscriber during conversation the connection will be automatically severed. This would lead to frequent complaints. It may be urged that this would take place in the case of an automatic system. Quite so, but in manual systems one of the advantages is that the operator has the power of discrimination and momentary signals of this kind would be ignored. Referring to the suggestions for the cord circuits, the proposals involve two additional relays per position. Would this not introduce a number of microphonic contacts? The question of accommodation in many of the smaller exchanges is a serious factor which must be taken into consideration, and as the space available is often so cramped and limited it would be a difficult matter in some cases to find room for additional relays. The author says that it is not essential to withdraw the plugs immediately; but if the operators were allowed to depart from this practice would not the result be a tendency towards slackness in operating? With the present system of lamp signalling at exchanges the fundamental basis on which the system has been built depends upon a lamp flash for every function to be performed; any departure from this practice would cause confusion in the minds of the operators. In the author's proposal it would be possible to have a maximum of 17 lamps glowing on the keyboard in front of the operator. Would not this throw a glare upon the bank of calling lamps? There is also the cost of the wear and tear of these lamps. The supervisors when walking round behind the operators would have a difficulty in noting the number of lamps glowing on the horizontal keyboard. Presumably the author does not intend to alter the position of these lamps from the horizontal to the vertical plane. Is it intended that the pilot lamp should be retained? The author has made suggestions for improving the service by modifications of the apparatus; but it may be explained that the Department in addition to spending large sums of money on apparatus equipment is improving the service by increasing the number of junctions and trunk lines throughout the country. It may be of interest when I state that in this district alone the sum of something like £40,000 is at the present time being expended in laying cables for junction lines between Newcastle, North Shields, South Shields, and Sunderland, and that a

¹ Paper by Mr. W. Aitken (see p. 320).

further sum of about £30,000 is being expended on the construction of new trunk lines in the district.

Mr. W. M. BATCHELOR: I think the author's suggestions are fundamentally wrong in principle. No doubt he is acquainted with the No. 9 common battery switchboard of the Western Electric Company. This board was designed to provide in a cheap form a central battery service for small exchanges having accommodation for about 800 subscribers' direct lines. The principle of negative signalling was adopted, but although the board is of a fairly modern type it is being discarded wherever it has been installed, mainly owing to the inadequacy of negative signalling. It is essential in telephone practice to have a definite signal for each requirement. A glowing lamp indicates to the operator that something must receive attention, and the absence of a signal means that everything is clear. The author's proposal is to revert to an obsolete method of signalling. Again, one of the most important features of the present system is the definite supervisory signal from each side of the cord. In the author's proposal for private branch exchange boards the clearing signal is being reduced to one in place of the double clearance now obtained. In this, in effect, he appears to be giving the equivalent of the clearing signal obtained on the old magneto boards. I may say that other methods of dealing with this subject have been proposed by two officers of the Engineer-in-Chief's Department of the Post Office, and the system that they have designed is now being investigated by the Department. In their system it is not proposed to abandon positive signalling, and in this feature it would appear to have a marked advantage over the author's system. At the bottom of page 325 the author suggests that the "B" operators might leave the junction circuits connected until they were required for another connection. Present practice, however, prohibits this, because with keyless junctions if the "A" operator were to connect to the junction before the "B" operator had disconnected from the line last in use, a false call would be sent out.

Mr. F. G. C. BALDWIN: The title of the paper implies that the methods which the author suggests should be adopted may be applied in improving the service generally. This is not so, however. The paper deals with central battery systems only, and takes no account of the numerous large magneto systems that are in existence at the present day and to which the alterations described cannot be applied. The central battery system ever since its introduction has been subject to constant improvements, most, if not all, of which have tended to make its operation increasingly automatic, and the author's suggestions are a further step in this direction. If adopted, the methods suggested would constitute a very drastic departure from the standard central battery practice that has been generally adopted not only in this country but also abroad, and it seems very probable that any advantages which might be gained would be more than counterbalanced

Mr. Baldwin.

Mr. Baldwin.

by the disadvantages that would accrue from the introduction of the methods put forward in the paper. From the operating standpoint the adoption of a negative clearing signal seems particularly undesirable. At present the operator has one idea in mind, viz. to keep the signal lamps out; the combination of positive calling and negative clearing signals is certain to be at least disconcerting, and would probably tend towards confusion and error. It seems to me that the author underestimates the extent and cost of the alterations which he suggests should be made. In addition to the fitting of the additional relays and the extra springs to the speaking key, other alterations would practically involve the complete re-wiring of the cord circuits. It is by no means conclusive that automatic disconnection on a manual system is desirable. One of the principles on which operators now work is that they must restore their cords as quickly as possible. This is not altogether with the idea of effecting a quick clear, but also in order that a maximum number of cords may be available. If the operator is aware that the withdrawal of the plug is not absolutely necessary in order to open the subscriber's circuit to further calls, the result will probably be that the cords will not be restored, and discrimination between cords in use and out of use will then be difficult and lead indirectly to an increase in the time of answering, which at present is satisfactorily low. The author has referred, although briefly, to incorrect operating on the part of the subscriber; now the subscriber or his staff is himself frequently responsible for much of the trouble that he experiences, but he usually places the blame without discrimination upon the operators. The average subscriber is not at all anxious, or sometimes even willing, to co-operate in endeavouring to secure a generally efficient telephone service, and he either cannot or will not understand that his indifferent treatment of the telephone causes trouble to his fellow-subscribers. As an example, only as recently as a fortnight ago a subscriber complained to me that the operator declined to accept a call in the "name" of a subscriber and he considered it a hardship that he should be compelled to give the number. The adoption of such unreasonable attitudes by subscribers operates adversely on the telephone service. Then as regards the alleged frequent reply, "Engaged." The average subscriber cares very little or nothing for his incoming traffic. His outgoing calls are his chief consideration. Numerous subscribers' lines are so heavily worked that it is almost an exceptional thing to find their telephones disengaged, and yet when representations are made to them that the present line or lines cannot cope with the traffic they usually decline to have additional lines, and so their customers or clients go elsewhere to do business. The suggestions made in the paper would, if adopted, seem rather to increase the risk of "cut off" than diminish it. In addition to the possibility of the operator restoring a wrong pair of cords, the automatic disconnection advocated in the paper will absolutely sever a connection should a momentary "clear" be given either accidentally by the calling subscriber or by an intermittent defect on his line or apparatus. Such a "clear" would at present be disregarded by the operator.

Mr. Shaw

Mr. HERBERT SHAW: I think the chief reason for the existing dissatisfaction arises from two primary facts. The first is that the National Telephone Company, knowing that

its lease would terminate on the 31st December, 1912, Mr. Shaw naturally intended to make no further capital expenditure than was necessary. The second is that the Post Office never realized that the expiry of the lease was drawing near, and so it took no trouble to prepare for the transfer, especially in regard to the expenditure necessary for new work. The service which has been recently experienced is worse than that under the National Telephone Company, at least in the opinion of many business men. Had Parliament known as much about the telephone service in 1905 as is known now, I am sure that the country would never have agreed to the transfer. In regard to details, I agree that the principle of the measured-rate service is sound. Although I admit that any ordinary flat rate may result in a line being overloaded, I also think that the measured-rate service is exorbitant in price and too limited in regard to the number of permissible calls. I infer this from the experience of other countries, and if the same method of calculation is retained I am convinced that dissatisfaction will be expressed throughout the country. I consider that each subscriber should have a meter on his instrument and that the necessary arrangements should not be solely in the hands of the charging authority. I also think that until some recording meter is so installed the measured rate should not have been introduced. The authorities seem to think that 4,000 calls per annum is sufficient for one line, and that with a greater number it becomes overloaded, although it amounts to only 12 calls a day. I cannot agree with this view. The National Telephone Company considered that 6,000 calls per annum would be a reasonable number for one line. The present charge is too high and the number of calls allowed is too small. Another trouble locally is that there are not sufficient junction wires connecting the City Exchange and the old National Telephone Company's Exchange in Pilgrim Street. I am very glad to learn that at the present moment a further number of extra cables are being installed. I think it will be agreed that it is unsatisfactory to have two separate exchanges; when the new building is erected it is to be hoped that a better service will be available. I do not wholly blame the Post Office authorities: subscribers are very often at fault. An assistant may be asked to ring up another subscriber and, having awaited a reply, informs his principal, who finds that the subscriber required is not there. This is a great nuisance and is responsible for the waste of much time. Greater expedition should also be used in handling calls. Another trouble is that a large number of wires are carried overhead, and naturally some of them are blown down in stormy weather as well as being easily put out of order by other causes. I venture to think, however, that a real and decided improvement has taken place recently and that ultimately many of the evils will be eliminated, as they indeed have been during the last few months.

Mr. H. KITCHEN: In Fig. 1 it appears to me that the lamp signals are confusing. Lamp L₁ glows continuously during the period that the cord circuit is in use; whereas lamp L₂ glows until the called subscriber answers, but it does not glow if the calling subscriber clears previously to the called subscriber. Both lamps glow if the called subscriber clears first. I am afraid this cannot be called an improvement on the present double supervisory signalling. On page 322 the author says in justification of negative

Mr. Kitchen

signalling that the number of lamps glowing is a valuable indication of the operator's load. It is scarcely necessary to point out that an operator's load is not in proportion to the number of cords in use at any one time. The automatic registration of calls described on page 323 appears to be a somewhat delicate arrangement. If I read the diagram correctly, the passage of the recording impulse is made through the flexible contacts of relay R. Connections with two arms are made for a very short period, and as they must also be made simultaneously I shall be surprised if considerable trouble is not experienced in maintaining them in working order. The junction working shown in Fig. 3 has a decided drawback, inasmuch as the "B" operator is unable to test for the engaged signal until the "A" operator has connected her subscriber. This appears to be a retrograde step, and would considerably retard order-wire junction working which is at present the most satisfactory part of central battery telephony. I am afraid that the suggested tone test cannot be regarded as an entirely satisfactory device.

Mr. F. W. GASKINS: I should like to add a few remarks in connection with complaints Nos. 1 and 6, which have so far not been touched upon and which cannot in my opinion be cured by the addition of relays or extra springs in any part of the circuit. The author admits that the complaints are not very specific, and those who are engaged in telephone work are in a position to say that a large proportion of such complaints are without any foundation in fact, whilst many can be—and are—traced to the delinquencies of subscribers themselves. If we take the whole of the telephone subscribers in this country and ascertain the total number of legitimate complaints in hand at any one time, it will probably be found that the ratio is only a fraction of 1 per cent. I am convinced that many of the complaints made by subscribers would never be made at all if they were better acquainted with the conditions inside some of the larger exchanges during the busy hours of the day. There is no doubt, however, that on the completion of the work which is now in progress in almost every large town in the country, such as the installation and extension of internal and external plant of the most up-to-date type, very many of the complaints of the nature of those under discussion will disappear. These schemes are being expedited, since the State telephone authorities are quite as anxious to provide—as are the public at large to obtain—a perfect telephone service. With regard to complaint No. 6, I hold no brief for the operators, but as a member of the staff of the authority responsible for the telephone service, I cannot let the statements made pass unchallenged. I must say that I think the author's remarks with reference to the operating staff are somewhat harsh and perhaps rather stronger than the facts will actually justify. To support this view I would point out two outstanding features which should certainly ensure a service of no less efficiency than was provided before the transfer. In the first place the traffic staff is controlled by practically the same officials as before, and secondly the transferred operating staff especially have been most generously treated in the matter of remuneration, etc., by the Post Office. The author's object is most laudable, but to my mind there appear to be some grounds for doubt as to whether the modification of existing plant by the method

suggested would prove such an unmixed blessing as the paper might afford reason to expect. It is possible to conceive that the additional mechanism proposed to be used and the suggested methods of lamp working might be the cause of an amount of trouble outweighing any improvements likely to follow the adoption of the author's proposals. It would be interesting to have information on this point, and I should like to ask the author whether he would be prepared to take the responsibility of the installation of the proposed extra apparatus, and afterwards of maintaining an exchange, concurrently giving an undertaking that the total number of complaints would be less, or at least no more numerous, than before, if he were to adopt the improvements suggested in the paper.

Mr. W. G. GUNN: Are the improvements suggested in the paper to be justified by the fact that the staff can be reduced; or does the author suggest that as the Government is the paymaster the question of the extra cost is immaterial?

Mr. G. E. GILPIN: I do not quite see how satisfactory speaking-circuit connections could be maintained through four relay contacts as is shown in Fig. 1, for, as has already been mentioned by Mr. Elliott, and also as a result of experience, it is believed that such arrangements usually give rise to working difficulties. In regard to the plugs and cords being left in the answering and multiple jacks after a clearing signal had been given, say on position No. 1, it does not necessarily follow that the subscriber answered on No. 1 position would be the first to originate a second call—as this may be made by the subscriber into whose line the plug in the multiple was inserted—when the calling indication for the latter might be upon, say, position No. 3. At this point the second subscriber could be switched through to a third party, and then if after a few moments the first subscriber called, the operator on No. 1 position would push over the speaking key of the pegs and cords already left in the jacks and so cause a triple connection to be made.

Mr. W. BAXTER: As a telephone subscriber, I should like to say that although the service is not by any means perfect, it is very good on the whole. I concur with the author that much depends upon the competence of the subscriber's operating staff. Some years ago I had experience of a private branch exchange with about 8 or 10 circuits, and as the newest office boy had always to attend to this exchange, complaints were very numerous. Eventually a permanent operator was employed and trouble became almost a thing of the past.

Mr. W. AITKEN (in reply): With reference to Mr. Elliott's remarks about the possibility of premature disconnection by momentarily touching the switch circuit, I may say that this applies also to the full automatic system. On the proposed system the calling subscriber on replacing his receiver will restore everything to the normal. On the common battery system if anybody accidentally lifts the receiver, say when cleaning the instrument, a call is given. The sooner the subscribers are taught that this movement of the switch hook will cause automatic disconnection the better, since full automatic systems will eventually be adopted.

With reference to the space necessary, and generally as to the cost of the modifications, I think that this cost is practically negligible compared with the total cost of a

Mr. Gaskins.

Mr. Gunn.

Mr. Gilpin.

Mr. Baxter.

Mr. Aitken.

Mr. Aitken.

telephone exchange. The cost of an exchange where 50 operators are required may amount to as much as £6 per line, whereas the cost of installing these modifications is probably only about 5s. per line. In modern common battery exchanges special racks are provided to carry relays, and I think that there would be no difficulty in finding room for 34 relays per position. I also do not quite follow Mr. Elliott's point with regard to the number of contacts and relays; in automatic systems more and more relay contacts are being introduced, and they have stood the test of very severe service universally.

Mr. Elliott also remarked about the glare. Should this be found inconvenient the light can easily be subdued by using coloured lamp caps. In regard to supervisory lamps on the horizontal board, Mr. Elliott asks if the pilot lamp would be retained. It is not usual to have a pilot lamp for the supervisory signals, and I have said that the multiple panels remain unaltered. Speaking generally, it may be said that at present lamps are provided on common battery systems to tell the operators to carry out certain functions. I propose to disconnect the line without any signal and to provide signals to protect the called subscribers only. If no lamp is glowing in front of a cord, the cord is idle and there is therefore no need to instruct the operator to do anything.

Mr. Batchelor says that negative signalling is fundamentally wrong, but I do not propose in my system to give any signal at all, as the disconnection would have already been carried out. In a common battery system two supervisory lamps are necessary to inform the operator that the plugs must be withdrawn to disconnect the circuit, but if the disconnection is beyond the control of the operator, why give her such signals? All that is necessary is to tell the operator that the plugs are available for other uses. In the No. 9 common battery switchboard referred to, there were no answering jacks and the line signals were not directly associated with the lines. I believe that these are now being replaced as the small capacity for which they were designed is reached.

Mr. Batchelor also referred to the automatic system proposed by two Post Office engineers. I only know that there is such a system, and that their patent was applied for some eight months later than mine. I have heard that they are obtaining similar results in a different way. With reference to false calls on junctions, once the receiver has been replaced the circuit will be automatically disconnected at both ends.

Mr. Baldwin said that the system is not readily applicable to magneto systems. I believe that it could be applied, but that it would not be worth the trouble. The magneto system for large exchanges is obsolete, and the sooner such apparatus is replaced the better it will be for the service. Mr. Baldwin thinks that the efficiency may be reduced by the introduction of this system. At present if an attempt is made on a manually-operated system to get say a dozen consecutive calls through, it will be found to work exceedingly badly. On an automatic system I have no hesitation in saying that the calls will be effected in one-third of the time. This speaker seems to suggest that operators would leave the plugs in, but the supervisor will of course see that this is not done. I advocate only that the plugs might remain in rather than a calling subscriber be kept waiting. With my system there is nothing

to be gained by withdrawing the plugs instantly, and the operator will answer the calls without any hesitation, knowing that the cords are available for use at any moment.

Mr. Shaw mentioned a point on which I should like to comment, namely that assistants, usually office boys, are deputed to make calls for a subscriber. I think there are two sides to that question. It is most annoying to hear a boy at the other end of a telephone line say, "Is that So-and-so?" and, on receiving the reply "Yes," remark, "Wait a minute," then going away without giving any idea as to who wishes to speak or what is wanted. The service would be very greatly improved if subscribers would initiate their own calls instead of deputing this to boys.

Mr. Kitchen refers to the operation of the meter. I do not anticipate difficulty in obtaining a suitable relay.

Mr. Gaskins said that my remarks in regard to the operators are harsh. I had no intention of being so. He also asked whether I should be prepared to install my system and guarantee that there would be no complaints; but that is not my business.

In reply to Mr. Guns, I put the paper forward as being suggestive, and I think the improvement claimed and the simple way of attaining the results merit very serious consideration. The question of reducing the staff, or rather giving each operator a greater number of lines, is not of primary importance, but rather the improvement of the efficiency of the service.

As to the triple connection referred to by Mr. Gilpin, I do not see why this should be the case. It infers that the plugs are not to be withdrawn in a reasonable time. Should the peculiar combination arise, the operator would also be in circuit and detect the trouble. There is no microphonic action in good relay contacts.

To sum up: I think that too much importance is being placed by my critics on two-lamp supervision. In an ordinary common-battery system there is much in its favour, but I do not agree that even there it is essential as a disconnecting signal. One lamp would be equally efficient if controlled by the caller or either subscriber, as was the case in the "ring-through" system. Double supervision is not effective on common-battery systems when a call is through to a trunk exchange, neither is it efficiently used on "A" positions when connection is made with a junction to a magneto exchange. One signal is also reckoned as sufficient at a "B" position. Double supervision was not invented because it was desirable in itself; it was simply a by-product. The cord circuit had to be divided by repeaters and similar apparatus so as to supply current to the microphone of each line connected, and two signals necessarily followed. They proved useful because they indicated the condition of each side of the circuit.

On automatic systems introduced by the Post Office the disconnect control is placed in the hands of the calling party, proper means being provided to prevent the called party being "hung up." I provide an exactly similar arrangement.

The lamps associated with the answering plug may be coloured red, and they indicate to the operator and the supervisor at any time the number of "live" connections. The calling cord lamps are white as at present, and indicate by glowing that the called party is being "hung up." They also act as supervisory lamps to indicate when the

Mr. Aitken.

called party answers. The fact that no lamps are glowing indicates idle cords, as at present—whether the plugs are in their sockets or in jacks. Where is the negative signalling? No signal is necessary to disconnect and none is provided. The operator, when convenient, returns idle plugs to the sockets.

The interpretation of the signals is certainly slightly different from the present common-battery methods, but so slight that an operator would learn it in two minutes, and in a minutes would appreciate all the advantages accruing from the lessened responsibility and ease of

operating. Knowing that the disconnection was under the control of the subscribers, that the lines immediately thereafter test idle, and that a lamp glowing (otherwise than as mentioned above) is a new call for a connection, I believe that the operators' work would be much less worrying and exacting. The advantages from the subscribers' point of view are:—instant release from a connection when the receiver is replaced, repeat calls instantly answered, the reply "Line engaged" reduced to the minimum, together with a number of more indirect advantages.

DISCUSSION ON "ELECTRIC BATTERY VEHICLES." *

SCOTTISH LOCAL SECTION, 24TH MARCH, 1914.

Mr. A. PAGE : It has no doubt occurred to many of us to enquire why this apparently new interest in the development of electrically-propelled vehicles has arisen. It would appear to be chiefly due to the energy of the American manufacturing firms and to the efforts of the electricity supply companies in cities like Chicago and New York in obtaining new business. The matter seems to have been taken up in this country during the past two years mainly because of the desire of central-station engineers for more load of the off-peak class. The increasing cost of petrol and the smell and noise of petrol-driven vehicles have also given an impetus to the movement. The evolution of the Edison nickel-iron-potash cell has latterly afforded those engineers who did not believe in any form of lead battery a feeling of returning confidence in the possibilities of the electric vehicle. Those interested in public health are also keenly alive to the possibilities of electricity for the propulsion of vehicles. It is agreed by all who have considered the question that if the smell of petrol and the soiling of our streets due to horse traction could be eliminated, a considerable addition would be made to the amenities of passenger traffic in main thoroughfares. There is a popular misconception that a battery-driven vehicle must always run at low speeds. It is quite possible, however, to get high speeds provided that the money is spent on battery equipment and motors of sufficient power. It is well, however, to acknowledge that the higher speeds are the legitimate sphere of the petrol-engine vehicle and should be left to it. The standard speeds now fixed by electric-vehicle manufacturers are the outcome of long tests to ascertain the most economical speeds at which these vehicles should be run. It is claimed that they run at a fairly constant speed—the average of the very high and the very low speeds of the petrol car. The tendency of petrol-car drivers to maintain full speed so long as they can do so with impunity, is at once very costly in tyres and in the wear and tear of working parts, in addition to being quite unnecessary. At present the electric vehicle may be most advantageously used for city work, especially for commercial purposes. Its advantages are the ease of manipulation, absence of noise and smell, low maintenance cost

(especially for tyre renewals), absence of reciprocating motion, low running cost, high starting torque, rapid acceleration, and easy hill-climbing. The disadvantages are the limited radius of operation and high first cost. Where electric vehicles are confined to the class of work for which they are peculiarly adapted these objections are unimportant. In the electric vehicle there are no cylinders, gear box, carburettors, ignition, magneto, or clutch to cause trouble. The lead-sulphuric acid battery, which 10 years ago was the cause of the failure of several well-meant efforts to popularize the electric vehicle, has been very greatly improved within the last five years. The question of whether a lead battery or an Edison battery should be employed resolves itself into what the buyer is prepared to pay in the first instance. A first-class lead battery can be obtained at about one-third of the cost of the nickel type. The lead battery with careful attention will run a vehicle 10,000 miles on good roads. The Edison battery, on the other hand, is guaranteed for four years, and no reservation is made regarding mileage. It is possible in four years to run a vehicle 60,000 miles. On the whole I think that the balance of argument is in favour of the Edison battery, although I know that in America many people say they prefer to have a new lead battery every year. Recent improvements in lead cells are the reduction in weight and the increased strength of the plates, the use of separators between plates, and generally the production of a sound, workmanlike article with the cell totally enclosed and no chance of leakage of the electrolyte.

The Edison cell has positive plates of nickel hydrate and negative plates of iron oxide. The electrolyte is an alkali consisting of a 20 per cent solution of potassium hydrate plus a small percentage of lithium hydrate. The positive plates in the A.4 size are made up of 15 double rows of spirally-wound steel perforated tubes. The spirals are held in position by 8 steel rings threaded on to the spiral tubes, the spirals having double-lapped seams. The diameter of each spiral is 0.25 in. The nickel hydrate or active material fills the steel tube in a series of thin layers, between which is placed metallic nickel. This latter is used as a conducting substance, so as to give as many paths as possible for current passing through the tube.

* See p. 493.

Mr. Page.

The 30 tubes are held vertically by a steel supporting frame. The negative plate consists of three rows of thin nickel-plated steel pockets finely perforated. Each pocket, after being filled with iron oxide, is subjected to high pressure, so that all the pockets become practically a part of the electro-plated supporting grid. Each cell of the size shown contains four positive and five negative plates. The plates of each group are bolted together and connected to the terminals in a sound mechanical manner, the terminals being tapered at the part outside the steel boxes. Ebonite is used for insulation purposes between adjacent plates, and also between the plates and the case. The sides of the boxes, which are electro-plated, are corrugated for strength. The terminal rods are brought out through stuffing boxes and glands made of ebonite or compressed paper, which also serve as insulators. The various parts are all fitted so that when the cell is assembled it can be shaken violently without suffering harm. It is also watertight, there being mounted on the cover a valve which acts as a vent to allow gas to escape, but which prevents anything entering from the outside. The valve also acts as a separator, freeing the escaping gas of the entrained electrolyte and returning it to the solution. The filling of the cell with fresh electrolyte or distilled water is effected by means of an opening at the top provided with a special filler. This opening is closed by a gas-tight spring cap. The cells give off no destructive and unpleasant fumes, which are a bad feature of the lead-type cell. The Edison cell has double the capacity of the lead cell for the same weight, although the overall dimensions are about the same in each case, and it can be left without harm for long periods in a discharged state. The size of cell that we use, namely, 150 ampere-hour capacity, costs 72s. each. The voltage of the Edison cell, when fully charged, is 1.8, as against 2.5 for lead cells. To avoid explosion a naked light must not be allowed near the battery while it is being charged. The electrolyte is neutral as far as action on the outer steel case is concerned.

A good feature of the electric vehicle is that owing to the presence of a battery motors can be installed on trucks for driving pumps or cranes. In other words, the electric drive has the same range of flexibility in a vehicle which it has elsewhere. It is difficult at present to secure reliable information regarding the cost of running electric vehicles. Judging from the number of people who call to discuss the question at the Glasgow Corporation Electricity Department offices, there is no doubt that very little encouragement is needed to ensure a large fleet of electric vehicles being in use in Glasgow in the near future.

It may be of interest to describe the electric van belonging to the Glasgow Corporation Electricity Department: The vehicle is of the light van type to carry 2,000 lb., and the chassis was built by the Anderson Electric Car Company of Detroit. The body was built in this country to our requirements. There are no changing or reversing gears, the former being accomplished by cutting resistance "in" or "out" in conjunction with a series-parallel arrangement of field, the latter by a reversing switch. A tray fixed to the chassis below the floor level carries the cells. This tray is large enough to take 60 cells of the Edison A.6 type, having a capacity of 225 ampere-hours,

but in this vehicle 60 of the A.4 size of Edison cell having a capacity of 150 ampere-hours are installed. The motor is four-pole series-wound. The handle for working the controller and the reversing switch is placed at the steering wheel. The controller is of the drum type giving four forward and four reverse speeds. An ampere-hour meter is fixed to the front of the dash-board and registers the input and output of the battery. When charging, owing to the instrument being constructed with a differential shunt, the pointer comes back to zero more slowly than on the discharge, the meter thus automatically allowing for the loss in the battery. Our usual method of working is to charge at the normal rate of 30 amperes during the night for seven hours. This time is, however, often reduced by starting at 50 amperes and working back to 30 amperes as the battery voltage rises. Boosting charges are given at the midday meal hour, charging at the 50-ampere rate, although no harm is done to the battery if the charging rate is increased to four times the normal. The only objection to this method is that the battery does not give the same mileage. The motor drives the differential shaft through a silent tooth chain. Both rear wheels are driven from the differential shaft by roller chains. The motor is geared down 11.6 to 1. There are two foot brakes, one of which acts on the differential shaft and the other on the hub of the rear wheels, the back brake being of the internal expanding type. The weight of the van is 34 cwt., including battery, the weight of which is 7½ cwt. The maximum speed is 10 miles per hour. We chose the A.4 type of cell, which on a good asphalt level road will carry the van 40 miles. Our tests show that the average result to be obtained on Glasgow roads is 33 miles on one charge. The van, empty, as actually tested, will stop and start on a gradient of 1 in 4. The speed up very steep hills is about 3 miles per hour. Solid rubber tyres are fitted on all wheels. The van was purchased in the beginning of March, 1913, since which time the mileage has amounted to 10,200. Table A gives the mileage for four weekly periods up to date, also the number of units per car-mile for each of these periods.

TABLE A.

Glasgow Corporation Electricity Department. One-ton Electric Van—Running Statistics for One Year.

Four Weeks Ending	Units per Mile	Miles run
April 2, 1913	0.65	560
April 30	0.59	813
May 28	0.58	907
June 25	0.54	860
July 23	0.52	949
Aug. 20	0.51	012
Sept. 17	0.53	854
Oct. 15	0.58	775
Nov. 12	0.65	875
Dec. 10	0.65	422*
Jan. 7, 1914	0.66	785
Feb. 4	0.66	957
Mar. 4	0.68	683†

Total mileage = 10,352.

Average number of units per mile = 0.61.

* Repairs 21 Nov.—4 Dec. † Repairs 17—20 Feb. and 26 Feb.—4 Mar.

Page.

It will be noticed that the number of units is less in the spring and summer months than in the winter months. This is undoubtedly due to differences in road conditions. The average number of units per car-mile for the whole period works out at 0.61. It will also be noticed that there have been few repairs. The repairs in March of this year included fitting new tyres to front wheels, new steering rod, new sprockets on the differential, and other small adjustments. In one year we have used one silent tooth chain and three sets of roller chains. From this record we have proved that the upkeep of the van is very much less than what we found by experience to be the case with a petrol-driven vehicle. The workmanship on the chassis is of a very high class. Roller and ball bearings are fitted throughout, the greatest care being taken to get the power of the motor applied to the wheels with the minimum loss. The electric vehicle has displaced two horse vans, and we are getting our work done more economically and in a much smarter manner. It is available for breakdowns and other work throughout 24 hours of the day, and is of great service when a "joiner's squad" is required for emergency work, especially at night, as all the tools and other gear wanted can be taken direct to the breakdown with the men. The chassis cost £560, and the body £45. The running cost depends largely on the use made of the vehicle. To get the best out of it the vehicle must be run as continuously as possible, and for not less than 10,000 miles per annum.

Another point in favour of the development of the electric car is that the price of electricity is steadily falling, whereas the cost of petrol is rapidly and continuously rising. In fact, the price of petrol has gone up 75 per cent during the last two years. In regard to touring by electric vehicles, this will involve the erection of charging stations at proper intervals throughout the country. I am afraid it will be a considerable time before such a development takes place. All the parts of the vehicle will have to be standardized so as to give the minimum of trouble to the electric vehicle user.

Craig.

Mr. J. H. CRAIG: The table given by Mr. Page, showing the cost of running the Edison-battery-equipped vehicle belonging to the Glasgow Electricity Department corroborates other results obtained both in London and in various American cities with similar types of vehicles. Such results undoubtedly justify us in holding that there is a most promising field open to the electric vehicle; but although we can prove its running costs to be less than those of its petrol-driven rival, we cannot expect to convert the purchasing public without a great deal of hard and uphill work. The petrol vehicle has been in the field for some time and is well entrenched in its position, not only for pleasure but also for commercial purposes. When I say this I do not forget that there were storage-battery-driven vehicles years before the petrol vehicle was brought into use. The battery of those days, however, was very different from the improved lead, or the perfected Edison nickel-steel battery of to-day. It was in August, 1892, that I equipped what was, I believe, the first electric vehicle (excepting tramcars) in America. This vehicle was a four-wheeled dog-cart, and was built in Brookline (Massachusetts) to drawings brought from London by a wealthy Boston man who was interested in the subject of mechanical road traction. The motor also came from

London and was a 4-h.p. "Immisc" machine. This Mr. Craig vehicle was equipped with E.P.S. pasted lead cells in ebonite tanks with lids. With the battery and a load of four people the vehicle weighed about 5,000 lb., and having iron tyres and not being well sprung it moved most ponderously. The acceleration was small, but on the level and with a good surface a speed of about 7 miles per hour could be reached. We now have batteries which are absolutely reliable, and under certain circumstances the electric vehicle can show a far lower cost per ton-mile than any other forms of traction. If the Glasgow Corporation Electricity Department will co-operate by providing satisfactory facilities for charging, there seems no doubt of a good demand in the near future.

Mr. W. H. L. WATSON: I understand that the recent Mr. Watson Glasgow municipal deputation which visited London did not buy electric vehicles because there seemed to be great difficulties about charging the batteries. I know, however, that this is not the case in this city, as there are excellent charging facilities in certain districts, and the fault lies with the city electrical engineer who has not advertised these charging facilities sufficiently. I think also that it would be desirable to indicate where batteries can be charged, even though there are only a few electric vehicles in the city. In my opinion there can be no doubt that in the next few years electrically-propelled vehicles will be used very largely in municipal work. In May of last year I received a letter from the Secretary of the Electric Vehicle Association of America, who stated that there were something like 30,000 vehicles in use; and before Christmas 1921 was informed that there had been an increase of 7,000 vehicles during the interval. If municipalities adopt electric vehicles in the future, they should provide adequate charging facilities for public use as well as for their own cars. Owing to the varied voltages and conditions of supply in this country, it is somewhat difficult to make arrangements at present, but in cities like Glasgow charging facilities are doubtless obtainable. I rarely go into a town without going to the supply station and asking for current and to enquire how long would be taken before the mains could be connected to my car. Sometimes I have waited for three hours, and sometimes for only 10 minutes. Occasionally I am charged 3d. or more per unit, and sometimes the charge is nothing.

Of course the supply stations cannot at the present stage do much; but having arranged charging facilities, they can ascertain purchase prices, running costs, number of miles per charge, and a host of data which they can submit to their customers, to whom such information might be made very convincing, as they can get at the user in a manner that the manufacturer can never do. Their reward is the sale of the current at off-peak times, and consequently a much improved load factor. As is usual in these matters the centre of operations is in London, where manufacturers are associated and are doing their utmost to foster fellowship and get assistance from central-station engineers. I should like to point out particularly that when electrical vehicles are sold they are supplied with an ampere-hour meter which shows at a glance the condition of the battery in regard to the amount of energy still left unused, and if the car stops for want of current it is to a great extent therefore the driver's fault. An instance occurs to me where a 2-ton van was loaded to the extent

of 3 tons 5 cwt. The van was capable of doing 40 miles in very dry weather, but 45 miles could be got out of it. The worst road in London was selected for test and the busiest traffic was traversed. It was found that on the average the car was taking 80 amperes on the flat, at the foot of a hill 140 amperes, and on the highest point of it 240 amperes. The van completed 36 miles for 269 ampere-hours at 110 volts, that is 29.5 kw.-hours. The total amount of energy required for the complete charge is 48 units, that is, a cost of 4s. with energy at 1d. per unit. These figures would appear conclusively to recommend the electrically-driven vehicle.

Mr. W. W. LACKIE: The Electricity Department of the Glasgow Corporation have had an electric vehicle in use for a year, and from the returns which I have had prepared I am satisfied that this vehicle is doing the work of two horse vans. A horse and van can be hired in Glasgow for from £12 to £14 per month, and the electric vehicle costs about £24 per month; but whereas the horse and van are only available for 10 hours per day from Monday to Friday, for 4 hours on Saturday, and not at all on Sunday, the electric vehicle is available for seven days per week and 24 hours per day. It is agreed that the petrol car has a sphere for which the electric car at its present stage is not suited; but for town work there is no doubt that the electric vehicle has many advantages over the electric car. In Chicago last year I saw (without exaggeration) hundreds of electric pleasure vehicles, and many of these were driven by ladies. It is a common thing there for a lady and gentleman to drive to the theatre, leave the car at the theatre door, and drive home again when the performance is over. Mr. Dalrymple mentions in his Report on his recent tour in the United States that he saw hundreds of people going to business daily in Detroit with their own cars which they left in the street until the time came for returning home in the evening. These, however, were Ford cars driven with petrol. I was told that in Chicago there are 700 electric commercial vehicles and 3,000 pleasure electric vehicles, as against about 1,800 petrol cars. In Glasgow there are about 3,000 motor-cars, 1,600 motor cycles, and 200 heavy motor vehicles, a total of 4,800, all of them petrol-driven, with the exception of the electric vehicle belonging to the Electricity Department. If the cost of the electric vehicle could be brought down to the price of the petrol car, there is no doubt that it would bear comparison in other respects. I would certainly be satisfied with 10 per cent depreciation on an electric vehicle, whereas it is customary to write off 20 to 25 per cent in the case of a petrol car. With electrical energy at 1d. per unit the cost of fuel is one-third what it is for petrol. There is one point about which I am not satisfied at present, viz. the adoption of 110 volts as the standard pressure for charging batteries. This pressure has been taken from American practice, where they have never adopted pressures of 200 and 250 volts for lighting. I think it would simplify matters very much if the battery-makers would supply in this country a battery suitable for plugging on to a 250-volt circuit with a small resistance. Mr. Page has referred to the Edison battery and the lead battery. I learned in New York that one company were prepared to supply either an Edison battery or a lead battery, but the price for the former was much higher, viz. about 3 times, than the price for the

latter. The lead battery is guaranteed to do 9,000 miles, and after that it can be renewed for £40. It would appear that if the Edison battery lasts for 4 years, which it is guaranteed to do, it is to be preferred to the lead battery. The cost of a lead battery is £72, and of the Edison battery £201, for a half-ton truck. From the supply authorities' point of view when it is considered that a small electric vehicle will bring in £20, a commercial vehicle £30, and a large van motor £50 per annum, it will be seen that the revenue from these vehicles is well worth cultivating.

Mr. W. L. SPENCE: My association with electric-battery vehicles goes back to a three-wheeled two-seated dog-cart designed by Mr. A. B. Blackburn and made in 1897 by the Electric Construction Company, of which he was then General Manager. The control was peculiar: the front wheel was steered with leather reins and was so carried that it tended to run in a straight line. A single pedal brake was provided and the speed was varied by a greater or less pressure on the back-support over the seat. The maximum speed was about 20 miles per hour, and the distance coverable about 30 miles. The photograph exhibited proves it to have been a very presentable vehicle to have been running 16 years ago. It was shown at the Crystal Palace in the year named. Coming to the more modern aspect of the subject, the commercial one, I think that if we are to have electric-battery vehicles generally adopted they will require to be much more moderate in initial cost than at present. I consider that it would be unwise to boost too much the Edison battery, which is practically the subject of Mr. Page's introductory remarks. First cost is very largely considered by prospective purchasers of commercial vehicles; and even if it were universally conceded, as it is not, that the alkaline accumulator is the cheapest in the long run, there would still be scope for the lead accumulator, which can be bought for one-third of the price and has a higher efficiency. Weight is certainly in favour of the Edison type, but when everything is considered the lead-battery vehicle costs less to buy, weighs but little more when loaded, performs as well, and may be no more expensive in ultimate total cost of operation. In connection with the engineering side of the question, the motors used on electric-battery vehicles are invariably series wound, and they are, I believe, never provided with multiple-speed mechanical gear. This I submit is wrong. The storage battery is essentially a constant-voltage contrivance and the motor should be shunt wound in order to suit it. With series-wound motors control is necessarily rheostatic and involves substantial losses. One may have series-parallel control with two motors or with the battery in halves, but that only gives two efficient speeds, and it is much better practice in all cases to keep the battery in a single block charged and discharged as a whole. This can be done quite well with a variable-speed shunt-wound motor used in combination with a multiple-speed gear. As a contribution towards the solution of the problem of a cheap and efficient electric battery chassis I have brought a drawing showing my proposal. The motor will be a small high-speed machine with a variation of 2 to 1, or better 3 to 1. The transmission is by duplicate friction gear of 3 to 1 ratio with two Cardan shafts to two five-axle worm gears and is not provided with a differential. The total speed

variation may be 9 to 1 without any series resistance losses. This is more than adequate to meet all possible requirements. It means that with a top speed of say 25 miles per hour the speed in traffic may be less than a slow walk—2½ miles per hour. The system is fully recuperative, braking being dynamic with all the current going into the battery, and, as speed reduction is torque multiplication, there are no undue demands on the battery at any time either for starting or for hill-climbing, hence the distance coverable on one charge will be increased by 15 to 20 per cent at least, probably much more.

Mr. A. P. ROBERTSON: Mr. Page has put the case of the electric vehicle very well before us, although I think only from the point of view of town work. Doctors and professional men would find that the electric vehicle would be much better than the petrol vehicle if they had some method of charging the former at their own homes, because we all know how easy it is to charge up the petrol vehicle. A doctor might run his car 50 miles a day and be called out in the middle of the night. If his car were at the central station or garage to be charged, it would not be of much use to him, and in such a case he would require some means of charging it at his own door. The electric vehicle for a doctor or professional man is by far the best because of the ease of control and the absence of vibration. These are very useful attributes; and in addition the electric car is very much cleaner and it can be started from the seat. This is one of the uses which will bring the electric vehicle into prominence in towns, and I think there is too much made of it as a commercial vehicle only. There are a great many pleasure petrol cars; I do not know the percentage, but it looks as if there were more pleasure cars than commercial ones, and therefore the pleasure cars should not be overlooked. If, however, an owner of such a car found he could only run the car 50 miles on one charge, he would not go in for the electrically-driven vehicle unless there were facilities for recharging batteries quickly. I think that batteries should be standardized. If that were done and some kind of exchange set up, this form of traction would become much more popular. I suggest that roadside depots might be established for the supply of batteries or for charging, something on the lines of the changing of horses in the old stage-coach days. Such a course is necessary, especially with the pleasure vehicle, but standardization of voltage is also necessary. The question of gears also requires to be considered. We should have some method of running the car at low speeds without inserting resistance. A series-parallel system for the battery would solve this and might be arranged in the controller, which would do away with gears; or if this could not be done, then we must have something similar to the gear of a petrol-driven vehicle. As this form of traction is practically in its infancy designers should specially interest themselves in it.

Mr. E. SEDDON: We have heard a great deal in the past about smoke nuisance from chimneys, but I think that the smoke nuisance from petrol cars is even more intolerable. I agree with one of the speakers that the shunt-wound motor with the shunt field excited across the terminals of the battery whatever the applied pressure to the armature may be, appears to be the most efficient for electric-vehicle work. I believe that the average lead cell

yields from 6 to 8 watt-hours per lb. weight, whilst the Edison cell yields 14 watt-hours per lb. weight, so that the latter type appears to be 100 per cent more efficient than the former. Moreover, Mr. Page's figures show that the cost of Edison cells is about 300 per cent higher than that of the lead type of cells, so that it looks as if the Edison Company would have to reduce the price of their cells if these are to be generally adopted. I notice that present practice with regard to tyres is to use the solid type, even on some of the moderately light vehicles. I think that this is a mistake, as we should do everything possible to increase the mileage of these vehicles; in this respect I should like to quote from a paper read by Michelin, the well-known French tyre-maker, before the International Automobile Congress as long ago as 1900. He gives a number of statistics relative to the efficiency of pneumatic tyres as compared with solid rubber and metal tyres. His experiments are interesting, as showing how the efficiency of the pneumatic tyre in point of traction economy increases directly as the speed of the vehicle. Using an electric wagon weighing 1,980 lb. and a uniform pressure of 80 volts, he obtained the following figures for the tractive effort when running against the wind on a level macadam road over a distance of 1,000 metres:—

Iron tyres	53.9 amperes
Solid rubber tyres	48.5 "
Pneumatic tyres	44.2 "

These results show a saving of 10 per cent for solid rubber tyres and of 18 per cent for pneumatic tyres as compared with iron tyres. The average speed was 7.3 miles per hour. At a speed of 12.3 miles per hour, he obtained a saving of 13 and 28 per cent respectively for solid and pneumatic tyres. Of course, I agree that no one to-day would dream of putting iron tyres upon a vehicle of this kind, but these figures show the advantage of using pneumatic tyres instead of solid tyres. I was surprised to hear Mr. Watson's statement that frequently he could not get his car charged at power stations without waiting some time. I should be very surprised if he could, as there are only a few stations in this country in a position to supply at a pressure of 80 volts or thereabouts, except from large boosters or exciters, which is a costly arrangement. It may eventually be necessary for the battery-makers themselves to provide charging stations; an overall charge could then be made, including maintenance upon a ton-mile basis.

Mr. J. A. ROBERTSON: It is very gratifying, I think, that this important question of battery vehicles is being considered by a committee representing all the interests involved. This is pre-eminently a case for standardization, and although we are very much behind at present, the progress made will be on very sound lines once the industry has become established. One of the reasons why battery vehicles have made so much progress in the United States is the close co-operation which exists between the manufacturers and electric supply authorities. In this country the supply of electricity is largely in the hands of municipalities, and it is therefore more difficult to obtain combined effort. In the past, the tendency has been for the supply authorities and the manufacturers to stand apart; and if this attitude is maintained there is very little hope for the battery vehicle in this country. I believe that the direction in which special

Mr. J. A. Robertson.

efforts should be made is with the commercial rather than with the pleasure vehicle. Municipalities can do much here by adopting battery wagons for collecting refuse and for purposes such as street sweeping and watering. For these purposes the battery vehicle has enormous advantages and the limitations which exist in the case of the pleasure vehicle are of little importance. I visited the municipal garage at Paris in May of last year and saw several refuse-collecting wagons, one of which had been in operation for two years—the result being sufficiently good to warrant the municipality in ordering a large consignment of these wagons. I think that sufficient justice has not been done to the lead-plate battery. For commercial wagons the greater weight of a lead battery does not constitute a serious disadvantage, and in the later types of cells the heavy discharges do not appear to injure the plates to the same extent. Everybody must recognize the great work done by Mr. Edison in developing his battery, and its unique advantages in the way of lightness and mechanical strength will no doubt lead to its general adoption for pleasure cars, but for the heavier commercial cars I believe that the lead battery will hold its own. The limitations of the battery vehicle must not be overlooked, and it must not be thought that the battery vehicle is at once going to oust the petrol car. For a hilly district the cost of maintenance will be much higher and a larger battery will be required than in a district which is comparatively level. I was impressed by Mr. Page's operating figure of 0·75d. per ton-mile for the Glasgow Corporation's battery vehicle. For a petrol-motor wagon of 4 tons' capacity which has been in use for nearly a year in Greenock, the cost of petrol works out at 2·1d. per ton-mile. Of course the district is hilly, and the battery figure would be somewhat higher than that given by Mr. Page, but it would still show a considerable saving over petrol at its present price.

Communicated: No reference has been made in the discussion to the possibility of using electric batteries for tramcars. In districts where objections are taken on the score of appearance to overhead equipment, the self-contained battery-propelled car should have a large field. The depreciation of the battery should be less and the efficiency somewhat better than when used for road work. In considering a case, it would be necessary to compare the first cost of the battery with the saving in overhead equipment and feeder cables, while the battery losses may be set off against the saving in transmission and the improved load factor to be obtained at the power station where the batteries could be charged during the night. Several trials have been made in America and it would be interesting if we could obtain some information in regard to operating costs.

Mr. Lawson.

Mr. J. LOWSON (*communicated*): I can confirm the statement made by Mr. Aytton as to the simplicity of the electric vehicle, its freedom from vibration, smoothness of running, and the consequent lessened wear and tear. This was proved to me about six years ago, when I tested an electric landaulette in London, fitted with an Edison battery of the earlier type. The battery on this car was supplied by the Deutsche Edison Akkumulatoren Company. The capacity was approximately 14 kilowatt-

hours with an average discharge pressure of 80 volts. Mr. Lo. With one charge the car was expected to cover a distance of 56 miles on level well-kept roads when carrying six persons including the driver, and to run at a normal speed of about 16 miles per hour. The battery consisted of 64 nickel-iron cells of the Edison type, containing a 21 per cent solution of potassium bicarbonate, and weighing in all about 11 cwt. The total weight of the complete car was about 30 cwt. It was calculated that the depreciation in the capacity of the battery after two years' running would not be more than 15 per cent. The motor was fixed below the chassis and the power was applied through a reduction gear to the rear axle, giving a direct drive at all speeds. The controller was fixed below the driver's seat, and constructed to give five speeds forward and two reverse. The cost of the above battery at that time was £150, and the price of the complete car £775. If, as Mr. Aytton says, the vehicle of to-day is not to be judged by the experience of even a few years ago, then the electric vehicle is coming to stay, and the sooner the better if petrol is to increase in price at the rate it has been doing lately. It seems to me that the only disadvantage at present of the electric vehicle is its first cost. With reduced prices, charging stations established at all power stations and garages throughout the country, the demand will become very extensive.

Mr. A. PAGE: With reference to charging facilities, Mr. P. Lackie's suggestion that electric vehicle manufacturers should try to standardize batteries for a pressure of about 200 volts seems the most promising way out of the difficulty if space could be found for the batteries. Where charging facilities are required the Glasgow electricity supply authorities will not be found wanting. There would undoubtedly be a considerable increase in the demand for battery vehicles if the first cost were reduced. Our van cost £560 without the body, which came to about £45, so that the overall price was in the neighbourhood of £600; and we obtained a petrol car to do the same work for about £400. The fact has not been sufficiently emphasized in this discussion that the lead battery weighs at least twice as much as the Edison battery; this will militate considerably against the extended use of lead batteries, and also bears on the question of chassis design and tyre troubles. The strong construction of the Edison battery coupled with its light weight is also greatly in its favour. I do not agree with the use of the shunt-wound motor; and if gear changing is adopted, one of the soundest arguments when endeavouring to sell electric vehicles, viz. their simplicity of control, will be lost. As to pleasure cars, there is certainly a field for electric vehicles for professional men, but the fact is that the majority of those who use cars for business purposes want the car for a run into the country at the week-end. We are just at the beginning and are not yet in a position to give these runs into the country, except where there are charging facilities. Until charging stations are provided we cannot push the sale of the pleasure vehicle. Mr. Seddon said that the ratio of the weight of the lead battery to that of the Edison battery was something like 14 to 8; but it should be remembered that the life of Edison cells is 4 or 5 times the life of the lead type of cell.

DISCUSSION ON

"CURRENT-LIMITING REACTANCES ON LARGE POWER SYSTEMS." *

MANCHESTER LOCAL SECTION, 7TH APRIL, 1914.

Mr. A. E. MCKENZIE: I think it is not generally recognized that reactances in some part of a large generating system are highly desirable as a means of reducing the disastrous effects of short-circuits when faults occur either on the generators, feeders, or busbars. In laying out a new system I think most engineers will agree that the best place for the insertion of the reactances will be in the busbar sections themselves, because the feeders and generators can be so arranged that there will be very little interchange of power under normal conditions between the different sections. It is a very difficult proposition, however, for those in charge of generating stations where extensions have been taking place for many years, and where machines of larger magnitude have been gradually installed, to determine the positions in which reactances should be placed, because under certain conditions very great interchanges of power will occur between the sections. I am of the opinion that under such conditions it would be better to install reactance coils in the generator leads so as to limit the short-circuit current of the latter to about 7 or 8 times the normal value. Engineers who contemplate doing this, however, should first of all satisfy themselves that the extra field current necessary to compensate for the drop of pressure across the reactance can be carried by the rotor windings without too high a rise in the temperature of the latter. I myself have quite recently made some tests of this nature, and I found it impossible to use reactance coils in the generator leads. If additional reactance is necessary, I think that where group feeders are supplying a number of feeders, reactances of 4 or 5 per cent can be placed with advantage in the group feeders. I think that the authors have perhaps rather magnified the effect of short-circuits on feeders. During the last 12 years at the Manchester Corporation Stuart-street works, about 95 per cent of the faults on the system have, I believe, started through a fault on one phase of a feeder to earth; and if proper balanced protection is fitted to each feeder, my contention is that in nearly every case the feeder can be disconnected without any consumer on the system knowing that anything has occurred except those on that section which is interrupted. Where the neutral of the system is earthed through a resistance, very seldom need the fault develop into an actual short-circuit between phases. Then with regard to faults on generators which are fitted with balanced protection—and as I have said before, my opinion is that it is the only method which should be used for protecting generators—the same remarks apply: in 99 out of 100 cases the machine will be disconnected before the fault actually develops between the phases; and if a suitable device is used for switching off the field of the generator immediately the main switch is opened, I think that generator-makers will then have fewer repairs to do in the future than in the past. In my opinion, where a new system is being laid out it will be far

better to obtain the reactance necessary to reduce the current on the generators to a safe value by employing high-tension step-up transformers having high internal reactance. Mr. McKenzie.

Mr. S. J. WATSON: The authors apparently deal only with very large generating stations, because they refer to those having an output of 80,000 to 100,000-kw., and then set out to consider whether reactances should be installed in the generator leads, the feeders, or the busbars. In considering the matter in the light of the diagrams, it occurred to me that in the case of a power station with such a large output the plant should be in sections each quite independent of the others. It does not appear desirable that in the case of a 100,000-kw. plant all the machines should be run in parallel on one set of busbars. Certain conditions might arise where exceedingly large currents would be supplied to a fault notwithstanding the use of reactances, and the supply to consumers taking hundreds of kilowatts would thus be jeopardized. Districts or groups of districts should be independently supplied from separate busbars, and with such a large output I think that the economy of the station itself would not suffer to any large extent, because at times of light load it would still be possible to parallel the different sections so that the main generators would run under satisfactory economic conditions. I should have liked some additional information as to the cost, the dimensions, and the losses in these reactance coils. The largest reactance coil illustrated by the authors on the screen was of only about 400 or 500 kw. capacity, although they mention that reactance coils are made to deal with 20,000 kw. It seems to me that considerable housing accommodation will be required for coils of such a large size. The cost cannot be a light matter and there must be appreciable losses, all of which I think would tend to restrict the use of such coils. Dealing with the question of the necessity for reactances, one of the most important points to consider is whether the generator windings can withstand a short-circuit. The authors refer to this question in several places in the paper, and it seems to me that if the generator end-windings are very strongly bracketed—because this is the weakest part in a machine—there need be very little fear for the generator itself if a rather bad short-circuit occurs. In this connection it is worth while remembering that the present tendency is more and more towards the incorporation of larger reactance in the machine itself. The prime cost of such a machine is appreciably reduced, but one of the arguments against this tendency is, of course, that the machine has much worse regulating qualities. This defect, if such it be considered, can easily be provided for by some form of automatic regulator, and in any case the possibility of injuring the generator windings is thereby considerably reduced. Another point which impressed me is that if in the case of a 10,000-kw. power station 3-phase alternating current is.

* Paper by Messrs. K. M. Faye-Hansen and J. S. Peck (see p. 511).

Mr. Watrow: being generated at a pressure of 11,000 volts, this output will represent about 600 or 700 amperes, and even with a bad short-circuit the current that can flow into the fault will not be very high. In the case of a similar continuous-current system, however, where the normal full-load current would be about 25,000 amperes, the current on short-circuit would probably be 10 to 15 times greater than the above, and the possible damage would be rather terrible to contemplate.

Mr. W. T. T. Bateman: The previous discussion seems largely to have circled round the use of reactances for machine protection, whereas I think it should be considered more from the point of view of the switchgear, since a generator can only deliver, say, 25 times its full-load current (this is perhaps a maximum figure) whilst the switch on a feeder or generator circuit may have to interrupt a current equivalent to many such generators in parallel; thus the greater strain comes upon the switch. Probably the largest ordinary type of oil switch is not capable of dealing with a greater momentary short-circuit output than say 250,000 k.v.a. at the instant of tripping, so that where the momentary k.v.a. output exceeds that figure, reactance is absolutely essential from the switchgear point of view. The authors do not appear to have mentioned a type of reactance which has been successfully used to a considerable extent by the American Westinghouse Company, and which comprises a reactance contained within a compound oil switch consisting virtually of two oil switches in parallel. One element of the oil switch breaks first, leaving the other element in circuit with reactance in series, both the latter element and the reactance being short-circuited in the first position by the former element. This second element finally opens the circuit through the reactance, and the current broken at the time of opening the circuit is thus brought within the limits of circuit-breaker design. I should like to ask the authors, What would be the approximate voltage across the generator terminals during a short-circuit when an external reactance is used in the generator circuit? We know of course that the busbar voltage falls to approximately zero, and it would be interesting to know if a voltage approximately normal would be maintained across the terminals. I should further like to ask the authors, What diminution of the final value of the current of short-circuit is due to the fixed external reactance? We know that in the case of a short-circuit on an alternator the current may fall to approximately $2\frac{1}{2}$ times full-load current, due to armature reaction, eddy current losses, etc. That is, the impedance of the generator increases from the instant of short-circuit until the current falls from, say, 10 to $2\frac{1}{2}$ times its normal full-load value. I should like to know what effect the external reactance in a generator circuit has on the later portion of the curve of short-circuit. With regard to Fig. 10, I should like to know the authors' reason for placing reactance coils in the feeder circuits in addition to reactances in the generator circuits; the only reason that I can see, apart from generator protection, being that an attempt is made to decrease the size of the feeder circuit-breakers over the generator circuit-breakers, the generator circuit-breakers being large enough to handle any fault which might occur on the busbars, and the feeder circuit-breakers any fault which might occur on the feeders, the latter fault occasioning a smaller short-

circuit current than the former owing to the additional reactance.

Mr. H. A. RATCLIFF: I should like some further information in regard to the so-called "doubling effect" mentioned on page 511. It appears to be similar to that occasionally obtained when switching on transformers, but I am not quite clear as to the extent of the effect. Is it possibly of sufficient importance to upset calculations relating to the effective reactance of a circuit? If it has the same effect as that obtained with transformers, does it depend upon the previous magnetic history of the circuit, and is it of the same order for both the air-circuit and the partial iron-circuit type of coil? It is difficult to believe that the use of these reactance coils—at any rate so far as the protection of plant is concerned—will be the final solution of the problem. I am inclined to think that in the future design of generators and transformers it will be considered desirable and even necessary to introduce internal reactances for their own protection. Undoubtedly the principal use of reactance coils will be for sectionalizing busbars, and probably also for the protection of switches, for which latter purpose, as Mr. Bateman has mentioned, they can be connected through auxiliary switch contacts and will therefore only be in the circuit momentarily; they can therefore be comparatively lightly built and conveniently enclosed in tanks. One great advantage of external reactance coils arises from the fact that under abnormal conditions the mechanical and electrical strains in a circuit are presumably greatest where the reactance is greatest, and reactance coils are more easily constructed than generators to withstand these strains. It is interesting to note the authors' statement that in the case of transformers the additional internal reactance can be provided without increased cost. There is also one other possible advantage of external reactance coils, namely, under certain conditions it might be desirable to vary the total amount of reactance in a circuit; this would be possible with separate reactance coils, but not in the case of self-contained reactance. Reactance coils for the protection of plant will mainly be used in existing generating stations, and it is therefore perhaps unfortunate that these are the very conditions under which the difficulties incidental to their satisfactory location are greatest. The authors appear to have considerably reduced these difficulties by their particular design of coil; for although in many cases it would be impossible to install the air-circuit type of coil, it would be a comparatively simple matter to install the tank-enclosed and magnetically shielded type. I should like, however, to ask whether the instantaneous reactive effect of the coils under short-circuit conditions is in any way reduced by the presence of iron in the magnetic circuit. It is frequently supposed that reactance in a circuit increases the difficulties incidental to switching operations, that is to say, the greater the reactance in the circuit the more difficult it is for the switch to break the circuit. I hardly think that this is the case in practice, because I think the modern high-tension oil-break switch is far better able to deal with pressure rises than with heavy current rushes, and consequently the reduction in the possible maximum value of the current produced by the reactance coils more than compensates for the possibly increased pressure rise at the switch terminals. It would be a very poor switch indeed

Ratcliff. that was not able to deal with reasonable high-pressure rises across its terminals.

Worrall. Dr. G. W. WORRALL: There does not appear to be any necessity for reactance coils in the generator circuit as a measure of protection to the generators, and although their presence would certainly limit the rise of current at the source, there would be a danger of reduced busbar pressure. The authors seem to favour the reactance coils between the busbar sections, but this would introduce considerable difficulties. In order to avoid error in the instruments and heating of the metal due to the stray field, the air-core reactance must not be near the switchboard; yet if the reactance is installed far away the busbars would have to be extended, and this would introduce difficulties from the point of view of safety. The difficulties might not be so great when each busbar is in a separate concrete cell and the oil switches and instruments are on another floor of the building, as in Continental practice. The introduction of inductive reactance into a circuit would certainly affect the operation, and it would appear that some distinction should be made between overhead lines and underground cables. In the former case the line possesses large inductance and small capacity, but in the latter case small inductance and large capacity, the terms "small" and "large" being used merely relatively. The most serious objection to the use of reactance coils appears to be that they introduce another link in the chain, and hence another source of weakness. It should be the aim of engineers to reduce the number of links, not to increase it; and it seems quite possible that the introduction of this additional apparatus, while safeguarding the system in one direction, would weaken it in another. The one may outweigh the other, but that can be settled only by experience.

Mellis. Mr. D. B. MELLIS: In my opinion the paper has covered the ground very fully, but there is one point which has not been elaborated, and which seems to me to be of great importance. The function of a reactance coil is to deal with very heavy overloads, and consequently if it is to be efficient its inductance must not vary with the current passing through it. In other words, there must be no iron within the coil, as it would become saturated and the induction density would very soon cease to be proportional to the number of the applied ampere-turns. In the high reactances mentioned in the paper for use between busbar sections an external iron circuit is permissible, as the reactance is so great as to limit the current, in the case of a short-circuit, to a comparatively small value, so avoiding the possibility of the iron becoming saturated. In this case, however, the iron is not inside the coil but external to it, where it has by no means so great an effect in controlling what the inductance of the coil will be. If, however, reactance coils are not used, and generator reactance is relied upon to keep the short-circuit current within bounds, the result will not be very satisfactory, as it is not possible to design a generator which has no iron within the windings of its armature. It must be emphasized that armature reaction is not of value for keeping back the instantaneous short-circuit current, but only armature self-induction, and this is controlled by the induction density possible in the iron within the windings. For this reason it would appear that safety can in no case be ensured without external reactance, the coils of which

should be as free from iron as possible. Some speakers Mr. Mellis have referred to the use of a reactance coil, normally short-circuited, but inserted in the circuit when the oil switch trips, before finally breaking. This arrangement would seem not to meet the situation. While it might be of some use in assisting the oil switch to break a moderately heavy overload (in which case the value of a reactance is debatable, since a resistance would be much cheaper), in the case of a really bad short-circuit on a system with a great generator capacity the reactance would be cut out until the enormous short-circuit current had already attained its full value, and the oil switch would be blown to pieces.

Mr. E. THOMAS: It would seem that in point of time our knowledge of this subject is several years behind that of the United States, for we are discussing it as though it were a new matter, whereas it was discussed there at length two years ago and with experience of the behaviour of reactances in practice. It would appear from this paper that the principal importance of the use of reactance arises from the following considerations:—(1) That machines are not safe against the stresses of short-circuit; (2) that under emergency conditions oil switches as now made are not safe protectors of the plant installed; (3) that a shut-down may be avoided by limiting the amount of current that can flow if a feeder or generator breaks down. The paper is written from a manufacturer's point of view, and as the design and construction of machines and oil switches have hitherto been entirely in their hands, the admission of weakness in clauses (1) and (2) must be felt by users of large electrical plant to be very serious and noteworthy. In regard to the machines, it has been agreed that the reactance of the armature itself can be considerably increased. It used to be much greater, and the steady short-circuit current of really good machines by first-class makers was commonly less than twice the full-load current. Better regulation was then demanded; but with the much larger plant and systems now in use it is now recognized as of less importance, and it is agreed that a return must be made to higher internal reactance. Similarly, better clamping and support of the end connections of armature coils are called for and are quite possible. It is not too much to say that no engineer ought now to accept a machine with insufficient internal reactance and coils not supported strongly enough to withstand with a reasonable factor of safety the stresses of infrequent short-circuiting. The low factor of safety of present-day oil switches is a much more serious matter, and their inadequate size would appear to require especial attention. It is well known that with a sufficient length of break well under the surface of an adequate quantity of oil any arc can be extinguished, and experience with the present switches shows how reasonable and practicable the requirements are. Switches that will extinguish emergency arcs will cost more and take more room; but a very moderate extra expenditure with increased provision of space will not be grudged. It is, however, pertinent to ask whether we cannot avoid heavy short-circuits altogether. After discussion with a number of experienced central-station engineers I am satisfied that bad short-circuits in the station itself can be almost eliminated by adopting certain simple precautions. With strongly built machines possessing sufficient internal reactance, with

Mr. Thomas: suitable oil switches, and if the above precautions be taken against short-circuits, the addition of reactance coils will still add a little to the safety of a large station; but to do so they should be very well built and have the phases suitably separated, or they will introduce greater risks than those against which they guard.

Mr. Ferguson.

Mr. S. FERGUSON: Reactance coils have been introduced because of the very high initial currents that alternators give on sudden short-circuit. It seems to me that it is best to put reactances in the generator leads in proximity with the machine; in the foundations, for example. In the majority of English stations reactance coils could not be installed in the generators, feeders, and busbars as the cost would be prohibitive. There are many advantages in installing them in the generator circuits in preference to the feeder circuits, in addition to those arising from the reduced number required in those circumstances and the ease with which they can be installed. When placed near to the generator the reactance coils protect everything, whilst when placed in the feeder circuits they protect the feeder cables and sub-stations only. It is quite unnecessary to protect these beyond a certain distance from the generating station, as the impedance of the feeder is sufficient to limit the current to a reasonable value. A 2-mile length of 0.15 sq. in. cable is as effective in limiting the current on a 5,000-volt system as a 3 per cent reactance coil. It must be admitted that feeder reactance coils are useful in preventing the busbar pressure from falling if a short-circuit occurs just outside the generating station; but are such short-circuits sufficiently frequent to warrant the large expenditure of installing reactance coils on all the group feeders? It is also generally conceded that feeder faults develop slowly and usually go to earth first. Limiting resistance in the neutral cuts down the current and the feeder is cut off before the fault develops into a short-circuit. On reviewing the serious breakdowns which have occurred in the past it is found that far more have been due to central-station faults than to feeder faults. The former would be taken care of by generator reactances but not by feeder reactances. The drop of pressure on the busbars is not so great if a feeder is short-circuited 1 mile or more from the generating station. To take an example: A short-circuit between two phases 1 mile from the generating station on a 0.15 sq. in. feeder; 30,000 kw. of plant (running at $\frac{3}{4}$ load) 6,000 volt 3-phase, having 6 per cent inherent reactance and 6 per cent external reactance. I estimate that the busbar pressure would not fall initially below about 5,000 volts, and the initial current would be of the order of $\frac{3}{2}$ times the normal output of the plant. There would, of course, be a further drop in pressure as the armature reaction asserted itself, but the amount would depend on the speed of operation of the feeder circuit-breaker. Another advantage is that the switches on the whole system need only have a smaller breaking capacity. The authors seem to rate busbar reactances according to the capacity of the busbar sections, whereas I believe it is American practice to rate them on the average normal capacity of the generators. The drop in pressure across the reactance is expressed as a percentage of the "star" voltage and not in terms of the "phase" voltage in the case of three-phase systems. The expression "breaking capacity" in connection with oil switches appears also

to require a standardized meaning. In practice there is quite a number of interpretations of this expression. The ability of a switch to open a short-circuit on a definite size of plant is largely influenced by the inherent reactance of the generators, as well as by the value of external reactance. These factors should receive consideration when the term is defined. With reference to the short-circuit currents described in the paper, it would appear that no account has been taken of the decreased value of the generator reactance due to saturation at the high currents, so that the short-circuit currents will be somewhat higher than the figures given.

Dr. E. ROSENBERG: In the early days of electrical engineering there was no need for artificial reactance. The generators regulated badly, and even with full-load current it was difficult to maintain the correct voltage. The same problem occurred in transformers, which when first built had considerable leakage between their high-tension and low-tension windings, and also a considerable pressure drop on the low-tension side for constant voltage on the high-tension side. A large voltage drop occurred on the cables also. The regulation of generators, transformers, and cables has been improved, but improved too much, and the necessity has arisen for introducing new safeguards which, as has been remarked, mean an additional link, and therefore the possibility of new trouble. We certainly cannot revert to previous practice and build machines, transformers, and feeders of such poor regulation as formerly, because our requirements have become more refined, and nearly constant voltage is now required at the consumers' premises. There is no doubt that for the present these additional reactance coils are necessary in many cases in order to limit the effects of short-circuits, but it is not so certain that they will remain a permanent feature. Reactance coils have been introduced previously for paralleling alternators; it was found that reactance coils inserted in generators which were working badly in parallel sometimes removed this trouble, and it then seemed that the provision of reactance coils for alternators running in parallel would be a standard arrangement. Alternators have since been designed which do not require additional reactance for running in parallel, and I believe it to be possible that the reactances mentioned by the authors will disappear in the future. Generators are built which can reasonably withstand the effects of short-circuits, at least if these do not occur too often. With repeated short-circuits of course a cumulative effect will arise and may cause trouble not only on the end windings, but under certain conditions in the rotor also, especially if the rotor is excited from busbars with considerable resistance in series. Transformers are now designed to resist breakdown under "dead" short-circuits. The extremely close regulation that was sometimes asked for has now been dropped, and by increasing the internal impedance from 1 per cent to, say, 4 per cent, the short-circuit current has been reduced from something like 100 times to more nearly 25 times the normal current, and this the transformers will withstand if properly constructed. Additional reactance in the line is necessary merely because our cables have such an exceedingly low reactance. It is to be remembered, however, that before the introduction of the 3-core cable single-core cables were used. Certain serious disadvantages became apparent, but the possibility

Mr. Ferguson.

Dr. Rosenberg.

remains of designing a feeder with a moderate amount of inherent reactance either by using single-core cable throughout, or by making a certain length of the feeder of single-core cable and only the remainder of 3-core cable. The iron armouring must not be applied in the same way as on single-core continuous-current cables, but the problem of effective sheathing and armouring can be solved for single-core alternating-current cables. Natural reactance is thus obtained, and also increased safety against short-circuits between phases. This can be used for feeders and also for the connection between the machines and the switchboard, introducing there a natural reactance, which although very small is nevertheless useful, especially if the conductors are kept a certain distance apart, and it also does away with trifurcating boxes, which are a source of danger. The appendix dealing with the effect of reactance on the parallel operation of alternators is excellent, and the introduction of the three terms "synchronizing force," "stabilizing force," and "remnant synchronizing force," will make the study of the phenomenon very much clearer in future than it has been hitherto.

Messrs. K. M. FAYE-HANSEN and J. S. PECK (*in reply*): We agree with Mr. McKenzie that for extensions it is often difficult to find space for reactance coils, and that it is also difficult to decide how they should be arranged. This is one reason why we have been very careful not to lay down any very rigid rules regarding the position of the reactance coils. Mr. McKenzie mentioned that feeders and generators usually break down first to earth, and that then a suitable protective gear will cut out the fault before it develops into a short-circuit. He is right in stating that most faults are taken care of in this way, but a certain proportion of them are due to mechanical damage. For instance, faults occur through subsidence of the soil or are due to careless workmen, and in such cases very heavy short-circuits may occur between phases, where no protective gear as at present designed will act quickly enough to prevent the maximum short-circuit current flowing. Reliance must in such cases be put upon reactances in the circuit. We agree with Mr. McKenzie that where transformers are used in series with generators it is quite satisfactory, and is good practice to put the necessary reactance in the transformers.

Mr. Watson advocated the division of the supply for very big stations. This is a matter where the central-station engineer ought to be the best judge, but the present tendency is to build such stations with all the machines connected to the same busbars; and there are sound economical reasons why this is done, while there are indications that generating stations of increasingly larger capacity will be adopted. Regarding the size of reactance coils, the 720 k.v.a. reactance coil mentioned would correspond to a 20,000 k.v.a. alternator, so that the size does not work out to be so large as Mr. Watson fears. The cost is certainly a very serious matter, and it is comparatively high because the reactance has not only to be designed for the normal continuous rating but for the kilovolt-amperes at short-circuit, which of course is even much higher than the normal k.v.a. rating of the generator itself. If the normal k.v.a. rating for such a reactance coil be adopted, the cost would approximate to that of a transformer of 5 to 10 times the capacity. The losses in the react-

ance coils are really very small indeed. Under normal conditions coils of between 5 and 10 per cent of the alternator capacity give between 2 and 4 per cent loss of this rating, so that on the generator itself only a 1 per cent reduction in efficiency occurs, and as the load diminishes the loss is reduced approximately in proportion to the square of the current. It is unquestionable that generators can be made to withstand short-circuits, and more reactance is introduced in these circumstances into the generator, although its regulation is made worse. This is not a very important feature in large generating stations, because fluctuations in load are small, and in addition the regulation is usually effected by means of automatic regulators. It is also true that a cheaper and more efficient generator can be built when the regulation is not such an important requirement. Mr. Watson also refers to the enormous fault current in the case of continuous-current stations. The current may be very large, but it is the value of the kilovolt-amperes rather than the current which has to be considered, and on account of the low voltage of the continuous-current system the resistance in the circuit is always sufficient to keep the number of kilovolt-amperes down to a few times the normal magnitude. Practically in all cases the resistance in the fault is so large that the fault current is not so much greater than the normal full-load current, as is so in the case of high-tension alternators.

As Mr. Bateman says, reactance coils are inserted largely in order to protect the switchgear and to limit the duty of the switches. In this way the cost of the switchgear is often greatly reduced, while in some cases the limit of the breaking capacity of a single switch has been reached, though with the reactance type of circuit-breaker, which is rather an expensive piece of apparatus, we believe that the breaking capacity can be brought up to anything at present wanted. The reactance coil has not only to protect the switches, but it has also to maintain the voltage on other parts of the system during the fault. The voltage on the generator terminals at short-circuit, with reactance-coils in series with the alternator, will depend on the ratio between the armature reaction and the external reactance. Usually it will be something in the neighbourhood of half voltage. With an internal reactance in the generator of 6 per cent and an external reactance of 6 per cent there will be half voltage on the terminals of the alternator with a direct short-circuit. Gradually the generator reactance increases from 6 per cent, and the voltage at the terminals of the alternator falls. Thus the reactance coil has the effect of reducing the instantaneous current at short-circuit to a very large extent. In the case mentioned it would reduce it to one-half, but the reduction in the steady short-circuit current is very small indeed.

Mr. Ratcliff asked about the so-called "doubling effect" and thought that this was the same as that which is met with in transformers. It is the same thing except for this difference, that in transformers when this doubling effect is obtained double the saturation occurs. An air core only doubles the current, but an iron core may increase the current very many times. If the iron core is very near saturation, the value of the current may be very great; but in cases where the iron is far below saturation, as with these choke coils, the current as well as the flux is only doubled.

In reply to Dr. Worrall's question whether any such

and
Peck.

Messrs.
Faye-
Hansen and
Peck.

reactance coils have been installed in this country, some have been supplied for the London Electric Supply Corporation, some for the London County Council, and others are installed on the North-East Coast. Dr. Worrall also spoke about the question of stray fields. These will of course have an influence on any instruments near the busbars if the former are not shielded against stray fluxes, but there is no doubt that the introduction of the air reactance coil also introduces the danger of the instruments reading inaccurately. Dr. Worrall also asked about the possibility of resonance. Resonance may occur just as it is possible between alternators, cables, etc., but we think that the probability of its taking place is not increased by installing reactance coils.

We do not agree with Mr. Mellis's statement that for these reactances no iron should be introduced. If oscillograms of the short-circuit currents in alternators are taken, it is found that the current actually has the normal periodicity, and so long as the iron is not saturated it has exactly the same effect under short-circuit conditions as under normal conditions, so that the iron in reactance coils is no more objectionable than the iron in the generators themselves.

Mr. Thomas asked to what extent external reactances limit the forces on alternator windings. In cases where the reactance is of the same order as the armature reaction of the alternators the current falls to one-half and the forces to one-quarter of their normal magnitude. It may be very easy to design an alternator to withstand the short-circuit forces with reactance coils in series, while in special

cases it may be very difficult to make it to withstand the forces without the reactances, but we think that at present alternators of any size can be made to withstand short-circuits. We agree that it is necessary to use oil switches which are ample for the duty to be performed, but the duty may be much less when reactances are used. We think that it would be unwise to design a very large station without reactance coils unless transformers are used which are designed with the necessary reactance.

Mr. Ferguson mentioned that feeder reactances should not be installed because the resistance of the feeder itself limits the short-circuit current. For a 6,600-volt cable one mile long this is true, but it is very likely that with 6,600 volts a breakdown might occur very much nearer to the station, and the higher the voltage the greater is the danger zone within which the damage might be serious in case of a short-circuit. It is very difficult to say what is the best way of rating busbar reactances, but it is necessary to express the rating clearly. In the paper we have adopted the total capacity of the busbar section as a standard. We think that for busbar reactances it is much better to refer the size of the reactances to the size of the busbar sections rather than to that of the alternator, as there may be one or ten generators on that section and the action depends entirely on the full output of the section. Regarding the breaking capacity of the switches, we agree that this also ought to be stated clearly; probably the best way of doing so would be to state the ultimate kilovolt-amperes which could be broken without rendering the circuit-breaker unfit for service.

THE NEW CENTRAL TELEGRAPH OFFICE, CALCUTTA; AND STANDARD FITTING AND EQUIPMENT OF TELEGRAPH OFFICES IN INDIA GENERALLY.

By C. T. WILLIAMS, Member.

(Paper read before the CALCUTTA LOCAL SECTION 5th February, 1914.)

ABSTRACT.

For several years past the Indian Telegraph Department has been introducing standard fittings into offices, and the new Central Telegraph Office just opened in Wellesley Place, Calcutta, is fitted on standard plans. It is representative on a large scale of the fitting of all offices of any importance in the Department. On the ground floor of the new building there are three entrances, one on the west into the public counter hall, one on the north for the operating and general staff, and one on the south for offices and officers' residences. At this entrance an electric lift gives access to all floors, besides which there is a staircase of reinforced concrete.

The ground floor contains the public hall, the battery and power rooms, the cable room, the workshop, and various dining and retiring rooms for the staff.

On the first floor are the instrument room, message office, cloak room and lavatories, volunteer armoury, the superintendent's and other offices, and a small workshop.

The instrument room is 150 ft. long by 75 ft. wide, and its floor, like all the others in the building except the ground floor, is built on the "Kleine" patent hollow-brick system, covered with $1\frac{1}{2}$ in. of Indian patent stone. The second floor, which is really a mezzanine floor, opens at each end to the instrument room, forming a kind of balcony looking down into it and adding to its apparent size, besides being an additional source of ventilation.

The third floor can later on, if necessary, be used as additional galleries of the instrument room. It is at present divided up into smaller rooms for offices.

The fourth floor, to which access is gained by staircases from the third-floor corridor, contains the quarters of the superintendent and other resident officials.

LIGHTING.

The instrument room has abundant light from windows and upper wall lights on the east and west, the windows all being fitted with the usual "jilmil" shutters for use as sun protection. All walls and roofs are white throughout. Artificial lighting is supplied by 52 inverted reflector pendants with opal shades below and white enamelled dispersing reflectors above, each pendant containing three 50-c.p. Osram lamps.

ELECTRIC FANS.

In the instrument room are 52 three-bladed ceiling fans on a level 1 ft. below the lamp pendants and one fan per 87 sq. ft. of superficial area at a height of 11 ft.

CABLE ROOM.

On the ground floor there is a cable room into which come seven paper-insulated Callender's 20-conductor cables, lead-sheathed. These are terminated in standard

pattern cast-iron boxes filled with paraffin wax with porcelain-insulated terminals. From the terminals the connections to the distribution frame are made by means of 5-conductor No. 20 S.W.G. lead-sheathed cables with I.R. insulation, passing through a trough to the frame. These wires are attached first to a heat coil, and then to the bar of a lightning discharger of the usual pattern, the details of which are shown in Fig. 1. From the front panels of the frame on which the above appliances are carried, connections are made by means of "jumper"

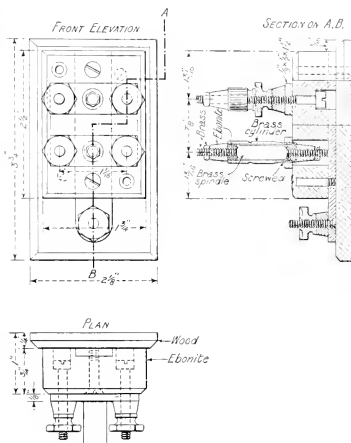

FIG. 1.—Lightning Discharger.

wires to the back panels and thence upstairs to the office "line switchboard" by 5-conductor lead-sheathed cables.

The lightning discharger consists of the small brass cylinder shown in Fig. 1 through which passes a spindle 239 mils in diameter. The air-space between this and the body of the cylinder is 5 mils. The cylinder is screwed into the brass plate to which the line wire is attached, and the insulated rod referred to then makes contact with a common earth-bar fitted underneath. These small-capacity dischargers have been found to be sufficient protection generally in the plains, but for hill stations, where lightning is very much more prevalent, special

plate dischargers with choking coils are used. Of course the far ends of the cables are also protected.

EARTH CONNECTIONS.

In the cable room the earth wires coming from the switchboard (three 7/18 S.W.G. cables) are joined to the two main earths X and Y by cables of four strands of copper wire weighing 300 lb. per mile. The Z or auxiliary earth is formed of a coil of galvanized iron wire buried some distance away in a hole filled with charcoal. Connection is also made with the iron frame of the cable end boxes. The earths X and Y are formed by two $\frac{7}{8}$ -in. thick galvanized iron cylinders buried in charcoal, each being furnished with two copper straps riveted and soldered. One of these cylinders goes down about 12 ft., well below perpetual water level; and the other not so far, as it was found to be impossible to dig so deeply. Provision has been made for watering it by means of a drain in the dry season. The earth X is joined to the instrument tables by 4 strands of 300 lb. per mile copper wire looped all round the instrument room, and the connection to each table is by means of a yard or so of 7/18 S.W.G. cable, so that the resistance is inappreciable. The earth Y is connected to the centre of the battery. The use of three separate earth-wires is generally practised in the Indian Telegraph Department to provide facilities for testing the resistances of the earth-plates. Normally all are joined in parallel, to reduce resistance and to avoid a failure of communication in the event of a leading wire breaking, but for purposes of test X + Y, X + Z, and Y + Z can be taken, and having tested these three pairs by a Wheatstone bridge, or other method, it is easy to calculate the resistance of either X, Y, or Z. The maximum permissible resistance generally is 10 ohms, but the author has known a case where on a rocky plateau the earth resistance was as high as 1,500 ohms.

BATTERY ROOM.

The battery consists of 200 Tudor J2 cells with a capacity, on light discharge, of 73 ampere-hours. This battery, being earthed at its centre, gives a "positive" and a "negative" battery of 200 volts. Voltages are tapped off by lead-sheathed wire 1/18 S.W.G. carried along the battery stands or porcelain cleats to the fuse box and thence upstairs to the battery switchboard by lead-sheathed wires.

The walls or plinths carrying the battery stands, as well as the floor, are coated for $1\frac{1}{2}$ in. with special cement made of $4\frac{1}{2}$ parts of quartz sand to one of Portland cement. This is said to be less liable to be attacked by spilt acid than ordinary cement. The floor slopes towards a common drain and the plinths and floor can be washed down with a hose pipe. The battery stands are of teak painted with 4 coats of acid-proof paint. They are of section $3\frac{1}{2}$ in. deep by 2 in. wide.

The battery leads are 7/18 S.W.G. cables, lead-sheathed and rubber-covered, protected by a special 25-ampere fuse. The voltages supplied to the switchboard in the instrument room are:—

Positive: 8, 20, 30, 40, 60, 80, 90, 100, 110, 120, 140, 160, 170, 180, and 200.

Negative: the same but omitting the 8-volt point, which is used for local bells and automatic switches.

The charging takes place in groups of 40 and 20 cells. Starting from the earthed centre of the battery we have + A = 40 cells; + B = 40 cells; + C = 20 cells; and similarly 3 groups on the negative side. The reason for charging them in this way is that the bulk of the discharge comes on the 0 to 80-volt and 0 to 160-volt points. The 160 to 200-volt portions are used only for the "Wheatstone Automatic" and the "Baudot" systems during such times as the insulation of the telegraph lines is exceptionally low and the received currents at the distant ends are weak. These two 20-cell batteries are therefore charged only occasionally as required.

A special battery of 15 cells is provided on a separate stand for driving the motors of the "Baudot" instrument.

MACHINE ROOM.

In the machine room there is a large switchboard for the three sets of mains which supply the three motor-generators. Two of these pairs of mains are 7/18 S.W.G. and one pair are 3/18 S.W.G. Henley cables. The switchboard has three panels for the three motor-generators and other panels for charging any sets of cells. There are two motor-generators driven at 220 volts and capable of supplying 20 amperes at 120 volts. There is a smaller machine driven at 220 volts at 6.6 amperes and capable of giving 50 amperes at 15 volts. All machines are fitted with field regulators for varying the voltage on the secondary side. The two first-named machines are used for charging the J2 cells at 18 amperes, and the small one for charging groups of 5 "S.G.3" cells at anything up to 20 amperes.

The "Baudot" motors, 20 in number, take about 1 ampere each, and as the Chloride "S.G.3" cells have a capacity of about 120 ampere-hours it is sufficient if 5 cells are charged daily for a short time. There are a few other small motors for the Wheatstone automatic; the "Creed perforator receiver"; the "Gell" Wheatstone transmitter, etc., which are operated from the main battery; but the policy now is to get all motors wound for 220 volts as far as practicable, so that use can be made of the ordinary electric supply.

WORKSHOPS.

The larger repairs are done at the large factory at Alipore, where about 1,000 men are employed in constructing telegraph posts (steel galvanized), wireless telegraph steel masts up to over 204 ft. high, castings, furniture, cable, and apparatus of all kinds. The repair department is always busy, as the whole of India and Burma send repair jobs there. At the Central office there is a workshop next to the machine room with half a dozen Indian mechanics; and there is a small workshop in a room behind the main switchboard, but only one "Baudot" mechanic is usually kept there, to be ready for demands requiring immediate attention.

INSTRUMENT ROOM.

The addressing and gumming of messages is done in the instrument room by people seated on either side of a 30-ft. table. This has a trough down the centre, in which runs an endless belt, so that as the messages in their envelopes are got ready they are thrown into this trough and shot out at the far end for dispatch.

The switchboard is divided into three panels, the right

and left ones being for the battery and the central one for lines and instruments. The voltages required can be tapped off to any particular instrument or group of instruments by means of cord plugs fitting into brass thimbles, which are permanently connected together at the back of the ebonite panel by brass discs. There are also a number of battery points connected permanently to corresponding sets of apparatus. For coupling up a number of tapping-off points U-links are used, whilst any special voltages may be taken off by the cord plugs.

There are 1-ampere fuses fitted on most of the circuits, while the main fuses in the battery room are of 5- and 10-ampere carrying capacity. The wires to the battery room and the cable room go direct from the back

The separators are 12 in. apart and the method of wiring is to pass the wire inside them and bring it out round the separator which is nearest to the point of application and then through a $\frac{1}{2}$ -in. hole in the table to its terminal. This system enables wiring to be done quickly and renewals and changes to be made easily.

For carrying typewriters (of which a large number are used for receiving from Morse instruments instead of writing messages), special recesses are provided on the tables as shown in Fig. 2. Revolving-arm sounder-holders are used with these, which can be adjusted to any height or angle to suit the receiving telegraphist. The typewriters are "Remington," specially made with capital letters only and a special paper roller and tearing-off apparatus. There is

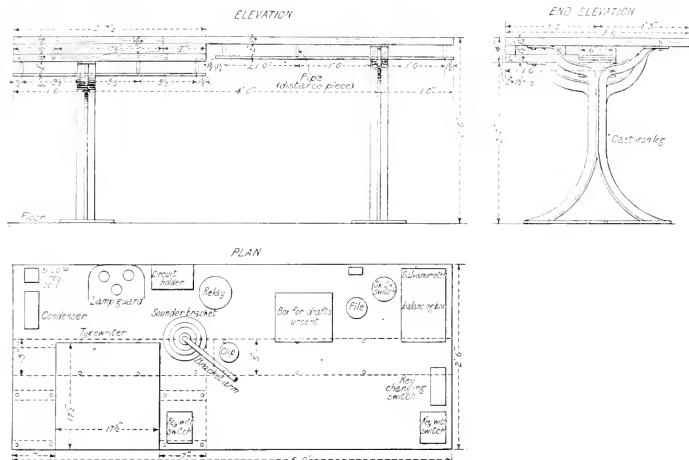

FIG. 2.—Instrument Table showing Typewriter Recess and Arrangement of Apparatus for Simplex-Duplex.

of the switchboard. Also 5-conductor lead-sheathed rubber-covered cables go by steel-lined troughs in the floor to the ends of the instrument tables. There are two troughs 15 in. by $3\frac{1}{2}$ in. one on each side of the room. The troughs are cement-lined and fitted with a sheet steel trough with cover. A bridge piece is fitted opposite to each table on which is riveted a $2\frac{1}{2}$ -in. diameter iron pipe up which the cables go to the table level. Thus the conductors are well protected, and the floor could be flooded with water (in case of fire) without injuring anything.

The instrument tables are of special design (Fig. 2). The legs are of cast-iron and up the centre of the under surface is a wooden wiring trough, consisting merely of a board 6 in. wide separated from the table by 2-in. pieces of pipe through which a wood screw passes.

no duplicate copy; the original is delivered to the addressee and only a skeleton copy of the particulars, i.e. prefix, time, etc., made by a special clerk is retained. There are 32 simplex duplex sets of apparatus in Calcutta so fitted.

The instrument room comprises a Wheatstone automatic section with all the Wheatstone apparatus and two "Creed's Perforating Receivers."

SYSTEMS IN USE.

Morse system.—There are in India and Burma thousands of small offices known as combined Post and Telegraph Offices, and in these the single-current closed-circuit system of Morse is almost entirely used. The battery, as a rule, is at the principal office and except at fairly large offices, where accumulators are used, it is of the Minotto type of Daniell's cell. Normally a current of about 10 to

15 milliamperes is flowing in the circuit, and the armature of the sounder (wound to 500 ohms) is held over against the pull of a spring. On a station pressing the key the circuit is broken and all sounder armatures fly over to the opposite side and give a dot or a dash according to the length of

The function of the condenser is to return the sounder armature to its normal position of rest near its upper stop, but the actual pulling down is done by the battery current. The current can be made very small indeed because, as it is unnecessary to employ a strong spring to return the

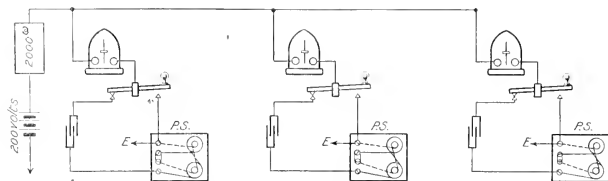

FIG. 3.—Single-current Polarized Sounder with Condenser.

time during which the key is pressed. In the Dubern sounder, which is generally used, the armature is pivoted vertically so that it moves in a horizontal plane, but the ordinary form of sounder may of course be used. The Dubern pattern is particularly sensitive owing to the pole-pieces being arranged to give a pull on opposite ends of

sounder armature to its rest position, it can be, and is, so adjusted that it remains indifferently either at the rest or the working stop. Closed-circuit Dubern sounders are gradually being replaced by Vyle's sounders, which in fact are becoming the standard Morse instrument for all purposes. They are wound differentially and to a high

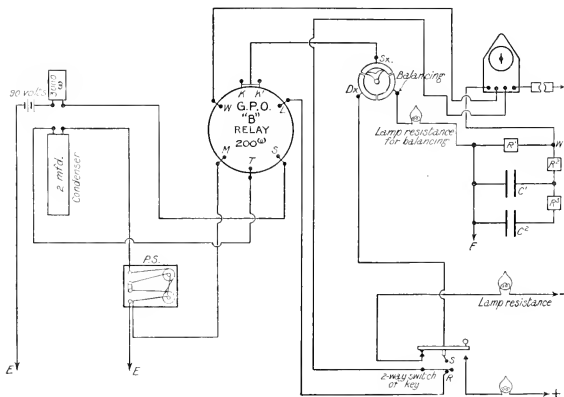

FIG. 4.—Double-current Simplex-Duplex.

the tubular armature. As many as six stations are joined in series.

Polarized sounder-condenser working.—Fig. 3 represents the latest system in use for small offices on lines which are not very long, say up to 200 miles in length, and of which the insulation is good. Normally the line is attached through a 2,000 or 3,000-ohm coil to the battery of about 100 volts so that the condensers are all charged.

resistance, so that they can be worked *direct* on duplex circuits up to about 400 miles in length.

Concentrator system.—For working a number of wires connected to small offices with very little traffic use is made of the "concentrator." There is only one at present in Calcutta. It is connected to 28 "combined" office circuits and these are worked by 12 sets of apparatus instead of 28. No circuit has more than four stations

altogether, that is, three besides Calcutta. When an office has a message he calls CA and this causes the needle of a single galvanometer (or indicator) to oscillate. The attending operator at the concentrator puts his own sounder plug in and answers; if all sets of instruments are engaged he takes the message himself; if not he plugs the line on to a vacant instrument and the message is taken by the operator there. On completion, the operator presses a push button which causes the line to be again connected to its indicator.

Simplex-duplex double-current system.—For long lines the double-current system is used, and Calcutta has nearly 60 such circuits. The author thinks that the connections have been simplified about as far as they possibly can be (Fig. 4). The condenser is normally charged, and on the relay tongue going to marking or M the condenser dis-

charges through the sounder and actuates it. By this method of working great economy of battery power is effected. It will be noticed that two signalling keys are fitted on the special duplex tables for typewriters, together with a switch for changing from one to the other. This is convenient because it permits of single-handed working when desired. The receiving operator can stop the sender.

The Wheatstone automatic system.—The system is worked up to about 150 words per minute between Calcutta and Bombay, and at anything up to 100 between Calcutta and Rangoon (1,110 miles). There is a repeater at Akyab; and, on the route *via* Mandalay, which is about 1,600 miles long, there are repeaters at Gaubati and Mandalay. The system is used for ordinary traffic and news, the latter especially. As an example of its use, on the arrival of the

weekly mail from England a large consignment of perforated tape prepared in London is received at Bombay, is at once passed through the transmitters to Calcutta, Rangoon, Madras, and other places *en route*, and appears in the Friday evening and Saturday morning issues of newspapers as "News by the Mail."

The system has been in use since 1900, and reports of council meetings, speeches, etc., are transmitted by it. The receiver tape is written up by hand, or is typed up; and the speed at which work is turned out depends upon the number of writers or typists employed. It was of the utmost use during the Coronation Durbar. On this occasion the news for English papers was received at Bombay on a Creed's automatic-perforating receiver and the punched tape was then reproduced at about 90 words per minute. This tape was handed to the Eastern Tele-

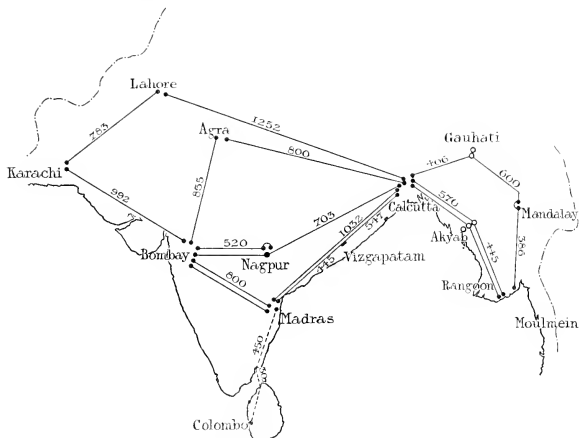

FIG. 5.—Installation of the Baudot System.

graph Company, passed through a machine called a Creed's translator, which turned out tape punched with holes suited for cable transmission, and was then passed through cable transmitters to Europe *via* Aden, Suez, and Alexandria.

On Fridays most of the English mail news for Rangoon is received at Calcutta on a Creed's perforating receiver and as soon as it is received it passes through a transmitter on to Rangoon. In fact one end of the tape is in the transmitter as soon as it is long enough to reach it, and reception and transmitting goes on simultaneously. "Creed's Printers" are about to be installed at Calcutta and Rangoon, which produce by aid of the perforated tape a typed tape at about 90 words a minute. The motive power for all Creed's apparatus is compressed air; and at Calcutta a high-power air compressor capable of

driving several such sets at a time has recently been installed.

There are two sets of automatic high-speed repeaters at Calcutta which enable Bombay, Madras, or Simla to work to Rangoon when necessary for special press.

It might perhaps be mentioned that the bulk of the Indo-European Company's traffic between Karachi and London and Manchester is done by this system, there being no less than 14 automatic repeating stations between Karachi and London. In January, 1909, an interesting experiment was made one Saturday night by joining Karachi through to Calcutta *via* a repeater at Agra, and London was worked through at about 35 to 40 words per minute. After some time London was asked if they would like to speak to Rangoon, and, as they were agreeable, by joining through repeaters at Calcutta and Akyab, London and Rangoon worked both by tape and hand perfectly and exchanged complimentary messages "from the Orient to the Occident." It was quite the *entente cordiale*, and as an interesting experiment in land-line telegraphy has probably never been surpassed. The length of line was over 8,000 miles. The speed obtained was 27 words per minute in one direction and over 30 in the other.

Baudot system.—The Baudot printing telegraph has been in use on the Continent of Europe for many years and was introduced to India in 1905. It is now the most valuable system for ordinary traffic and is in use on the circuits shown on the rough map (Fig. 5). The messages are printed in Roman capitals on a paper tape which is gummed on to telegraph forms. Although fairly complicated the receiver is a marvel of robust workmanship and—for what it does—of simplicity. Given a line free from interruption the amount of work that can be steadily done is most satisfactory. An average of over 150 messages per hour for 20 hours on end have passed between Calcutta and Rangoon; and 120 is common. There is no strain on the receiving operator and the sending operators get so used to the keyboard that it is easy for them to be sending one message and discussing corrections in another at the same time. The author does not mean to infer that this is a usual practice, but it is an easy feat. There are several works on the system, both in English and French.⁶

* POULAIN and FAIVRE—"Cours d'Appareils Baudot"; C. T. WILLIAMS—"The Baudot Printing Telegraph"; HODGE and D'ROZAIRO—"Baudot Multiplex Printing Telegraphs"; A. C. BOOTH—"The Baudot Telegraph System Duplexed." *Post Office Electrical Engineers' Journal*, vol. 3, p. 536, 1910-11; PENDERBY—"Baudot Printing Telegraph"; Departmental Code Book, Indian Telegraph Department—"Hints on Practical Baudot Working."

The author may add that, although the Baudot system works well over 1,000 miles of copper wire without a repeater, it is found to be advisable to use one on some circuits. A special form of repeater is in use, but an ordinary fast duplex Morse repeater can be used. It is first balanced on a Wheatstone set of apparatus and is then switched over to work Baudot. It works quite well, but the drawback is that one cannot read what is passing, so the regular Baudot repeater is preferred where a Baudot receiver can be switched in so that the printing of the passing messages can be observed.

The Indian Telegraph Department was one of the first outside the Continent of Europe to adopt the Baudot system and they have never had cause to regret it. At least one-fourth of the traffic of the Calcutta office is done on it with only 8 or 9 sets of apparatus.

They had for some time in use the Murray automatic printing system, which printed messages in column on a typewriter.

Other telegraph offices.—The author has dealt with all the systems in use at Calcutta and this is necessarily representative of those at other large offices. The most important improvement during the last few years has been the substitution of accumulators for primary cells at most offices of importance. In the smaller offices there is a standard charging plant consisting of two Hornsby-Akroyd 2½-b.h.p. oil engines driving Crompton belt-driven shunt-wound dynamos giving 8 amperes at 135 volts. At some of these offices a few lights are installed and perhaps one or two fans as well; but usually when such an office is now refitted a direct-coupled Lancashire shunt-wound dynamo, driven by a Bellis & Morcom oil engine and giving 27 amperes and 75-108 volts at 900 revs. per minute is installed, and from this the lights and fans for the office can easily be supplied. Most of these offices are of the second class, closing normally at 9 p.m., and the only load—besides telegraph repeaters—after 9 p.m., consists of two or three lamps and a fan for the men in charge of repeaters. The battery used in these offices is generally 200 Tudor J1 cells earthed at the centre and having a capacity of about 20 ampere-hours.

In this paper the author has omitted all reference to outside construction work and has said nothing about the many cables in use for crossing wide rivers, the long spans of steel wire carried by high masts built of tubular steel or of old railway rails, but he has, he hopes, given a fair idea of what is being done by this important public department.

EXAMINATION PAPERS SET AT THE ASSOCIATE MEMBERSHIP EXAMINATION, MAY, 1914.

ENGLISH ESSAY.

(Time allowed : 3 hours.)

INSTRUCTIONS.

Not more than two questions to be answered. One essay of merit will suffice to obtain a pass.

The maximum number of marks obtainable is the same for each question.

Marks will be awarded for grammar, spelling, punctuation, clear and simple style, orderly presentation of facts or arguments, and power of expressing ideas in good English. Candidates are not necessarily required to have special or technical knowledge of the subject-matter of their essays.

1. Discuss the future of aviation, in peace and in war.
2. A common saying is that "History repeats itself." How far is this saying true or false?
3. What is the value of mathematics in science, and what are its limitations, more particularly in respect to engineering science?
4. Should our railways be nationalized?
5. Write an account of the life and character of any person well known in history, science, or literature.

TRANSLATION FROM FRENCH.

(Time allowed : 3 hours.)

Candidates should follow the original French; but if the literal translation should appear awkward or obscure, they should explain their meaning.

A.

On admet généralement ce principe dualiste d'avoir dans un dynamo deux organes dont les fonctions sont bien distinctes: l'inducteur et l'induit; l'un d'eux est ordinairement le stator et l'autre le rotor.

Cela n'est cependant pas une nécessité physique; il suffit que le bobinage de l'induit soit en mouvement dans un champ qui ne coïncide pas avec son champ propre; c'est ainsi, par exemple, qu'un alternateur produisant du courant réactif s'excite sur son propre induit.

Un exemple de machine à excitation interne est le suivant:

Un anneau Gramme à deux collecteurs est entouré d'un anneau de fer; on envoie du courant continu dans un des collecteurs; il se produit un champ magnétique et l'anneau en mouvement donnera une différence de potentiel entre des balais calés sur le second collecteur à angle droit des premiers. Mais si l'on fait débiter du courant au second

collecteur, son enroulement tendra à agir comme inducteur sur l'autre, ce que l'on évitera en plaçant un enroulement compensateur du second enroulement sur l'anneau extérieur. D'autre part la machine peut aisément être rendue auto-excitatrice.

On peut réaliser aussi une machine à excitation indirecte: Soit un induit à collecteur compensé par un bobinage Ryan disposé dans le stator; en plus des balais normaux, disposons à angle droit deux balais transversaux en court-circuit sur le même collecteur. Si la compensation est un peu surabondante, le flux dû à l'excédent est inducteur par rapport aux balais en court-circuit, et il suffit d'un faible champ de surcompensation pour obtenir un fort champ excitateur transversal qui sera utilisé pour la production du courant par les balais principaux et l'enroulement de compensation.

B.

Il s'agissait à Lyon de réunir l'énergie provenant de huit stations centrales hydrauliques indépendantes, pour la distribuer sur de vastes réseaux dont les lignes convergent à Lyon, point extrême de la distribution.

En raison des variations de saison des débits des diverses stations génératrices, il était nécessaire de coupler ces dernières pour profiter des hautes eaux des unes en été, ou des réserves d'eau accumulées par les autres en hiver.

Avec le système de distribution par courants triphasés, il aurait été nécessaire de faire travailler toutes les usines en parallèle, avec le risque de voir le service général interrompu ou compromis en cas de court-circuit ou d'accident sur une ligne.

C'est pour obvier à cet inconvénient que le système courant continu série a été choisi et, comme il s'agit là d'une application spéciale réalisée pour la première fois, car l'installation remonte à 1905, il est intéressant d'insister sur le caractère particulier qu'elle présente et qui met en lumière un avantage offert par le courant continu série.

Des huit stations génératrices hydrauliques de la Société, cinq furent équipées en courant triphasé transporté à 45,000 volts, et trois furent installées avec du courant continu série 150 ampères constants et avec une tension pouvant atteindre 100,000 volts pour une distance de transport de 200 km.

Quinze groupes récepteurs furent installés à Lyon, dont six placés au centre de la ville et alimentés par un câble souterrain, haute tension, placé directement en prolongement des lignes aériennes de transmission.

C.

La présente Note a pour but de faire connaître une méthode nouvelle de chauffage électrique permettant d'éviter l'usage dispendieux du platine dans les fours à résistance métallique et d'atteindre des températures plus élevées qu'à l'aide de ce métal précieux.

Le chrome est, en effet, moins fusible que le platine et très peu altérable; tandis que ce dernier ne peut être chauffé sans danger au delà de 1,600°, le chrome paraît pouvoir fournir des températures voisines de 2,000°; mais

l'absence de malléabilité et de ductilité de ce métal, qui rend impossible l'emploi de lames ou de fils, en a fait rejeter l'emploi.

Il paraît cependant souhaitable qu'à côté des fours à arc engendrant plus de 3,000°, les laboratoires possèdent des fourneaux à résistance métallique, peu coûteux, fonctionnant avec un ampérage modéré et pouvant être chauffés directement à des températures inférieures ou supérieures à 2,000°; l'étude approfondie des réactions endothermiques des fours électriques serait facilitée par ce fait.

Dans ce but, nous nous sommes proposé d'utiliser, comme substances chauffantes des fours à résistance métallique, les poudres granuleuses des métaux réfractaires: chrome, molybdène, tungstène; les essais préliminaires que nous résumons ici ont porté sur l'emploi du chrome, aluminothermique, concassé, pulvérisé au broyeur à boulets, débarrassé de fer par l'aimant, puis trié au tamis; nous espérons revenir bientôt sur l'emploi des autres métaux réfractaires.

On sait que si l'on veut faire passer un courant appréciable à l'aide d'une force électromotrice modérée à travers une masse de grains métalliques, il faut comprimer la poudre; celle-ci obéit à la loi d'Ohm à partir d'une pression minimum dépendant de la nature et de la grosseur des grains. Mais l'emploi de la pression pour frayer un courant son chemin à travers le métal ne serait pas pratique dans le cas d'enceintes chauffantes de formes variées. On peut s'en affranchir par plusieurs moyens.

D.

Dans une Note précédente, j'ai montré que l'écoulement dans un tube capillaire, sous une pression élevée, de solutions même très concentrées de sulfate de cuivre dans l'eau, produisait aux extrémités du tube une différence de potentiel: 1° proportionnelle à la différence de pression; 2° d'autant plus petite que la solution est plus concentrée.

J'ai fait depuis des expériences avec des pressions pouvant atteindre 300^{mm} et j'ai mesuré la différence de potentiel produite par l'écoulement de solutions contenant jusqu'à 1 molécule-gramme de sulfate de cuivre par litre. Si l'on porte en abscisses les concentrations en molécules-grammes par litre, en ordonnées la différence de potentiel correspondante rapportée à 1^{mm}, on obtient une courbe de forme hyperbolique ayant pour asymptotes les deux axes de coordonnées. La même forme de courbe se retrouve pour les solutions de sulfate de zinc, d'azotate de cuivre. Le Tableau suivant donne, pour une différence de pression de 1^{mm} et pour diverses concentrations, les valeurs en volts de la force électromotrice de filtration correspondante à chaque sel.

Les forces électromotrices mesurées ne dépendent que de la pression et de la concentration, mais non de la longueur et de la section du tube.

Lors de l'écoulement des solutions de sulfate de cuivre et de zinc, le potentiel à la sortie du tube est plus élevé qu'à l'entrée, indiquant un transport d'électricité positive dans le sens du courant liquide; mais il n'en est pas ainsi pour tous les sels. Les solutions d'azotates de cuivre et de zinc, de chlorure cuivrique produisent une différence de potentiel en sens inverse.

MECHANICS, PHYSICS, AND CHEMISTRY.

Every candidate must take Section A together with either Section B or Section C.

(Time allowed: 3 hours.)

SECTION A. APPLIED MECHANICS.

(Not more than FOUR questions to be answered.)

1. State the laws of friction of solids on solids. Two bodies, A and B, are connected together by a light chain and are pulled along a horizontal ground by another chain attached to A. Find the acceleration due to a pull of 100 lb. weight, the weights being, $A = 80$ lb. wt. and $B = 90$ lb. wt., and the coefficient of friction between each body and the ground being $\frac{1}{3}$. Also find the tension in the connecting chain.

2. Explain how the principle of the conservation of energy is employed in calculating the change of velocity during movement along curved surfaces.

A heavy ball is suspended from a fixed point by means of a light chain. Prove that if the ball be withdrawn from its equilibrium position through any angle of 90° or less and then let go, the velocity gained in falling to its lowest position is proportional to the chord of the arc of fall.

3. Prove that the motion of the centre of mass of a body is the same as that of a particle of mass equal to the total mass of the body acted upon by the vector sum of all the forces acting anywhere upon the body.

A square plate A B C D (side = 2 ft.) is acted upon at A by a force of 2 lb. wt. which acts parallel to A B, and at B by a force of 3 lb. wt. parallel to C D. Find the acceleration of the centre of mass, the total mass being 40 lb.

4. Define moment of inertia and explain the part it plays in connection with the rotation of rigid bodies.

A garden roller (mass = 1 cwt.) is pulled up a lawn whose inclination is 5 in 100. If the handle is inclined at an angle of 45° to the ground find the force required to move it, assuming the rotating part to have a weight of $\frac{1}{4}$ cwt. and a spin-radius (i.e. radius of gyration) of 1 ft.

5. Define simple harmonic motion.

A piston moves backwards and forwards with approximately simple harmonic motion through a maximum range of 4 ft. in half a second. Write down an equation for the motion; also one to give the velocity at any instant; and calculate the kinetic energy at distances of 1, 2 and 3 ft. from the end of the stroke; the mass of the piston being 200 lb.

6. Define the metacentre of a floating body and explain how its position can be ascertained from theory.

Prove that a cubical block of wood will not float horizontally in water although it does so in mercury. Take the specific gravities of wood and mercury as 0.5 and 13.6 respectively.

SECTION B. PHYSICS.

(Not more than FOUR questions to be answered.)

1. State the principal properties of saturated and unsaturated vapours.

A mixture of air and water-vapour is enclosed above the mercury in a barometer tube whose open end is immersed in a deep vessel of mercury. If the tube be lowered so as progressively to alter the pressure of the contained gas how will the volume change?

2. State the two laws which govern the transformation of heat into work, and outline the experimental evidence upon which they rest. How is the transformation effected in an ordinary heat engine?

3. In what way does the illumination of a surface depend upon (a) the distance from the source, (b) the obliquity of the surface to the incident rays.

Prove that if three sources of light simultaneously cast shadows of a rod which are equally dark, then the intensities of the sources are directly as the square of their distances from the screen.

4. Define the refractive index of a body for light. How would you measure with accuracy the refractive index for different colours for glass in the form of a prism?

5. Obtain a formula for the couple on the coil of a suspended coil galvanometer, all necessary data being supposed given.

6. Show by considering three arms, containing batteries and connected in parallel, that the current in any arm is the sum of the currents which would flow in that arm if the three batteries each acted alone the other two being absent.

SECTION C. CHEMISTRY.

(Not more than FOUR questions to be answered.)

1. Give a short account of the modern method of preparing oxygen, and explain how you would examine a sample of this gas for (a) nitrogen, (b) water-vapour.

2. A current of electricity is passed through aqueous solutions of potassium chloride, (a) when the electrodes are in compartments separated by a porous septum, (b) when the electrodes are in the same cell and the contents are kept well mixed. Describe the changes which occur in each case. Assume the electrodes to be unaffected chemically.

3. Give a full description of the preparation of any two of the oxides of nitrogen and explain the method you would use to determine the percentage composition of either of them.

4. To what substances in solution is the hardness of water usually due? How may the hardness be determined? State what you know of any processes for softening hard waters.

5. What volume of ammonia, measured at standard temperature and pressure, is required to neutralize 50 cubic centimetres of a solution of sulphuric acid containing 49 grams of H_2SO_4 per litre.

(Atomic weights, H = 1, N = 14, O = 16, S = 32.)

6. Mention two oxidizing and two reducing agents, and describe experiments with them to illustrate their properties as such agents. Where possible write equations to express the chemical reactions involved.

ELECTRICITY SUPPLY: GENERATION, TRANSMISSION, AND DISTRIBUTION. (FIRST PAPER.)

(Time allowed: 3 hours.)

(Not more than EIGHT questions to be answered.)

1. Explain the terms: reactance, power factor, hysteresis, impedance.

2. Describe, with accompanying sketch, some form of synchronizing gear for paralleling alternators.

3. A power station is to be designed to give an effective output of 5,000 kw., with an annual load factor of 25 per cent. State what number of generating sets would be best installed, and their sizes, having due regard to adequate reserve plant. If turbo-alternators are to be employed, state what evaporative duty of boilers would be required; and assuming that surface condensers are used and that the circulating water has an inlet temperature of 56°F ., what maximum quantity of water per hour would be required with a 5,000-kw. output.

4. State the advantages and disadvantages of electrically-driven *versus* steam-driven auxiliaries in any average power station.

5. Compare the use of aluminium and copper for a 3-phase transmission line in which spans of not less than 200 yards must be adopted. The conductivity of copper and aluminium being in the ratio of 10 to 6, the tensile strengths as 2.44 to 1, and the relative costs as 7 to 10.

6. Explain what is meant by corona; and state the general effect of high altitudes on high-pressure transmission lines.

7. A load of 100,000 k.v.a. is to be transmitted a distance of 6 miles by underground cables. The pressure to be adopted is 20,000 volts between each of the 3 phases. What would be a reasonable section of cable to employ, and what number of cables should be laid? Describe generally how they should be laid so as to ensure practical immunity from failure of supply.

8. Describe with diagram some practical automatic method of cutting out a high-tension cable in the event of breakdown of insulation.

9. What is the advantage of a 3-wire system as compared with a simple 2-wire distribution?

10. It is proposed to distribute energy by a 3-phase 4-wire system, and the declared pressure at the consumers' terminals is 220 volts. For what pressure should a 3-phase motor be wound, and how should the whole installation of motors and lighting be connected so as to prevent any unbalancing of such a distribution system?

11. Describe some well-known form of house service meter; and state what is the practical limit of accuracy.

Also enumerate some of the faults which may occur in practical working.

12. A consumer requires a supply of 3-phase energy for motors representing a total of 100 h.p. Insurance against failure of supply is an important requirement. State what apparatus the supply authority must fix at the consumer's works to enable the public mains, with a pressure of 6,600 volts between phases, to supply the works motors at a pressure of 380 volts between phases.

ELECTRICITY SUPPLY: GENERATION, TRANSMISSION, AND DISTRIBUTION. (SECOND PAPER.)

(Time allowed: 3 hours.)

(Not more than EIGHT questions to be answered.)

1. A power station equipped with 1,000-kw. steam sets has an annual load factor of 30 per cent. (a) What number of units per kw. demand does this load factor represent? (b) Given good condensing facilities and normal boiler-house efficiency, what weight of coal of average calorific value (say 13,500 B.Th.U.) should be required per unit generated for reciprocating engines and turbines respectively, taken as a yearly average?

2. A rotary converter is required to work either converting 3-phase energy to continuous current, or in an inverse way converting from continuous-current energy to 3-phase. Describe what auxiliary apparatus must be supplied with the rotary and why it must be used.

3. Prepare a short classified schedule of equipment required, with an approximate estimate of the cost per kw. for the complete equipment, for a power house containing eight 2,500-kw. generators.

4. It is required to check the steam consumption of a turbo-generator situated in place at a public supply station. What apparatus should be used? Describe shortly the observations which should be taken.

5. The input to a 3-phase star-connected line is 10,000 k.v.a., and the initial pressure is 30,000 volts between phases, the power factor being 0.95. The line is designed for a pressure-drop of 10 per cent of the initial pressure. State

- The current in each conductor,
- The voltage between each conductor and the neutral point at the receiving end,
- The total energy received at the end of the line.

6. Describe what is meant by "skin effect."

7. Describe tests which should be made on any generator, for the measurement of (a) heating, (b) efficiency.

8. What are the effects of a low power factor on the economical running of a power house?

9. A system of 8-ampere continuous-current street arc lamps is to be connected across a 480-volt 3-wire system. Describe, with a diagram, what apparatus should be used to ensure a steady arc. How many lamps should be run

in the series; and what number of Board of Trade units would be consumed by the series of lamps in a year of 4,200 lighting hours?

10. What steps should be taken in a tramway (rail return) system to comply with the Board of Trade Regulations as to track leakage?

11. Describe, with diagram, the equipment necessary to complete a service between a public supply main and the consumers' terminals.

12. It is required to ascertain the distribution of light from a street arc lamp. Give a description of the apparatus which should be used and state how the tests should be made.

ELECTRIC LIGHTING AND POWER. (FIRST PAPER.)

(Time allowed: 3 hours.)

(Not more than EIGHT questions to be answered.)

1. A station is found to have an annual load factor of 22 per cent—the maximum load is 1,200 kw. What number of units would be sold during the year?

2. Describe, with sketch, an arc lamp, noting the principal parts of the mechanism.

3. Explain the terms power factor and slip.

4. Describe, with diagram, a method of wiring a large building on a 3-wire system, so as to obtain as far as possible a practical balance of load.

5. It is required to record the maximum number of units supplied during any half-hour to an industrial sub-station throughout the year. How can this be done?

6. A rolling mill is to be driven by a reversing 3-phase motor. Describe generally the type of control gear required.

7. A battery is to be used in parallel with a generator to supply a variable traction load. Describe a form of reversible booster which can be used effectively to maintain a steady load on the generator.

8. A portable hand-lamp supplied from a 250-volt circuit has to be used in a wet situation. What means should be adopted to minimize danger from shock arising through faulty insulation or leakage?

9. Describe a form of electrical furnace, with explanatory sketch.

10. A bulk supply is offered at £3 per kw. per annum of maximum demand and 0.33d. per unit metered. This supply has to be converted from 3-phase high-tension to continuous current. The buyer has to provide the necessary converters, which will cost him £5 per kw. to install and on which he allows 10 per cent per annum to cover all capital charges. What will be the resultant cost to the buyer on an annual load factor of 20 per cent, allowing for the average losses in conversion and the supply being taken continuously?

11. Continuous current is supplied to a railway section 2 miles in length on which an average of thirty 200-ton trains run every hour. An average of 65 watt-hours per ton-mile are required to be delivered to the train. State what would be the resultant energy required to be delivered from the high-tension power station after allowance for losses in distribution, rotaries and transmission cables, assuming 3-phase high-tension generation and reasonable proximity of the power house to the track.

12. A tramway system is found on inspection to give 10 volts drop between a distant point on the track rails and an earth-plate at the generating station. Assuming the bonds to be in satisfactory condition and the rail return to be electrically sound, what steps should be taken to bring the drop below the Board of Trade limit of 7 volts?

ELECTRIC LIGHTING AND POWER. (SECOND PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. An installation of four 10-h.p., two 25-h.p., and one 35-h.p. motors, and 100 40-c.p. metal filament lamps is to be supplied from a public supply 3-phase 4-wire main. The pressure across phases is 380 volts, and the lighting is to be, as near as possible, balanced between phases and the neutral. For what pressure must the lamps be supplied; and what must be the section of each core of the service main, neglecting drop in volts?

2. Describe a method for regulating the speed of an alternating-current variable-speed motor.

3. Describe, with diagram, the connections for either a Ward Leonard or an Ilgner plant, for a winder to be fitted in a mine shaft.

4. Sketch, with time as abscissa, and volts as ordinates, the discharge curve on a constant resistance of a secondary battery and describe briefly what are the principal requirements to maintain a battery in efficient condition.

5. Describe one of the following systems of charging for electrical energy :—

- Assessment or rateable value.
- Wright's or Hopkinson's maximum demand.
- Telephone.
- Sliding scale.

6. The power factor on a 3-phase public supply system is found to be very low, viz. 0.65 : what steps can be taken to improve this?

7. What is a negative booster? Describe its application.

8. State the principal requirements in the design of a railway motor for a suburban service having high schedule speeds and frequent stops.

9. What is the advantage of interpoles in the construction of motors?

10. What is a damping coil? Describe its effect on the design of machines.

11. A single-phase system has been installed in a town where industrial power is afterwards required. Describe how this plant and system can be modified to supply power without waste of capital already expended, and state why the single-phase system must be changed.

12. Describe the Hopkinson method of testing generators or motors.

ELECTRIC TRACTION. (FIRST PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. Define schedule speed, train resistance, draw-bar pull, tractive effort and acceleration as applied to railway or tramway vehicles. Discuss the most convenient unit in which acceleration can be measured for traction purposes.

2. An electric train runs with an average speed of 22 miles per hour. The average distance between station stops is 1 mile, and the train stops 20 seconds at each station. What is the effect on the schedule speed of doubling the average speed and making the stops 30 seconds? What is the resulting average schedule speed?

3. A tramcar usually traverses half a mile between two stopping places in $2\frac{1}{2}$ minutes. It is stopped twice for 5 seconds and 10 seconds respectively to take up passengers. What is the average speed for the normal and for the stopping run?

4. A suburban railway about 20 miles in length has a regular service of stopping trains and occasional non-stop trains, both of the multiple-unit-controlled motor-coach type. Current is supplied to the trains through conductor rails from rotary converter sub-stations supplied from a three-phase generating station at 11,000 volts between conductors. Discuss the separate efficiencies and the overall efficiency you would expect to obtain between the high tension switchboard in the generating station and the motor-driven axles of the train :—

- for the frequent stopping service,
- for the infrequent stopping service.

5. In a town with an alternating-current supply of electricity for lighting and a continuous-current supply for a tramway, the tram rails forming the earthed return, the tramway runs for some distance close beside a railway. During Saturday afternoon football traffic it is found that the signalling track circuits on the railway, worked at 2 volts from a battery and using the earth for the return, are interfered with but at no other time. Describe why this is so and suggest the remedy.

6. A tramcar or the motor coach of an electric train is equipped with two continuous-current series motors. Give

a diagram showing first series and then parallel connections of the motors, with the successive cutting out of resistances from the motor circuit, assuming four controller notches with the motors in series and four with the motors in parallel.

7. Show diagrammatically and explain how, in passing from two continuous-current motors connected in series to two continuous-current motors connected in parallel, the change may be made without cutting off the supply from either of the motors.

8. A steam suburban railway service has lost half its traffic due to the competition of a tramway which runs nearly parallel with it for six miles in a densely populated district. The railway passes through a tunnel close to the terminus. Main line and suburban trains are compelled to pass over the same rails in the tunnel. Discuss what hopes there would be of the railway recovering its lost suburban traffic by electrifying the suburban lines.

9. In a conduit tramway the conductor tees (supplied with continuous current) are divided into half-mile sections insulated from each other, and each section is fed separately. It is found that the negative conductor tee frequently goes to earth. Describe the best way of remedying this defect.

10. On a short electric railway with continuous-current motor trains there are never more than three trains on the track at once. Rotary converter sub-stations supply these trains and the daily load factor of the steam generators is 40 per cent. Discuss the effect on this daily load factor of adding batteries (in parallel with the continuous-current sub-station busbars) charged and discharged by an automatic booster. Describe the action of any automatic booster with which you are acquainted suitable for working on a traction load and give a diagram of the field windings.

11. A large industrial town with a non-tidal river flowing through the middle of it has had a tramway system mapped out extending through 100 miles of streets. State whether you would provide one or two generating stations for supplying the 100 miles of tramway route with electrical energy and why.

12. Briefly describe, with sketches, the principle on which any type of surface-contact tramway system works. State the chief difficulties in maintaining a system of tramways worked on the surface-contact system.

ELECTRIC TRACTION. (SECOND PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. For the frequent stopping and starting essential to urban and suburban tramway or railway service what type of continuous-current motor is in general use and why?

2. A tramway some $5\frac{1}{2}$ miles long has 2 miles on the level. Of the remaining $3\frac{1}{2}$ miles there is an up grade to a summit and a down grade, the gradients varying between 1 in 20 and 1 in 100. The power station is at one end of the line. Discuss the best means of making the capital cost of generating station plant and feeders to the track a minimum.

3. A railway proposes to electrify 20 miles of suburban line, on which a service of not less than 4 trains per hour each way is to be run. It is situated in an industrial centre where a power company offers to supply electrical energy at four points in the line at $\frac{1}{4}$ d. per kilowatt-hour output from the sub-stations, the agreement to be renewable every 5 years when fresh terms may be negotiated. Should the railway generate for itself or accept the offer?

4. What are the advantages of commutating poles and of forced ventilation for continuous-current railway motors?

5. If the resistance to movement of a vehicle requires an input of 2 watt-hours per ton-mile for every pound per ton resistance when the efficiency of conversion is 100 per cent, state what actual input in kilowatt-hours per mile you would expect to supply to the motors :—

(a) For a motor-coach train weighing 100 tons equipped with 600-volt continuous-current motors, when running continuously at 30 miles per hour on the level.

(b) For a tramcar weighing 35 tons when running continuously at 12 miles per hour on the level.

6. Give a sketch plan of a car shed for holding 100 electrically equipped tramcars and a repair shop. Indicate the machine tools you would suggest should be provided for all repairs other than car-body repairs.

7. Give a sketch plan of a train shed for holding ten 6-car multiple unit motor-coach electric trains and a repair shop. Indicate the machine tools you would suggest should be provided for all repairs other than car-body repairs.

8. Under what circumstances do you consider it is justifiable to install a conduit system of electric tramways for urban working.

9. The draw-bar pull of an electric locomotive hauling a goods train of 320 tons on the level is 1 ton at 20 miles per hour. What does the pull become on a gradient of 1 in 80 in order to keep the speed the same up the grade as on the level?

10. If in the above example the maximum pull of the locomotive at 20 miles per hour is only 4 tons, to what speed would you expect the train to fall when going up the grade?

11. A double line of tramways with an overhead trolley wire for each line in streets 60 ft. wide changes its direction through a right angle. Poles between the tracks being prohibited, sketch the method you would propose for supporting the trolley wires round the curve.

12. A railway has decided to electrify an existing steam line with 100 miles of single track (of which 30 miles represent sidings) carrying both passenger and goods traffic. It has the option of buying at the same price per kilowatt-hour either single-phase current at a periodicity of 15 at any voltage up to 20,000 or continuous current at 1,500 volts, both delivered at 2 points dividing the line into approximately 3 equal parts. Which supply would you choose and why?

TELEGRAPHY. (FIRST PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. A Telegraph Office in which 2,000 primary cells—30 per cent being bichromate cells—are in use is about to be reconstructed and wired for the lighting of the premises by means of incandescent electric lamps (C.C. supply). The room in which the primary batteries referred to are accommodated is required for another purpose; in consequence, it is proposed to remodel completely this part of the telegraph arrangements at this office. Give an outline of the matters you would take into consideration with a view to determining whether the use of primary batteries should be retained or whether some other source of electric energy should be utilized for the purposes of the telegraph circuits at the office in question.

2. A 45-ft. telegraph pole standing in the back-yard of one of a continuous row of cottages—depth of cottages 23 ft., height of ridge of roof above street level 35 ft.—must be replaced by a 60-ft. pole owing to building operations. The back-yard in which the 45-ft. pole stands and in which the 60-ft. pole is to be erected is completely surrounded by buildings, and it is not possible to carry the 60-ft. pole through any of these buildings. The 45-ft. pole stands at a distance of 30 ft. from the kerb of the footpath in front of the row of cottages referred to and against a wall 8 ft. high parallel to the street in which the cottages are situated. Describe and illustrate with sketches the method you would employ to get the 60-ft. pole into the position in which it is to be erected in the back-yard, and state what tools and appliances you would require for the purpose.

3. Compare the relative advantages and disadvantages of aerial and underground conductors for the purpose of telegraph circuits.

4. It is necessary to carry extra high tension electric power wires across an important aerial telegraph line erected on and along a private road. You are instructed to meet the Engineer to the Power Undertaking for the purpose of coming to an agreement with him (with a view to the protection of the telegraph circuits) as to the method of construction to be adopted in the case of the power line at the point where it will cross the telegraph

line. Explain, with sketches, the method of construction you consider should be adopted in the case of the power line under the circumstances stated. What (if any) alterations and additions would you consider it desirable to make to the telegraph line in order to obtain the maximum amount of protection for the telegraph circuits?

5. A single core submarine telegraph cable, 163 knots in length, has developed an earth fault; the conductor, however, is not broken. Describe, with diagrams, the method you would adopt to localize this fault.

6. Describe, with diagrams, any central battery duplex system with which you may be acquainted and explain the principle involved in the arrangement described by you.

7. Describe a modern type of polarized sounder and illustrate with diagrams, showing the essential parts of the apparatus. State what advantages are obtained by equipping a telegraph circuit with the type of apparatus described by you in answer to this question.

8. Describe, with diagram, the nature of the arrangement which it is necessary to make in connection with the installation of a repeater on a simplex sounder circuit. What is the object of introducing repeaters on telegraph circuits, and under what circumstances is it usual to employ repeaters?

9. What are the principal classes into which receiving apparatus used in connection with radiotelegraphy may be divided? What are the essential requirements which have to be attended to in the designing of such apparatus?

10. Describe, with diagrams, any type of wireless wave meter with which you may be acquainted, and state the principle upon which its construction depends.

11. Explain, with diagrams, what is meant by (a) direct, and what by (b) indirect, excitation of a wireless aerial.

12. Describe, with diagrams, a (wireless) magnetic key and state the circumstances under which this type of key is usually employed.

TELEGRAPHY. (SECOND PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. It is proposed to install secondary batteries, maximum discharge current 7 amperes, for telegraph purposes in an important Telegraph Office with long distance quadruplex as well as minor circuits. The telegraph plant is accommodated in a part of a building already wired on the three-wire system, C.C. supply, 480 volts between outers. Give a description of the plant you would install for charging the secondary batteries in question and draw a

diagram of the connections between the several parts of the charging plant and the batteries.

2. What are the methods usually employed for preserving telegraph poles? Describe the details of one of these methods of preservative treatment and state what (if any) advantages it possesses over other methods of preservative treatment which have been adopted for the purpose in question.

3. State the essential details requiring attention in the design of multi-core types of subterranean cable used for telegraph purposes. Give a description of a type of subterranean cable suitable for long distance telegraphy.

4. A Telegraph Office is located in a brick building of substantial construction, rectangular in plan and facing due west—height from ground-level to eaves-gutter 55 ft. Three main aerial telegraph lines converge on the centre in which this office is situated; the directions from which these lines approach the building referred to and the number of wires on each line being as follows:—

- (i) Line from due East, carrying 42 wires;
- (ii) Line from North making an angle of about 95° with the first-mentioned line and carrying 37 wires; and
- (iii) Line from South making an angle of about 120° with the first-mentioned line and carrying 58 wires.

The office is an important testing station. It is not possible to erect ground poles in the immediate neighbourhood of the office. Describe, with sketches, the arrangements you would make and the structure or structures you would provide for the accommodation of the wires on the building in question and how you would carry the wires into the test-room.

5. State briefly what arrangements you would make and what testing equipment you would provide for tracing and localizing faults on the wires at a Telegraph Office into which 65 through and 40 terminal wires enter.

6. The removal of a Telegraph Office, into which 48 telegraph wires are led, has become necessary. The majority of the circuits, *i.e.* 75 per cent of them, are unimportant from the point of view of the volume of traffic carried over them, which amounts, between 8 a.m. and 8 p.m., on an average to 28 telegrams on the least busy and to 37 on the most busy of these minor circuits. The use of telephones in place of telegraph apparatus is not feasible owing to the existence of disturbing power wires, and by reason of the very considerable cost which would be involved in converting the existing single telegraph wires into loops for telephone working. Describe the nature of the installation you would under the circumstances provide in the new office in this case and give your reasons. Illustrate your answer by means of a sketch plan showing the size of room required (with allowance for expansion), general arrangement of instrument tables, position of the apparatus installed, etc.

7. Describe, with diagrams, the principle involved in the construction of the telewriter type of apparatus.

8. Compare the relative suitability of the Wheatstone automatic and Baudot systems for handling rush traffic at periods of abnormal pressure between important centres. Give a brief description of the transmitting apparatus used in connection with one or the other of these systems.

9. What are the fundamental differences between the spark and the arc systems of radiotelegraphy?

10. What is a wireless multiple tuner? What is the principle upon which its construction depends?

11. What is meant by the efficiency of a wireless aerial?

12. Give a description, with diagram, of the Marconi magnetic detector, and state the principle which is involved in its construction.

MANUFACTURE OF ELECTRIC MACHINERY. (FIRST PAPER.)

(Time allowed: 3 hours.)

(Not more than EIGHT questions to be answered.)

Due consideration will be given to conciseness and neatness of replies.

1. A works requires power from a supply company. Maximum demand 300 kw. The supply available is three-phase at 6,600 volts. Describe with sketches your idea of a suitable sub-station adjoining the works.

2. A firm manufactures a standard line of continuous-current motors. Taking a 10-hp. armature as an example, describe the manufacturing methods and system of checking you would employ to ensure inter-changeability.

What departures from standard dimensions would you consider reasonable to permit at different parts of the armature?

3. Discuss the mechanical difficulties experienced with the commutators of large continuous-current turbo-generators, and the various methods adopted for overcoming the same.

4. Fig. A is a light former made without joint. Describe the special tools and methods you would adopt for the manufacture.

5. A factory turns out a large number of repetition articles, such as are lamps.

Describe what you would consider a suitable system for determining the cost of labour of different processes, and of completed articles; for checking material spoiled, material disappearing, and scrap, and for inspecting

work at different stages of manufacture for throwing out defective work.

6. Various attempts have been made by amateurs to construct a continuous-current dynamo without a commutator. Leaving out of consideration unipolar machines, show from elementary principles why this is not possible.

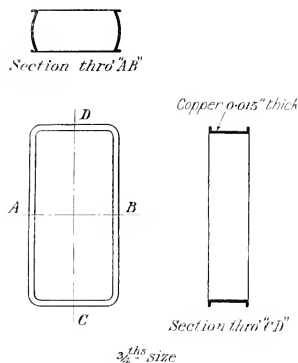

FIG. 8.

7. n points are interconnected in such a way that every point is connected to every other point with a resistance r . Any two of the n points, say a and b , may be taken as the terminals of the system or network.

Show that the resistance of the network between a and b is $\frac{2r}{n}$. If a difference of potential be applied between the points a and b , show that all the remaining points of interconnection are at equal potential.

8. A client requires an electric goods hoist, and states that the maximum load is $\frac{3}{4}$ of a ton, and the maximum height to which the goods are to be raised is 150 feet. The supply is to be 500 volts continuous current. A motor and gear are to be placed immediately above the well of the hoist.

If, without further information, you are called upon to give an approximate estimate for motor and gearing, what assumptions would you consider reasonable to make in determining the rating of the motor, and what is the rating of the motor worked out on your assumptions?

In wording your quotation, how would you safeguard yourself in view of your assumptions?

9. A generating station is to be equipped with ten 5,000-kw. three-phase, 6,600-volt machines. Give your ideas of the arrangement of busbars, main switches

and protective devices. Assume there are 50 outgoing feeders.

10. Give a diagram of a transformer arrangement for converting from 6,600 volts three-phase to 2,200 volts two-phase. Give the transformer ratios necessary.

11. Describe a reversible booster for use with a large battery, and explain its operation.

12. Give an instance of the circumstances in which resonance may arise at some point of a three-phase supply system, and explain the cause of such resonance.

MANUFACTURE OF ELECTRIC MACHINERY. (SECOND PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

Due consideration will be given to conciseness and neatness of replies.

1. A firm proposes to build a factory for :

- Standard Continuous-Current Motors up to 20 h.p.
- Or Alternating-Current and Continuous-Current Supply Meters.
- Or Metallic Filament Lamps.
- Or Lead-covered and other Cables, and Insulated Wires.
- Or Secondary Batteries.

The works are to be suitable initially for a turn-over of £50,000 per annum, but are to be capable of extension at a later date.

Choose any one of the above specialities, and sketch briefly your idea of the lay-out of the works, stating the main considerations which would influence you in the choice of site and locality.

State approximately the number of men you would consider necessary for the above output.

2. In fixing the selling price of a manufactured article, how would you take into account :—

- Cost of Material, Labour, Foremen's Wages, Heat, Light and Power in Works, Staff Wages, Rent, Rates and Taxes, Directors' Fees, Selling Costs, etc.

Discuss the position if the selling price calculated is above the market price obtainable for the article.

3. Fig. 1 represents a spinning. Sketch out a drilling jig for drilling the various holes shown in the sketch, assuming the articles are put through in lots of 1,000 at a time.

4. A firm proposes to equip a testing-room for testing 30,000 Continuous Current, 30,000 Single-Phase, and 1,000 Three-Phase Meters per annum.

What instruments would you install as standards and sub-standards?

Give reasons for your selection, and state what general arrangements you would recommend.

Power Factor" when applied to a three-phase load as a whole?

In Fig. 3 a three-phase generator is loaded unequally on lamps between phases. It is found that the currents in the three legs and line wires are not in phase with the terminal voltages, v_1 , v_2 , v_3 . It would appear from this that the power factor of the load taken as a whole was less

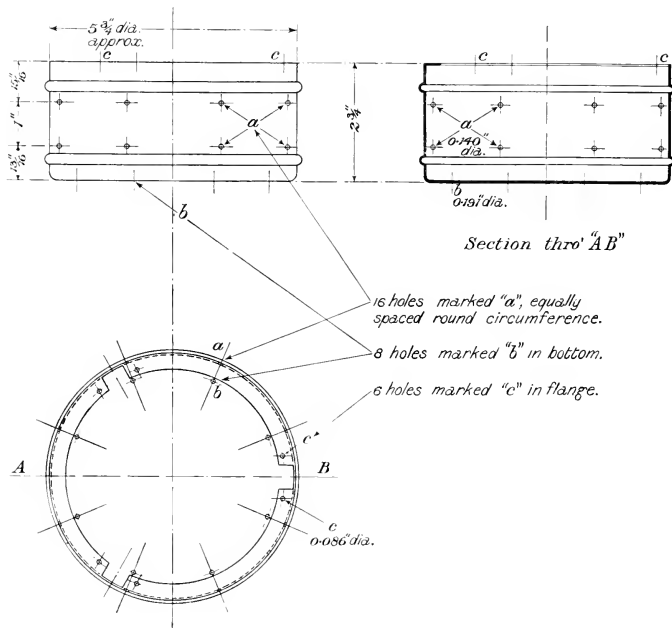

FIG. 1.

5. Fig. 2 represents an oil-switch designed for carrying heavy currents. When tested with full-load continuous current it works comparatively cool, but with the same value of alternating current at 50 cycles, the heating is very considerable. Where would you look for the seat of the heating, and what alterations would you make if re-designing?

6. What do you mean by the power factor of a single-phase load?

Distinguish between the cases when the supply E.M.F. is a sine wave, and when it is not.

Can you assign any meaning to the term "Three-Phase

than unity, although the power factor of each individual portion of the load is undoubtedly unity. How do you account for this?

7. A circular plate weighs 1 pound. 37 discs are punched out of it, these being all equal in size and of the largest size possible. You may assume that the edges of the holes just touch. What is the weight of the scrap?

8. State briefly the chief points dealt with by Mr. Sydney Evershed in his recent paper before the Institution of Electrical Engineers on "The Characteristics of Insulation Resistance."

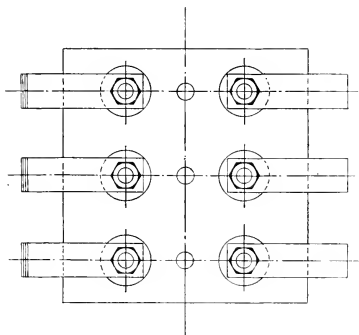

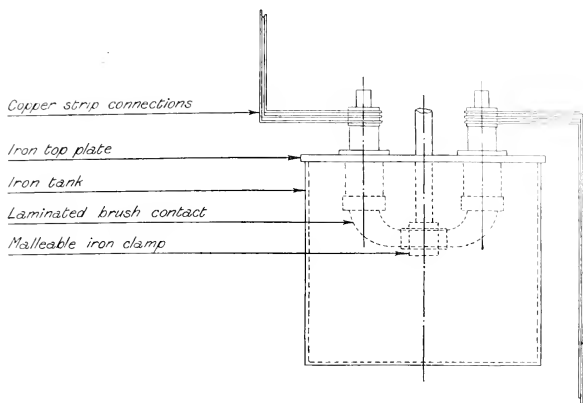

FIG. 2.

9. State the relative advantages of interconnecting a high-tension network throughout, and alternatively, of employing separate and independent feeders, each restricted to the supply of a definite area.

State briefly the methods of protecting feeders, inter-connectors, etc., in the two cases.

10. Give arguments for and against earthing the neutral point of a three-phase extra-high-tension supply system, supplying a widely distributed area.

11. Fig. 4 represents a network of resistances as follows:—

ab	4 ohms.
bc	10 "
cf	12 "
fa	2 "
ac	3 "
cd	3 "
dc	15 "

Show that the resistance between a and c is $5\frac{1}{4}$ ohms, and is independent of the resistance bd and fe .

12. An electric clock takes $\frac{1}{2}$ watt-hour per annum. Express this in foot-pounds per day of 24 hours.

An electric kettle brings a pint of water from 10°C . to the boiling-point in 7 minutes. 40 per cent of the total heat generated is lost so far as the heating of the water is

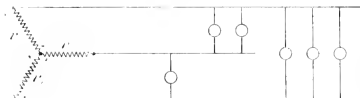

FIG. 3.

concerned. Express the energy supplied to the kettle in watt-hours, and in foot-pounds.

Through a solenoid of copper wire, heavy current is passed for two seconds. The current density is 15,000

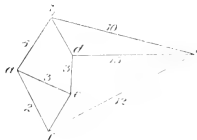

FIG. 4.

amperes per square inch. Determine the outside limit of rise of temperature at any part of the solenoid.

Specific heat of copper = 0.092.

Specific gravity of copper = 8.79.

Resistance of a centimetre cube of copper between opposite faces = 1.69×10^{-9} ohms.

DESIGN OF ELECTRICAL MACHINERY AND APPARATUS. (FIRST PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. A 1,000-kw. 3-phase 50-period 6,600-volt generator is to be designed to run at 500 r.p.m. Calculate :—

- The number of poles.
- The currents which will flow in the windings with a power factor of 0.8 with both delta and star connections.
- The true efficiency for the 3-phase winding at full load and 0.8 power factor, from the following data :—

Armature resistance between terminals : 0.6 ohm.

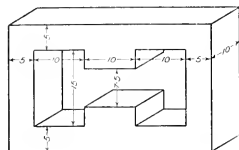

Field resistance : 0.5 ohm.

Field current : 150 amperes at full load 0.8 power factor.

Iron loss : 15 kw.

Friction and windage : 7 kw.

2. Calculate the amount of current required to give an induction of 6,000 C.G.S. lines per square centimetre in the iron for the choke coils shown in the sketch A.

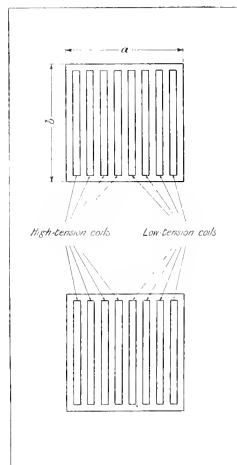

All dimensions are expressed in cm.

SKETCH A.

Number of turns, 50.

Magnetizing force required for the iron at specified induction, 12 ampere-turns (R.M.S. value) per centimetre length.

The current is at 50 periods.

$a = b$

SKETCH B.

3. What are the principal factors determining the section of a commutating pole and the ampere-turns upon it for a C.C. generator ?

4. Enumerate the different methods of obtaining voltage variation in a rotary converter.

5. Describe the relative advantages and disadvantages of squirrel-cage and slip-ring induction motors.

6. It is desired to design converting plant to operate under an average load of 750 kw. The cost of energy is $\frac{1}{2}$ d. per unit. What increase in cost of the plant is justifiable for each 1·10 per cent by which the average efficiency can be improved? Assume figures for interest and depreciation which you consider reasonable.

7. Describe the process of insulating a 500-volt C.C. 3-turn strap-wound armature coil, the section of each conductor being 40 sq. mm. Show cross-section of winding and insulation.

8. Describe the effect on the reactance voltage, of the shell-type transformer shown in sketch B, obtained by altering the proportion of the openings in the iron and by changing the disposition of the coils.

All high-tension coils have the same number of turns.

All low-tension coils have the same number of turns.

9. Describe a method of obtaining phase adjustment and friction compensation in an A.C. watt-hour meter.

10. Describe the construction of any one type of A.C. reverse power relay.

11. In the design of a 10,000-volt oil-switch for handling large amounts of energy, describe the features of design which should be given most careful consideration.

12. Give a diagram of connections for a 3-phase auto-starter, and a diagram of connections for a rotor starter for a 3-phase motor.

DESIGN OF ELECTRICAL MACHINERY AND APPARATUS. (SECOND PAPER.)

(Time allowed : 3 hours.)

(Not more than EIGHT questions to be answered.)

1. Give an armature winding diagram for a 4-pole 3-phase and also for a 2-phase A.C. generator having 24 slots.

2. Why are armature windings sometimes chorded (i.e. made with a throw less than full pole pitch) on :—

- (a) A.C. Generators,
- (b) C.C. Generators.

3. Show a method of calculating the approximate voltage regulation of a 5,000-k.v.a. 3-phase 10,000-volt A.C. generator at unity and at 0·8 power factor lagging from full to no load, the following information being given :—

No load saturation curve, Volts.	Field amperes
8,000	92
10,000	125
12,000	170
14,000	240

On short-circuit 95 amperes is required in the field to give 250 amperes through the armature.

4. Describe the reactance method of obtaining voltage variation of rotary converters and explain the effect upon the power factor.

5. State in a general way the difference between the design of a commutating pole winding for a C.C. generator and for a rotary converter.

6. A transformer of 10-kw. capacity runs 6 hours a day at full load and 5 hours a day at one-half load, while for the remaining time it runs light. What is the difference in yearly running cost between one transformer having at full load 1 per cent iron loss and 2·5 per cent copper loss and one having 1½ per cent iron loss and 1½ per cent copper loss, when the cost per unit (kw.-hour) is 1½ d.?

7. Describe the process of insulating an armature coil for a 6,000-volt A.C. generator having 10 turns per coil, each turn having a sectional area of 20 square mm. Give sketch showing cross-section of winding and insulation.

8. Describe what is meant by an auto-transformer (or compensator) and indicate the currents in the windings of a 100-kw. 3-phase star-connected auto-transformer having a ratio of 1,000 to 400 volts.

9. Describe briefly three commercial types of C.C. ammeters, and make a sketch showing the construction of one of these types.

10. Give a simple diagram of connections showing the switchgear you would propose for controlling four 1,000-kw. 6,600-volt generators with direct-coupled exciters and with 8 feeder circuits.

11. Describe the reason for using the resistance between the neutral point of an A.C. generator and earth, and state how this should be designed with reference to heating capacity and ohmic value.

12. Give diagrams of connections and approximate ohmic values of the resistance required for a C.C. motor starter, 10 h.p., 200 volts.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 23RD APRIL, 1914.

Proceedings of the 568th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 23rd April, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 2nd April, 1914, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Donations to the Library were announced as having been received from The Board of Education, D. Clerk, F.R.S., B. Gati, F. W. Hewitt, A. Home-Morton, A. E. Kennelly, D.Sc., G. A. Puente, W. J. Shaw, A. J. Tanner, and the University of Illinois; to the Museum from F. R. C. Rouse; to the *Benevolent Fund* from J. F. Avila, C. V. Drysdale, D.Sc., S. Evershed, J. Gilligan, R. K. Gray, J. S. Highfield, H. Hirst, E. de M. Makin, Sir Henry C. Mance, C.I.E., LL.D., C. C. Paterson, S. G. C. Russell, Sir David Salomons, Bart., S. Sharp, F. Smith, C. P. Sparks, W. C. P. Tapper, A. M. Taylor, and G. W. Warner; and to the *Building Fund* from W. M. Mordey, to whom the thanks of the meeting were duly accorded.

Messrs. E. A. Nash, R. W. Hughman, and F. B. O. Hawes were appointed scrutineers of the ballot for the election of new Members of Council.

A paper by Mr. H. W. Firth, Member, entitled "Electrification of Railways as affected by Traffic Considerations" (see page 609), was read and discussed, and the meeting adjourned at 10 p.m.

INSTITUTION ANNOUNCEMENTS.

CONVERSAZIONE.

The Institution *Conversazione* will be held at the Natural History Museum, Cromwell-road, South Kensington, S.W., on Thursday, 25th June, 1914, from 9 to 11.30 p.m. Invitation cards will be sent out shortly.

DISCUSSION ON

"CURRENT-LIMITING REACTANCES ON LARGE POWER SYSTEMS.*"

BIRMINGHAM LOCAL SECTION, 1ST APRIL, 1914.

Mr. R. A. CHATTOCK: The importance of this paper can hardly be overestimated in view of the altered conditions that have now to be met in the design and operation of large power stations. Reliability of supply must be one of the first considerations. The sectionalizing of generating plant is recognized as a prime necessity for this purpose. This process is easy as regards boilers, steam pipes, prime-movers and auxiliaries, but as regards switchgear, reliance has hitherto been placed on the breaking capacity of the switches. It has been evident for some time that under certain conditions of operation even the largest oil switches are damaged when they open, and they even occasionally fail to break the circuit. This would appear to be due to the very large amount of energy that is concentrated on the busbars. In modern generating stations this amount of energy is year by year increasing, and even now the limit of safety in the switchgear would seem to have been reached. The proposal to sectionalize the switchgear by current-limiting reactances, so that the energy to be dealt with by the switches now available may be kept within the limits of easy and safe control, is one that will very largely increase the reliability of the supply. The subject is one that has to be considered from several points of view, depending upon the general lay-out of the generating- and sub-stations to be protected, and the adoption of the best scheme is really a question upon which experts should advise. The chief objections to the use of reactance coils appear to be: (1) The lowering of the power factor; (2) the interference with the regulation of the voltage. A low power factor can of course be met by designing the generators to supply the wattless current required and by providing for greater energy of excitation. In this way payment must be made for the greater reliability of supply, and it is not really exorbitant. The interference with the regulation is, I imagine, a more serious question. The balance of the load between sections must be varying from

hour to hour, if not more rapidly, and the constant adjustment of the voltage on the various sections of a large system, required by the insertion of reactance coils between them, must be a very difficult operation. The authors do not say much about this. On page 512 they mention that "the voltage difference can be compensated for by varying the power factors of the synchronous machines." This, I take it, is done by adjustment of the excitation. I should much like to have some further explanation of what is necessary in such a case, and to know whether some special indicators of the conditions obtaining on each section can be provided for the guidance of the attendant. I gather that the authors recommend the division of the reactance in the generator circuits between internal and external reactances, and they seem to indicate that each of these should have a value of about 6 per cent. As I believe that modern turbo-alternators usually have an internal reactance of about 12 per cent, I should like to ask the authors if they would recommend this to be reduced and some of it to be put outside the generator, and whether they consider that 12 per cent total reactance would give sufficient protection. I realize the necessity for having some of this reactance external to the generator in case of a fault developing at the terminals of the machine. The suggested lay-out of a large system shown in Fig. 10 is very instructive. The point raised with reference to the short-circuiting of the busbar reactance coils through the sub-station busbars by feeders connected to different sections of the main busbars could, I suggest, be met by dividing the sub-station busbars and inserting reactance coils between these sections. The possibility of overloading feeder cables by the angular displacement of the voltage, referred to on page 517, is very undesirable and should certainly be guarded against.

Mr. E. P. HOLLIS: Although there has been comparatively little discussion in this country on the uses of reactance coils, objections thereto are beginning to crystallize, and it is now possible to appreciate the views

* Paper by Messrs. R. M. Faye-Hansen and J. S. Peck (see pp. 511 and 655).

Mr. Hollis.

of those who do not concur with the advocates of the employment of such coils. These objections are to my mind incapable of complete answer, and I propose to concentrate my attention on two of the more important ones rather than to discuss the wider field of the application of these coils. Engineers in charge of the operation of electric power-supply schemes have accepted almost unanimously the benefits that are claimed for reactance, but a few of them have expressed the opinion that special coils for insertion in the generator leads are superfluous, and that the whole of the reactance necessary can be embodied in the machine. It should, however, be realized that external reactance has special functions which cannot be performed by internal reactance: (1) Internal leakage reactance does not protect a generator against complete destruction by a heavy influx of power in the likely contingency of its breaking down. One of the most important functions of the external reactance is to offer such protection. (2) Internal leakage reactance does not protect the end windings of a generator against concentration of potential due to a high-frequency current entering from the line. Special reactance coils are given high insulation in order that they may act as breakwaters against such surges. (3) Once leakage reactance is embodied in the machine its value cannot be varied. Separate reactance coils are susceptible of such adjustment. (4) It is doubtful whether the path of the leakage flux of many generators with large leakage reactance is adequate to enable that path to remain unsaturated on short-circuit. The second objection taken to reactance coils is that of cost. On the debit side of the balance sheet there has to be placed the interest and depreciation on the cost of the reactance, together with any additional sum that should be debited owing to the floor space occupied by these coils: whilst on the credit side are a number of items, the exact value of which it is difficult to appraise, but which are nevertheless of great importance. These are: (1) The insurance of the generators against breakdown by external short-circuits. (2) The insurance of the end-turns against breakdown by high-frequency surges. (3) The insurance of the protection of the windings from complete destruction in the event of an internal breakdown. (4) A saving due to eliminating the need for quickly-operating switchgear. (5) A saving due to the fact that switchgear of a lower rating is necessary. (6) A saving due to eliminating the need for installing elaborate protecting devices. (7) A saving of penalties incurred due to complete or partial breakdown of the generating station.

Dr. Kapp.

Dr. G. KAPP: Referring to Fig. 2, I think that where feeder cables are joined by a ring main it would be advisable to have choking coils not only at the near end of each feeder as shown in the paper, but also at the far end. Such a precaution seems to be unnecessary where the feeder is not a cable but an overhead line. In the choking coils shown by the author on the screen there were many turns of wire and an air core a foot or so in diameter. In an overhead feeder there is also an air core in the loop formed by any two wires, but such an air core is several miles long and a few feet wide. The inductance of such a loop would be comparable with and might even exceed many times that of a choking coil with an air core, so that the addition of a special choking coil, at any rate at the far end, would not appear to be necessary. Mention

has been made in the discussion of the possibility of omitting the choking coil in the alternator circuit and so constructing the machine that the armature would contain an equivalent amount of inductance. Such a construction is, in my opinion, impracticable. High inductance could not be secured without at the same time getting an unduly large armature demagnetizing effect, so that the regulation of a machine constructed on these lines would be much worse than that of a machine having a moderate amount of armature reaction and an external inductance added. Such addition would, of course, also make the regulation worse, but not to so large an extent. A machine having only a moderately bad regulation could always be made to regulate well by the use of a Tirrill regulator or some equivalent device, so that it would appear that the authors' device of externally applied inductances would be quite compatible with good regulation, provided that each generator were fitted with some kind of automatic regulator taking charge of the exciting current. It should be remembered that such a regulator need not act very quickly, because with the large machines in question changes in load and power factor would take place very slowly.

Mr. F. H. CLOUGH: In general I agree with the authors' Mr. C.

conclusions. If criticism can be made, I should like to say that these reactance coils take up considerable room and it may be possible to dispense with some of them. Where large power-supply undertakings exist it is essential to take all reasonable means to ensure, first, the continuity of the supply, and, secondly, the protection of the apparatus connected to the system. It is usual, therefore, to divide the plant into sections, so that if a fault occurs it is limited to its own section and the rest of the plant is unaffected. This can readily be done with the boilers, prime-movers, and condensing plant, but there is a difficulty in sectionalizing the busbars, inasmuch as this would mean that the supply areas must also be divided, and in a case of failure of one section of the plant the whole of the area which depends on this section would be without supply.

The use of large reactance coils between sections of the busbars may be considered as a semi-isolation. I agree with the authors when they recommend that these should be installed. By properly proportioning them the result of a short-circuit or other breakdown can be limited to the section in which it occurs, but at the same time power may be supplied to any section from the adjacent ones so as to maintain the continuity of supply on it. The use of reactance coils in series with the generators and also in the outgoing feeders protects the apparatus rather than maintains the continuity of supply. The use of reactance coils in series with the generators, however, largely depends on the design of the latter. I think that all small generators can undoubtedly be designed so that they do not need reactance coils to protect them. For large generators this may not always be the case, although here again I feel that they can be dispensed with provided close voltage regulation is not necessary, as mostly happens, since the momentary variation in load carried by a large generator is usually a very small fraction of its rating, and even if comparatively large variations in loads are liable to occur, the voltage can be maintained constant by means of some form of automatic device such as the Tirrill regulator. It has been pointed out that a reactance coil in series with

ugh. the alternator reduces the amount of current that can flow from the neighbouring machines into a fault in its windings. I think, however, that it is unnecessary to install series reactances for this purpose, because if a serious fault occur in the windings of an alternator, it is usually sufficient to damage the machine very seriously even if the latter is running by itself; and therefore any additional flow of current only makes the burn-out more complete. Of course this reactance should not be necessary so far as the other generators are concerned, as these are designed so as to withstand a short-circuit at their terminals. The use of reactance coils in the feeders protects the switches, and if these are not capable of breaking the current that can flow into a feeder when a fault occurs, it may then be necessary to install the reactances. When Fig. 10 in the paper is considered and it is realized that wherever one reactance appears on the diagram there must in fact be three, one for each phase, the large space occupied by them is evident. Inquiry is prompted as to whether they cannot be avoided and whether there are not other means of giving the security and protection necessary. It would seem that so far as the feeder is concerned it should be possible to make use of Merz-Price and Merz-Hunter devices. In the former a current transformer is fitted to each end of a feeder cable and the two transformers are connected in opposition. So long as the cable is sound the current flowing into it must necessarily be equal to the current flowing out of it, and therefore the resultant current in the secondary transformers will be zero. If, however, an "earth" occurs, the balance is destroyed and the cable is disconnected by means of an automatic oil switch. In the latter method each conductor is in two parts and the current transformers are arranged on the assumption that the current will be divided equally between the halves of the conductor. In most of the electricity supply systems in England feeder cables are laid underground, and if they are well made there should be a very remote possibility of a short-circuit between phases. If a fault does occur it usually comes from outside, so that it becomes an "earth" before it can be a short-circuit, and this operates the protective devices and isolates the fault from the system.

hn. Dr. M. L. KAHN: The necessity of using current-limiting reactances in large alternating-current supply systems has been generally recognized; on the other hand it is certainly desirable to restrict the use of this apparatus to a minimum, as, apart from its additional cost, it requires considerable floor space and adds to a system already sufficiently complicated. The authors have stated the different points of the systems in which reactance coils may be desirable, and have set out clearly the advantages and disadvantages of applying them in different positions. As it is undesirable to employ such coils in all the different positions mentioned by the authors, it seems to me that the best compromise that can be effected is to put the reactance coils in the busbars and to use alternators with as high a reactance as possible. The reactance in the alternators themselves will then to a large extent take the place of reactance in the alternator circuits and also in the feeder circuits, as described in the paper. At the same time this has the advantage of reducing the current flowing in the alternator in the case of any breakdown across the terminals, and gives a more efficient machine. In large turbo-alternators the bulk of the losses is made up by iron loss and windage loss. By

increasing the reactance the flux in the machine can be decreased with a corresponding decrease in the iron loss. Further, the length of the machine can usually be decreased, and the amount of cooling air required can also be diminished on account of the reduction in the iron loss. As the windage loss depends on the amount of air required, and on the area of the cylindrical surface of the rotor, both of which can be reduced on machines with high reactance, the windage loss of such machine will be lower than the loss in machines with low reactance. The coarser voltage regulation of the machine due to the higher reactance is of minor importance, as machines of the size in question are invariably used in connection with automatic regulators, and the load in stations for which reactance coils are required is usually steady.

Dr. C. C. GARRARD: The first thing that is apparent on reading the paper is that by the introduction of reactance coils a considerable increase in the complication of the layout of the generating station is entailed. There is no doubt that there is a great tendency nowadays towards such complexity. If, in addition to these reactance coils, the large banks of high-pressure protective gear, condensers, etc., which are advocated at present are inserted, both the size and the expense of generating stations are bound to increase considerably, a result which may defeat the object in view. Nevertheless continuity of supply for public electricity supply stations is becoming of increasing importance daily; while therefore these added complications should be regarded as evils, even though necessary, their installation must be seriously considered if they should be able to increase the reliability of the supply. On the other hand, if the use of reactance coils can be avoided by improvements in the construction of other apparatus, it seems to me that this should be the path to be followed and that the prevention of trouble due to faultily constructed alternators and switchgear by the introduction of another piece of apparatus would be undesirable. The authors have considered the problem chiefly from two points of view:— (1) Of protecting the alternator from the collapse of its coils. (2) Of saving the oil switches from destruction. As regards these, I should like to ask two questions. Is it not possible to construct turbo-alternators which will withstand "dead" short-circuits? If so, would it not be far better to spend part of the money which would otherwise be expended in the generator reactances in strengthening the windings of the machines so that they can withstand such short-circuits? I also notice that the authors have not dealt to any extent with the question of increasing the internal reactance of the machines rather than that of putting the reactance in the form of a special coil in the generator busbar connections. It seems to me that a solution of the problem of generator protection from this point of view might be attained. The second question that I should like to ask is whether the limit of breaking capacity of oil switches has been reached. That is, given a certain station of a certain short-circuit capacity, cannot oil switches be designed to deal with that short-circuit? If so, it appears to me to be wrong to install smaller switches and endeavour to limit the short-circuit current; we should rather spend the money in installing switches of the proper size. In this connection I think that if reactance coils must be installed in order to safeguard the oil switches, the use of a switch is to be preferred which, in operating, first cuts in

Dr. Garrard. the reactance and then opens the circuit. In this case the reactance coil is normally short-circuited. The first action of the switch (within, say, the first $\frac{1}{2}$ second) is to remove the short-circuit on the reactance coil and the circuit is then opened after a certain time lag has elapsed. With this arrangement the generators are not protected against the very large rush of current that occurs during the first instant of the short-circuit before the armature reaction has had time to assert itself, but as stated before they should be able to withstand this. In my opinion the really important point of view from which to regard this subject is that of the drop in voltage. The reactance coils should be installed with the one object of preventing the pressure falling to such an extent, in the event of a short-circuit, as to cause synchronous machinery to drop out of step. Looked at in this manner it appears that reactance coils in the feeders, as in Fig. 2 in the paper, offer the best solution. As regards Fig. 10, which represents, as I understand it, the use of reactance coils carried out to the full extent, it is mentioned on page 518 that it is "preferable to have each sub-station fed from one section of the busbars." This of course prevents the interconnection of sub-stations, which I am afraid militates against reliability of the supply. I should also be glad if the authors would state whether the oil switches shown in Fig. 10 in series with and in parallel with the busbar reactance coils are automatic switches or are simply hand-operated. As regards the use of iron-clad choke coils, I do not quite understand the necessity of a "straight line" relation between the voltage and the current. Does this expression simply mean that the iron must not get saturated to such an extent in the case of a short-circuit that the permeability falls to practically that of air? The idea has been prevalent that iron could not be used, as, owing to the very short duration of the first rush of current, it did not have time to become magnetized, and therefore an iron choke coil was no better than an air coil. That is to say the initial rush acted as a current of very high frequency, which, as is known, will not magnetize transformer iron of ordinary thickness. If this be correct, it would seem that an iron circuit in any form would be bad, as it would increase the pressure-drop in ordinary working without giving any increased limiting effect in the event of a short-circuit occurring. Perhaps the authors would make this point clear, and state what would be the permeability of the iron under these conditions. I should like some further explanation of the "doubling effect." The experiment mentioned in the footnote on page 511 is not the same as that which would occur on a sudden short-circuit. The initial rush of current obtained by suddenly switching on a choke coil or transformer is due to the polarity of the remanent magnetism of the choke coil or transformer not coinciding with the polarity required, having regard to the particular point in the voltage wave at which contact is made on the switch. I fail to see how this phenomenon can occur in the case of a short-circuit. The question of the use of automatic voltage regulators when busbar reactance coils are used has been raised. If such a regulator be used with each generator, it must be set so that it keeps the voltage of each generator constant and equal to that of the others. That is, the pilot coils of the regulators must be connected to the busbars. If the busbar is sectionalized by reactance coils, I assume that each automatic regulator

will have its pilot connected to that section of the busbar to which its own generator is connected. With such an arrangement it would not be possible to operate on the principle shown in Fig. 6, as the automatic regulators would prevent the different busbar sections from being at different potentials.

Mr. H. K. TRECHMANN: Two speakers have made reference to reactance coils and patent protective systems, whence it might be understood that these perform in some measure the same functions. In my opinion this is not so, as current-limiting reactances are no more able to clear a fault than to prevent one occurring. No existing protective system can succeed in opening an oil switch before the current on a bad fault has reached quite large proportions. Further, it is almost impossible to plan a system of reactances which will successfully limit the fault current in any part of a large network, owing to the unavoidable complexity of the latter and to the large amount of energy which may be fed back from almost any point in it. Reactances are a troublesome complication from the point of view of arrangement, in addition to exhibiting the difficulties dealt with in the paper; e.g. the cost of installing a bank of reactance coils into the run of a set of heavy busbars must be very much more than that of the apparatus itself, and the extra space occupied by them is also deserving of attention. The designers of English generating stations have shown in the past an unfortunate tendency to economize the space for switchgear to a very small figure, and the designs of most English oil switches symbolize that tendency. An oil switch for dealing with heavy overloads must be immersed in a large bath of oil, and it must generally possess large clearances and a good head of oil above the break; many otherwise good designs are spoiled by an insignificant quantity of oil being allowed. To illustrate what is possible, it might be stated that an oil switch possessing only a little more than 5 in. of break has been tested with a "dead" short-circuit on 23,100 h.p. of generating plant at 12,000 volts and found to open the circuit successfully; and further, the damage to the contacts, etc., was not sufficient to prevent the switch being easily closed afterwards. Though one cannot say that reactance coils may be entirely dispensed with in the large schemes which are being prepared at the moment, it is certainly not too much to say that if some of the additional space be given to the oil switches, and if suitable designs for the latter be installed, their use can be considerably curtailed in even the largest systems, and the capacity of stations in which they are not used at all can be materially raised.

Mr. F. FORREST: Fig. 10 shows a well-thought-out method of dividing the busbars of a large power station by means of current-limiting reactances, so that every oil switch installed there could be depended upon to open the circuit which it controls under conditions of "dead" short-circuit. I am in hearty agreement with the authors when they state that it is very desirable to feed one sub-station from one section only of the generating station busbars. One reason for this is clearly stated in the paper on page 517, but the authors have not mentioned a second very important reason, which is as follows: Assuming that a sub-station is fed from two sections, and that the sub-station busbars are divided so as to keep the two sections distinct, then it is possible for these two sets of busbars to

Forrest. have a considerable difference in voltage. If this difference in voltage is steady, no particular difficulty arises, but in the event of a sudden transfer of load from one section to another at the generating station, a sudden rise or fall in the voltage of one of the sub-station busbar sections would also result. Since the whole of the sub-station rotary converters are connected in parallel by means of the continuous-current busbars, a sudden rise or fall in voltage on one set of machines to the extent of, say, 5 per cent. would certainly result in something very like a temporary shut-down. The introduction of reactance coils between the feeders and the generating busbars must have a beneficial effect in preventing the high-frequency potential surges set up in the network from unduly straining the insulation of the generators and switchgear. I should be glad if the authors, who are in touch with American practice and experience, can give any information on this point.

Turner. Mr. E. O. TURNER: I should like to obtain some information from the authors with regard to the provision of extra reactance in the generator itself. One speaker pointed out that this may be done by decreasing the total flux of the machine. At the same time, I presume, the number of armature conductors would be proportionately increased, so that although the additional reactance desired is obtained, it is at the expense of an increased armature reaction, with the result that the inherent regulation of the generator becomes worse. If the armature winding is regarded as a choking coil with a partial iron circuit, its reactance can be increased simply by burying the conductors deeper in the slots. Were this done the armature reaction would not be altered, and the regulation, especially at power factors of 0.8 and below, would be much less seriously affected. I should like to ask the authors whether this is feasible in practice, and whether generators are being manufactured having high reactance but normal regulation.

Taylor. Mr. A. M. TAYLOR: With reference to the question as to whether generator reactances should be external or

say nothing in their paper as to what happens outside the generating station, and I submit that in considering the protection of the generators this is a feature that must on no account be overlooked. If the feeders from the various busbar sections lead to common busbars in different sub-stations, the reactance coils in the generator busbars will be partially or entirely short-circuited thereby; and even if the busbars in the various sub-stations are divided from one another by reactances, the reactance coils in the generator busbars are thereby still partially short-circuited. Again, most electricity supply systems putting down stations of the size indicated will be already in possession of a station of perhaps one-third or one-quarter the size, which has to be connected in parallel with one or more of the sections of the new station. I have reproduced in Fig. A a rough approximation of the conditions that exist in a crowded city like Birmingham, where the whole of the power supply is concentrated within a comparatively small radius of the large generating station, as distinct from the Newcastle system, for example, where I believe the nearest large generating centres are some six miles apart. Allowance has been made in the diagram for the effect of synchronous machinery in the sub-stations. On the assumption that a short-circuit occurs somewhere near the busbars C, the admittance of the whole system into the section C has been worked out, and I find that it would be equal to 32 times the capacity of one busbar section, or about 70,000 amperes. Now if we consider any one of a group of 5,000-kw. generators on one of the main busbar sections, and assume that the short-circuit develops inside the winding and near to the terminals of the generator (which is in fact the position of greatest strain), there would be virtually no reactance between the busbars and the short-circuit if no external reactance were inserted in the generator leads. There would also be a tendency for this current to pass through a short part of the generator winding, and it would result in a force on the conductors

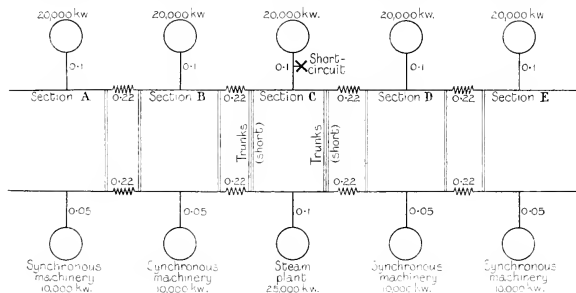

FIG. A.

internal, or both, I think that their application to every installation must be considered upon its merits. Fig. 1 in the paper represents very closely the arrangements that are proposed for the new power station at Birmingham. The busbars are here to be divided into five sections, and the output on each section is to be 20,000 kw. The authors

of the armature equal to 100 times that produced when the generator was tested on short-circuit. The armature conductors would almost certainly be instantly ripped out of their place, and much more serious damage would be done than would occur if the generator were merely short-circuited upon itself without the armature conductors

being shifted. Owing to the instantaneous nature of these forces automatic protective gear would not save the machine. For even if the oil switch opened in $\frac{1}{2}$ second, the danger would have been done in the first quarter-cycle, i.e. in $1/20$ th of the above time. No doubt there are many cases where the conditions which I have indicated above would not occur, and I submit that the only safe way to determine whether or not reactances should be inserted external to the generators is to work out, in the way that I have indicated, the actual admittance of the faulty section and see whether the currents which would pass would be such as to test any part of the machine more severely than would its own short-circuit current, under which it was tested at the time of purchase. It is also interesting to note that if the machine is constructed with, say, an internal reactance of 8 per cent and an external reactance of 8 per cent, and if it is short-circuited on its own internal reactance and will stand up to this, then it will be equally safe from the incoming current from the other generators as it is from its own short-circuit current. Another advantage secured by having an external reactance coil is that the latter may be placed far away from the generator and close to the switchgear, and that it may be so arranged that there are no cable or dividing boxes between the main busbars and the reactance coils. The cable and the dividing boxes are then protected from the busbars as well as the machine itself.

The authors suggest a 50 per cent reactance in the various sections of the main busbars. When this reactance is traversed by one-half of the full load of one section of the busbars, which is a condition that should certainly be made, there will then be a 25 per cent drop of voltage across the reactance even though, as in the case illustrated

in Fig. 8, the generator voltages A and B are equal. This difference of potential would exist as far as the feeding centre or sub-station, and considerable difficulties would be introduced unless reactance coils were employed to subdivide the feeding points. Moreover, if the feeders were connected even at a great distance from the station, considerable circulating currents would still pass between them. Although reactances are probably a necessity in the busbars of a 100,000-kw. system there are nevertheless certain serious disadvantages in their use. For instance, the space taken up by them is very considerable, and their effect upon the power factor of the generators is also rather serious. If we had a means for excluding the reactance until the time when it should be really wanted (that is until the short-circuit should occur), it would, I think, be granted that we should have an ideal system. I may here perhaps mention that about two years ago I designed a switch which would perform this function, viz. it would short-circuit a section, or sections, of the reactance coil during normal working, and when the rush of current came it would open and deflect the current through the reactance in something like $1/500$ second. I note that Mr. P. M. Lincoln in an article in the *Electric Journal* for December, 1913, suggests the use of ordinary oil switches for the same purpose, and argues that they would operate in time to save the synchronous machinery from falling out of step. He has omitted, however, to point out that such switches would in no wise prevent the tremendous shock that would come upon the generators, which would be virtually connected to a solid busbar without any reactance inserted in it.

The authors' reply to this discussion will be found on page 688.

SCOTTISH LOCAL SECTION, 21ST APRIL, 1914.

Mr. A. PAGE: This paper has come at a most opportune time so far as the staff of the Glasgow Corporation Electricity Department are concerned, as at the present time the design and lay-out of a 100,000-kw. generating station is being considered. It has practically been decided to install reactance coils in the generator circuits and between sections of the busbars; and as there will be step-up transformers on the feeders it will be quite easy to arrange for a 5 per cent reactance in the latter if it is considered desirable to do so. Some influential electrical engineers do not agree that reactance coils are necessary, but while such coils may be dispensed with in the case of a plant giving an entirely alternating-current supply to factories, or even a continuous-current supply to railways, where a supply for such purposes is added to the lighting supply of a large city I consider it to be absolutely essential that steps should be taken to prevent the present risk of breakdown. Reactance coils seem to provide a solution of this problem. There is, however, the difficulty of finding space for the housing of these coils, and as the authors, on pages 517 and 518, practically recommend for a 100,000-kw. installation 50 per cent reactance on the busbars, 10 per cent on the feeder groups, and 5 per cent on the generators, i.e. a total of no less than 75,000 k.v.a., the question obviously requires much consideration. These reactance coils will add very greatly to the cost of a station, and for the purpose of an estimate I suppose it would be safe to assume their

cost to be £1 per k.v.a. The first consideration must of course be the continuity of the supply, but at the same time we have to be very careful not to increase the capital outlay unduly. I note that there is no reference to harmonics in the paper, and I should like to know whether in that respect these reactances do not introduce a factor which may cause trouble with the insulation. There is also considerable complication in the switchboard connections owing to the presence of reactance coils. Although I am aware that the pressure across a choke coil is in quadrature with the current, and that the authors refer to the wattless current of the reactances, I should be glad of information in regard to the effect of such reactances on the coal bill. Most of our troubles here have been due to feeder breakdowns, and the advantages claimed on page 513 for the use of reactance on feeders seem to promise the elimination of such troubles. It would certainly be of very great advantage if we could keep our sub-stations running when the alternating-current supply is interrupted owing to a fault on a feeder. On page 515 the statement is made that a reasonable size of reactance is one which will give 50 per cent of normal voltage when carrying the full-load current of one busbar section; but in the station that we are considering at Glasgow this would mean a 15,000-k.v.a. reactance, which is clearly out

* P. M. LINCOLN. Protection against short-circuits. *Electric Journal*, vol. 10, p. 1217, 1913.

of the question. The vector diagram, Fig. 9, appears quite simple, but with these various voltages and power factors on the machines the lot of the engineer-in-charge will, I imagine, be a most unhappy one. On page 517 reference is made to the case where the same sub-station is supplied from several busbar sections in the power station. This should never be necessary, but it is not so easy to split up the continuous-current network supplied by a group of sub-stations. Some of the sub-stations might be supplied from one section of the power station busbars and others from other sections. In the event of a short-circuit on a high-tension feeder the plant in the power station would probably keep running, but I am afraid that there would be trouble on the continuous-current switchboards in the sub-stations. The table on page 518 is very interesting. From the point of view of maintaining the supply on all the sections, with the exception of the faulty one, combination No. 11 would appear to be the best. On the other hand, No. 5 proves to be surprisingly good on a feeder fault, although there is no busbar reactance. Such an arrangement would prevent the trouble on the sub-station continuous-current busbars to which I have already referred.

Mr. D. M. MACLEOD: The first consideration of those responsible should be to secure for the consumers a supply the continuity of which can be depended upon. The introduction of balanced protective gear has had the effect of limiting the disturbances arising from cable or overhead-line faults where these take the form of an earth or short-circuit. Not very many years ago a short-circuit at one point of a system meant the interruption of the supply at several other points far removed from the seat of the trouble, but with the balanced protective devices now available these occurrences are largely things of the past. The balanced protective gear, however, has a very important limitation in so far that it fails to provide any safeguard against busbar troubles, which may include the failure of such apparatus as series transformers, isolating links, and the busbar side of oil circuit-breakers. Where the usefulness of the balanced protective gear ends, that of the current-limiting reactance begins. It should be quite clear that on a supply where balanced protective gear is in use, switchgear and cables may be called upon to transmit very large overloads, and there is a serious danger that the generators themselves may become severely strained due to the heavy fault current with which they have to deal. As an indication of the mechanical forces that large generators have to withstand, I have seen several 5,000-kw. turbo-alternators in which twelve $1\frac{1}{2}$ -in. coupling bolts have been permanently distorted as a result of the machine's pulling up on successive short-circuits. The distortion was such that it was found impossible to withdraw the coupling bolts. The authors have dealt very fully with the uses and design of current-limiting reactances, and they have shown fairly clearly in which direction these may be usefully applied. I am not at all sure that the extensive application which they appear to favour is altogether to be commended. A very regrettable feature of many protective devices is their liability to fail in themselves. The failure of series transformers, for instance, is one of the most prolific sources of trouble in power transmission work, and it appears to me that current-limiting reactances would probably share the same weakness and cause as much trouble as what they were designed to

avoid. I think it is a common experience with generating plant employing an earthed neutral to find that the majority of faults which arise are due in the first instance to the failure of the insulation of one phase, and I am of opinion that if an efficient current-limiting reactance were inserted in the star-point earth connection the chances of any material damage either to generators, switchgear, or cables, would be very remote. I consider that it is the absence of such a device that is directly responsible for a number of the very serious plant failures which occur from time to time. I certainly would not favour the very free use of reactances which is suggested by the authors, for three reasons: (1) The benefit to be derived would not be commensurate with the expenses involved in their installation; (2) the space that they would require would practically mean the complete reconstruction of existing switchrooms; and (3) their use would interfere with the voltage regulation arising from unequally loaded feeders. On page 512 the authors refer to the case of a short-circuit on a generator and appear to infer that if a reactance were connected in the generator leads the circuit-breaker could be operated in time to disconnect the generator from the busbars and to save the machine from destruction. I think, however, that this is purely illusory, as in the event of a short-circuit on a large generator the draught set up due to the peripheral speed of the rotor would fan the short-circuit into a fierce flame, which would sweep all round the windings and destroy the generating set to such an extent as to involve re-winding.

Mr. J. A. ROBERTSON: This paper is one of the greatest importance to those engaged in the generation and transmission of power on a large scale. It appears to me that the only question is one of balancing the advantages of reactance for each particular case against the disadvantage of increased cost and somewhat greater complication. I was very much interested to learn from Mr. Page that the new power station at Glasgow is to be equipped with reactances as part of the system. I do not agree with Mr. Macleod that reactances should merely be used in the feeders, leaving the generators to take care of themselves. It would appear as if the use of reactances in the feeders, either where duplicate mains are used or on a ring system, would cause complications at the sub-station and interfere with the loading of the feeders. It is rarely the case that a short-circuit on a feeder causes a shut-down of the power station, or even of one generator. The most serious shut-downs which have occurred in recent years have been due to faults on the generator cables or series transformers, and it is here, I think, where some safeguard is called for. The lay-out of the plant could be arranged so that accommodation could be provided for reactances directly under the generator. I have sometimes thought that each generator should have an oil switch placed close to its terminals so as to interrupt the generator current if a fault occurs between the generator and the switchgear, which latter with remote control systems is now being placed farther away. The great improvement that has taken place in generators and switchgear during the last few years must also be taken into account when considering the question of reactances. A modern generator designed with 15 per cent internal reactance will withstand almost any fault that may occur on the system, and with oil-immersed switches capable of dealing with the maximum

Mr.
Roberson.

short-circuit current the possibility of a shut-down is very remote, except for defects in the generator or the generator leads. The effect of a short-circuit in the generator itself may be so disastrous that the use of reactance may be justified to limit the amount of damage. The paper is most valuable, and would have been still better if the diagrams had been extended so as to include the sub-station circuits.

Messrs.
Faye-
Hansen and
Peck.

Messrs. K. M. FAYE-HANSEN and J. S. PECK (*in reply to the discussions before the Birmingham and Scottish Local Sections*; communicated): It is interesting to note that practically all of the speakers who have had experience in operating large generating stations, or who expect to operate stations of very large rating in the future, agree that some form of reactance is necessary. Also there is practically unanimity of opinion amongst these engineers that reactances for sectionalizing the busbars are highly desirable. The objections which have been raised to these reactances are as follows:—(a) high cost; (b) difficulty of finding space in the stations; (c) loss in energy; (d) necessity for sectionalizing the busbars at sub-stations; (e) difficulty of maintaining the proper phase relation between generators supplying different busbar sections.

With regard to the question of cost, this is not a serious item where busbar reactances alone are used, *i.e.* their cost is not a large percentage of the total cost of the station. The difficulty of finding the necessary space for accommodating these coils is a question of much more serious importance, especially in the case of old stations where no provision has been made for them; but in the case of new stations, or where old stations are extended by new buildings, the proper space for these coils can usually be provided without difficulty. The energy losses in the coils may be neglected, as they are quite insignificant.

It seems to be the general opinion that ordinarily there will be little difficulty in supplying one sub-station from one section of the busbars or in sectionalizing the busbars in the sub-stations so that different sections of the busbars in the power station will not be connected to the same busbars in the sub-station, but it will be necessary to operate low-tension circuits in parallel. These low-tension circuits may be supplied with continuous current through rotary converters or with alternating current from step-down transformers so that the reactance coils between sections of the busbars may be short-circuited through the low-tension network. In the case of rotary converters there will be no difficulty if the voltages of the busbar sections in the power station are kept equal, as a phase difference between the alternating voltages would have no influence on the operation at the continuous-current end. In the case of transformer sub-stations supplying an alternating-current network, it would, however, be preferable to lay out the system so that each sub-station is only connected to one busbar section; the different sub-stations supplied from the same busbar section could, of course, be connected to each other by interconnectors, ring mains, etc. Further arrangements will be made in the power station to supply this set of sub-stations from another busbar section in case of trouble in this part of the generating station. We anticipate no difficulty, however, in operating under these conditions, because the resistance of the feeders and the reactance in step-down transformers and rotary converters will introduce a very appreciable impedance into the circuit which parallels the reactance

coils in the busbars, and it will only be necessary for the attendant in the generating station to make sure that his feeder cables are not overloaded. This can be easily determined by inspecting the ammeters in the feeder circuit.

There seems to be a misunderstanding on the part of several of the speakers in regard to the operation of generators connected to busbar sections which are separated by reactances; and the difficulties of maintaining the proper phase relations between the different generators under different conditions of load have been mentioned. We would point out, however, that this adjustment of phase relationship is maintained automatically by means of the turbine governors assisted by automatic voltage regulators, which will usually be coupled to each busbar section. The turbine governors ensure that each generator shall deliver its proper share of the load regardless of the distribution of loads upon the busbar section, while the automatic voltage regulators maintain equal voltage on all the busbar sections. Thus the generator voltages are automatically displaced in their phase relation, and the only thing required of the attendant is that he shall watch the ammeter in order to make sure that no generator is overloaded beyond its full value. If he finds that any generator is overloaded, then he must bring in additional generators, or must redistribute his loads, which is no more than he has to do at the present time where all generators are connected to the same busbars.

A large number of the speakers have referred to the desirability of building the generators with very high internal reactance so that no external reactance is required in the generator leads. As pointed out in the paper and the previous discussions, we agree with this view, but with the requirements of regulation still met with it is very difficult in large 2-pole alternators to obtain more than 6 per cent to 10 per cent armature reactance. If the generator will withstand the corresponding current rushes, we do not consider generator reactances essential. It is possible to increase the armature reactance without increasing the armature reaction (and therefore without making the regulation materially worse) by embedding the armature conductors deep into the iron. To obtain any large increase of reactance, however, it will be necessary to embed the conductors very deep, whereby the losses and the cost are considerably increased. The reason for this is that the arrangement must be made such as to prevent oversaturation of the iron inside the winding under short-circuit conditions. This can of course be done by making the slot opening wide enough, but it will generally be found more economical to install external reactance coils than to increase the armature reactance in this way.

It has been pointed out in the discussion that short-circuits usually come on slowly and that discriminating protective gear and quick-acting circuit-breakers should be a sufficient safeguard to the station without the use of reactances. While it is quite true that discriminating protective gear may do much to increase the safety factor of the system, the fact remains that "dead" short-circuits will sometimes occur, and that in such events no switch or relay is sufficiently quick acting to open the circuit-breaker before the rush of current has occurred. Furthermore, no discriminating gear can protect the generator in the event of a misphase, and it is well known that the strain on the generator may be greater in the event of the misphase

Messrs.
Faye-
Hansen
Peck.

than if the generator short-circuited directly across its terminals.

Several speakers have referred to the saving in the cost of switchgear which can be made by installing reactance coils in such a manner as to limit the maximum power that any switch can be called upon to break. On the other hand, it has been argued that if switches of ample capacity are provided there is no need for reactances, and the great simplicity of the design of large oil switches has been dwelt upon by one or two speakers. We find, however, that those manufacturers who have had the greatest amount of experience in building and testing large switches are the most careful in making statements as to what their switches will do before the latter have been tested. There are switches of the reactance type on the market to-day which are guaranteed to control the output of generating plant up to any desired value, but such switches are very expensive and require a large amount of space in the station. As Mr. Wedmore has pointed out, it is commercially impossible to supply every consumer with a circuit-breaker that will deal with a short-circuit with the maximum generator power behind it, and it is the author's opinion that a certain amount of reactance will prove far cheaper and will be safer than any attempt to provide all switches for the maximum breaking capacity of the system.

Reference has been made to the straight-line characteristic of reactance coils. By straight-line characteristic we mean one in which the voltage drop across the coil varies directly with the current through the coil. This is obtained exactly with an air coil, and can be obtained with very close approximation in a coil having iron in the magnetic circuit, provided the iron does not become saturated, and it is therefore necessary to design the coil at such a low induction with normal current that it will not be heavily saturated with the maximum current that will ever pass through it. Thus, if the maximum induction allowable is 25,000, then a 5 per cent reactance would be designed for an induction of 1,250 in the iron part of the circuit, a 10 per cent reactance for 2,500, and a 50 per cent reactance for 12,500. Thus it will be evident that the greater the percentage reactance the greater the advantage of the iron over the air core. It is also worth noting that while in an air-core coil a 10 per cent reactance is approximately double the size of a 5 per cent reactance for the same current, the increase in size is very much less in the case of the coil with an iron core.

It has also been suggested that iron should not be used in a reactance coil as its induction would not respond with sufficient rapidity to sudden changes in current. It should be remembered, however, that changes in current to which the reactance coil should respond are very slow as compared with static surges, and the oscillograph shows that these current changes, while often of great magnitude, are of normal frequency. Therefore, so long as the saturation is not excessive, the choking effect due to the iron is exactly the same as for normal current and frequency.

Reference has also been made to the doubling effect. This is exactly the same phenomenon as is experienced with transformers. There is, however, this difference in the result; the transformer is usually worked at high induction, and when by closing the circuit at the zero point of the voltage wave the induction rises to twice its normal value, a high degree of saturation is attained and

the magnetizing current may reach several times normal value. In the air coil the current cannot exceed twice its normal maximum value due to this doubling effect, while with the iron-core reactance the maximum current will not greatly exceed this double value if the iron is worked well below saturation. This is explained clearly in the article in the *Electric Journal* referred to on page 511.

Mr. Chattock asks how the voltage drop due to reactances in the feeders can be compensated for by varying the power factor of the synchronous machines. This can be done by the attendant in the sub-station, who will vary the field strength of the synchronous machines in such a way as to give constant voltage on the sub-station busbars. In certain cases an automatic voltage regulator could be used for this purpose. Where rotary converters constitute a considerable portion of the load on any sub-station they may be provided with compound windings in order that the power factor will be raised as the load comes on.

Mr. Clough states that "the use of reactance coils in series with the generators and also in the outgoing feeders protects the apparatus rather than maintains the continuity of supply." We were careful, however, to point out that the greatest argument in favour of installing reactance coils in the feeders was the assurance of continuity of supply due to the maintenance of the busbar voltage.

In the Manchester discussion Mr. Bateman asked how the voltage was divided across the generator and its external reactance, and what effect the external reactance had on the final short-circuit current of the generator. At the instant of short-circuit the voltage will be divided in proportion to the reactances of the generator and the external coil, i.e. if the reactance of the generator is 6 per cent and that of the coil is 6 per cent the voltage across the generator will be equal to that across the coil. As the armature reaction of the generator increases, the current will fall until it reaches a constant value. If the synchronous reactance of the generator is 44 per cent, the current will fall to twice the normal value, viz. $100/(44 + 6) = 2$. Without the external coil the current would be $100/44$, i.e. 2.27 times the normal value.

Mr. Page misunderstands our recommendation in regard to the size of busbar reactances, as it will not be necessary to transmit the full capacity of one busbar section across any busbar reactance. With a busbar section of 30,000 k.v.a. size, and a busbar reactance which will give 50 per cent of normal voltage when carrying full-load current of one busbar section, and assuming that the maximum current which it will be necessary (for any length of time) to transfer across the busbar reactance is 25 per cent of the full-load current of one busbar section, the k.v.a. capacity of the busbar reactance would be $30,000 \text{ k.v.a.} \times 0.5 \times 0.25^2 = 930 \text{ k.v.a.}$ This size of busbar reactance cannot be called excessive for power stations of the above size.

We quite agree with Mr. Taylor's statement that each installation must be carefully studied in order to determine whether the use of reactances is desirable, and if so to decide upon the proper lay-out of the system as a whole, including the size and disposition of the reactance coils.

We take this opportunity of mentioning that owing to a misunderstanding we allowed the proof of our reply to the Manchester discussion to be passed for press without being corrected.

ALTERNATING ELECTROMOTIVE FORCES IN PARALLEL.

THE SUBDIVISION OF THE CURRENT WITH ALTERNATORS AND TRANSFORMERS.

By A. E. CLAYTON, B.Sc., Associate Member.

(Paper received 26th March, 1914.)

INTRODUCTORY REMARKS.

Of recent years a large amount of attention has been given to problems connected with the parallel operation of alternating-current generators, but almost without exception the whole of the papers published on the subject deal with hunting and similar problems.

In the present paper the author discusses the manner in which the current is shared between the machines.

In "Alternating Current Phenomena" Steinmetz deals with the matter, employing the symbolic method, but his solutions are perhaps not very simple. The present author also uses the symbolic method, but he attacks the problem in a different manner from that employed by Steinmetz. The solutions obtained are remarkably simple; in fact, except for the use of the symbolic expression for impedance in the place of the symbol for resistance, the equations obtained might be those for cells working in parallel.

Let us first consider the case of a complex circuit arranged as in Fig. 1, in which there are two harmonic pressures in parallel between the points A and B.

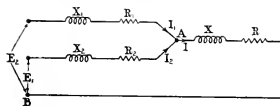

FIG. 1.

Resistance and reactance are included in each branch of the circuit.

Using symbolic expressions, except where otherwise stated, we have—

$$\begin{aligned}\text{Impedance } Z_1 &= R_1 + jX_1, \\ Z_2 &= R_2 + jX_2, \\ Z &= R + jX,\end{aligned}$$

where $j = \sqrt{-1}$.

Let E_1 and I_1 be symbolic values of the pressure and current in branch 1; and E_2 and I_2 be the corresponding values in branch 2. The pressures E_1 and E_2 may be displaced through any angle, but they have the same frequency.

The total current in the main impedance is then equal to the sum of the currents in the two branches, i.e.—

$$I = I_1 + I_2 \quad (1)$$

The pressure drop due to the impedance in branch 1 is $I_1 Z_1$, and the corresponding pressure drop in the main circuit is $I Z$; whence—

$$\begin{aligned}E_1 &= I_1 Z_1 + I Z, \\ &= I_1 Z_1 + (I_1 + I_2) Z \quad (2)\end{aligned}$$

Similarly—

$$E_2 = I_2 Z_2 + (I_1 + I_2) Z \quad (3)$$

By solving equations (2) and (3)—

$$I_1 = \frac{E_1 Z_2 + (E_1 - E_2) Z}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (i)$$

$$I_2 = \frac{E_2 Z_1 - (E_1 - E_2) Z}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (ii)$$

$$\text{and } I = I_1 + I_2 = \frac{E_1 Z_2 + E_2 Z_1}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (iii)$$

The potential difference V between the busbars A and B becomes—

$$\begin{aligned}V &= E_1 - I_1 Z_1, \\ \text{and it is also } &= I Z, \\ &= \frac{Z(E_1 Z_2 + E_2 Z_1)}{Z_1 Z_2 + Z(Z_1 + Z_2)}, \\ &= \frac{E_1 Z_2 + E_2 Z_1}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (iv)\end{aligned}$$

In the above it is to be noted that E_1 and E_2 are the values (symbolic) of the actual potential differences existing between the terminals of the sources of supply.

In dealing with problems in connection with alternating-current machines in parallel it is customary to divide the machine current into two components, one the load component and the other the synchronizing current.

We have for the current in branch 1—

$$I_1 = \frac{E_1 Z_2}{Z_1 Z_2 + Z(Z_1 + Z_2)} + \frac{(E_1 - E_2) Z}{Z_1 Z_2 + Z(Z_1 + Z_2)},$$

and for that in branch 2—

$$I_2 = \frac{E_2 Z_1}{Z_1 Z_2 + Z(Z_1 + Z_2)} - \frac{(E_1 - E_2) Z}{Z_1 Z_2 + Z(Z_1 + Z_2)}.$$

From the above two expressions it will be seen that the synchronizing or circulating current—

$$\begin{aligned}I_c &= \frac{(E_1 - E_2) Z}{Z_1 Z_2 + Z(Z_1 + Z_2)}, \\ &= \frac{E_1 - E_2}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (v)\end{aligned}$$

and the load components are respectively—

$$I_1' = \frac{E_1 Z_2}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad \text{and} \quad I_2' = \frac{E_2 Z_1}{Z_1 Z_2 + Z(Z_1 + Z_2)} \quad (vi)$$

The total load current $= I_1' + I_2'$.

From equations (i) to (vi) the symbolic expressions for the various currents, etc., are obtained; these symbolic values give at once both the effective value and the correct phase relationship of the various terms.

To illustrate the above method the author proposes to work out two examples, one with pressures in phase but of different values, the other with equal pressures having a phase displacement.

CASE 1.—Pressures in phase.

Effective value of $E_1 = 100$ volts, and of $E_2 = 90$ volts. Take the reference vector as being in phase with E_1 .

Then the symbolic value of $E_1 = 100 + j0$,

$$E_2 = 90 + j0.$$

Take the case with $R_1 = R_2 = 0.1$ ohm,

$$X_1 = X_2 = 0.8$$
 ohm,

$$R = 2.0$$
 ohms; $X = 1.2$ ohm.

We have $Z_1 = Z_2 = R_1 + jX_1 = 0.1 + j0.8$,

$$Z = R + jX = 2.0 + j1.2.$$

$$Z_1 Z_2 + Z(Z_1 + Z_2) = \frac{1}{(0.1 + j0.8)^2 + (2.0 + j1.2)(0.2 + j1.6)} \\ = \frac{1}{5.04j - 1.93} = -(0.173j + 0.0067).$$

$$E_1 Z_2 = 100(0.1 + j0.8) = 10 + j80j,$$

$$E_2 Z_1 = 90(0.1 + j0.8) = 9 + j72j,$$

$$(E_1 - E_2)Z = (100 - 90)(2.0 + j1.2) = 20 + j12j.$$

Whence—

$$I_1 = [(10 + j80j) + (9 + j72j)] \times [-(0.173j + 0.0067)] \\ = 13.3 - 12.9j,$$

$$I_2 = [(10 + j80j) - (9 + j72j)] \times [-(0.173j + 0.0067)] \\ = 11.7 - 0.5j,$$

$$I = I_1 + I_2 = 25 - 13.4j.$$

$$V = [(20 + j12j)] \times [-(0.173j + 0.0067)] = 0.16 - 5.8j,$$

$$V = 100 - (13.3 - 12.9j)(0.1 + j0.8) = 88.4 - 9.3j.$$

In the above expressions the real terms denote the components in phase with the vector of reference, and the imaginary terms the components at right angles to the vector of reference. The minus sign indicates an angle of lag.

The effective values can readily be obtained from the two components as shown in Table I.

As a check on the above the main impedance has a real value of $\sqrt{2.0^2 + 1.2^2} = 3.14$ ohms.

Hence the main current = $80/1/3.14 = 28.4$ amperes, and it lags behind the busbar potential difference by an angle = $\tan^{-1} 1.2/2.0 = 22.5$ degrees.

From the table above we obtain $28.3 - 6 = 22.3$ degrees.

The above example illustrates the well-known fact that the wattless current is obtained chiefly from the source having the larger E.M.F. The watt current is divided practically in the ratio of the E.M.F.'s, so that the power taken from the two sources is roughly proportional to the squares of their E.M.F.'s. The synchronizing current is practically wattless.

CASE 2.—Pressures equal in magnitude but having a phase displacement.

The reference axis will be taken in phase with E_1 , and the following values will be assumed:—

$$E_1 = 100 + j0,$$

$$E_2 = 100(\cos \alpha - j \sin \alpha).$$

Take the case when $\alpha = 10^\circ$; $E_2 = 98.5 - 17.5j$; $R_1 = 0.1$; $X_1 = 0.9$; $R_2 = 0.2$; $X_2 = 1.8$; $R = 8$; $X = 6$.

$$Z_1 Z_2 + Z(Z_1 + Z_2) = \frac{1}{(1 + j0.9)(0.2 + j1.8) + (8 + j6)(0.3 + j2.7)} \\ = \frac{1}{(0.0192 + 0.0296j)}.$$

$$E_1 Z_2 = 100(0.2 + j1.8j) = 20 + j180j,$$

$$E_2 Z_1 = (98.5 - 17.5j)(0.1 + j0.9j) = 25.6 + 86.8j,$$

$$(E_1 - E_2)Z = (1.5 + 17.5j)(8 + j6) = 93 + 149j.$$

$$\text{Whence } I_1 = -(-73 + 329j)(0.0192 + 0.0296j),$$

$$= 11.13 - 4.15j,$$

$$I_2 = -(118.6 - 62.2j)(0.0192 + 0.0296j),$$

$$= -4.1 - 2.3j,$$

$$I = 7.05 - 6.45j,$$

$$I_1 = -(-93 + 149j)(0.0192 + 0.0296j),$$

$$= 6.2 - 0.1j,$$

$$V = 100 - (11.13 - 4.15j)(0.1 + j0.9j),$$

$$= 95.2 - 9.6j.$$

TABLE I.

			Symbolic Value	Effective Value	Angle of Lag
E_1	Pressure	$100 + j0$	100	0
	Current	$13.3 - 12.9j$	$\sqrt{13.3^2 + 12.9^2} = 18.5$	$\tan^{-1} 12.85/13.3 = 44^\circ$
	Power	$100 \times 13.3 = 1330$...
E_2	Pressure	$90 + j0$	90	0
	Current	$11.7 - 0.5j$	$\sqrt{11.7^2 + 0.5^2} = 11.7$	$\tan^{-1} 0.5/11.7 = 2.5$
	Power	$90 \times 11.7 = 1050$...
Busbar p.d.	$88.4 - 9.3j$	$\sqrt{88.4^2 + 9.3^2} = 88.4$	$\tan^{-1} 9.3/88.4 = 6.0$
Synchronizing current	$0.16 - 5.8j$	$\sqrt{0.16^2 + 5.8^2} = 5.8$	$\tan^{-1} 0.15/0.8 = 82.5$
Main current	$25 - 13.4j$	$\sqrt{25^2 + 13.4^2} = 28.4$	$\tan^{-1} 13.4/25 = 28.3^\circ$

The effective values are given in Table II.

TABLE II.

		Symbolic Value	Effective Value	Angle of Lag behind E_1
E_1	Pressure	$100 + 0j$	100	0
	Current	$11.13 - 4.15j$	11.8	20.3°
	Power	...	1,113	...
E_2	Pressure	$98.5 - 17.5j$	100	10
	Current	$-4.1 - 2.3j$	4.7	151.5°
	Power	...	-305	...
Busbar p.d.	...	$95.2 - 0.6j$	95.5	5.8°
Synchronizing current	...	$6.2 - 0.1j$	6.2	1
Main current	...	$7.05 - 6.45j$	9.55	42.4°

As a check we have:—

The main impedance is $\sqrt{6^2 + 8^2} = 10$ ohms, and the effective current $95.5/10 = 9.55$ amps. The angle of lag behind the busbar potential difference = 36.9 degrees, compared with the above value of $42.4 - 5.8 = 36.6$ degrees.

The effect of the phase displacement between the E.M.F.'s is shown clearly; the source of the lagging E.M.F. receives energy at the mean rate of 365 watts; the

component and the first term the load component. Thus the load component—

$$I_1' = \frac{E_1}{Z_1 + Z(Z_1 + Z_2)/Z_2}$$

The equivalent impedance which gives rise to the load component is thus $Z_1 + Z(Z_1 + Z_2)/Z_2$. Z_1 is the internal impedance of the branch; thus the equivalent impedance offered by the main load Z is $Z(Z_1 + Z_2)/Z_2$, and the admittance is $Y_1 Y_2 / (Y_1 + Y_2)$, where $Y = 1/Z$, etc. Thus the equivalent load admittances for the two sources of supply are obtained by dividing the total load admittance in the ratio of their admittances, i.e. in the inverse ratio of their impedances. It will be noted that the value of the load component I_1' is quite independent of the value of the E.M.F. of the second source.

2. Synchronizing current.

$$I_2 = \frac{(E_1 - E_2)Z}{Z_1 Z_2 + Z(Z_1 + Z_2)}$$

$$= \frac{E_1 - E_2}{Z_1 Z_2 / Z + (Z_1 + Z_2)}$$

The equivalent impedance of the path of the synchronizing current is thus $Z_1 Z_2 / Z + (Z_1 + Z_2)$.

The last term is the actual series impedance of the two branches. The term $Z_1 Z_2 / Z$ takes account of the effect of the load components of the currents. When the load is light, Z is large and the equivalent impedance to the synchronizing current $= Z_1 + Z_2$. On heavy loads Z is small and the term $Z_1 Z_2 / Z$ must be included. When $Z = 0$, the synchronizing current also $= 0$.

Since the effect of the synchronizing currents depends upon their magnitude and their phase displacement, it is obvious that the restoring power developed will depend upon both the magnitude and the nature of the load.

TABLE III.

Co- ϕ	Z	I_1	I_2	I_1	I
0	$2.5j$	$27.1 - 86.1j$	$-35.2 - 86.9j$	$26.8 + 0.43j$	$-8.1 - 173j$
0.4	$1 + 2.29j$	$57.3 - 82j$	$-5.2 - 83.4j$	$27.2 - 0.8j$	$52.1 - 165.4j$
0.6	$1.5 + 2j$	$74.6 - 76.3j$	$12.9 - 78j$	$27.6 - 1.52j$	$86.5 - 154.3j$
0.8	$2 + 1.5j$	$94 - 64.6j$	$31 - 66j$	$28.4 - 2.6j$	$125 - 130.6j$
1.0	2.5	$127 - 10.7j$	$65 - 21j$	$30.5 - 4.2j$	$192 - 40.7j$
0.8	$2 - 1.5j$	$120 + 48.2j$	$66.5 + 46.6j$	$34.2 - 4j$	$196.2 + 94.8j$
0.6	$1.5 - 2j$	$113.5 + 79.7j$	$50.8 + 77.9j$	$35.5 - 3j$	$164.3 + 157.6j$
0.4	$1 - 2.29j$	$92.7 + 102.7j$	$32.2 + 97j$	$36.2 - 1.8j$	$124.9 + 204.3j$
0	$-2.5j$	$37.8 + 120.4j$	$-24.7 + 117.6j$	$37.2 - 1.4j$	$13.5 + 238j$

external circuit at the rate of $(9.55)^2 \times 8 = 730$ watts; the ohmic losses for the two sources at the rate of $(11.15)^2 \times 0.1 + (4.7)^2 \times 0.2 = 17$ watts. The mean power taken from the source of leading E.M.F. thus sums up to 1,112 watts. The synchronizing current is now practically at unity power factor so far as E_1 is concerned.

Let us now consider more fully the formulae that we have obtained.

1. Current.

The current in branch 1 is given by—

$$I_1 = \frac{E_1 Z_2}{Z_1 Z_2 + Z(Z_1 + Z_2)} + \frac{(E_1 - E_2)Z}{Z_1 Z_2 + Z(Z_1 + Z_2)}$$

The second term gives the value of the synchronizing

3. Main current.

$$I = \frac{E_1 Z_2}{Z_1 Z_2 + Z(Z_1 + Z_2)} + \frac{E_2 Z_1}{Z_1 Z_2 + Z(Z_1 + Z_2)}$$

$$= \frac{E_1}{Z_1 + Z(Z_1 + Z_2)/Z_2} + \frac{E_2}{Z_2 + Z(Z_1 + Z_2)/Z_1}$$

The total current in the external circuit is readily obtained by adding together the load components of the currents from the two sources.

EFFECT OF THE EXTERNAL ANGLE OF LAG.

In order to show the effect of the nature of the load the following case has been worked out—

$$E_1 = 500; E_2 = 500 - 50j.$$

$$Z_1 = Z_2 = 0.02 + 0.8j.$$

External impedance is constant and = 2.5 ohms, but the angle of lag varies from $+90^\circ$ to -90° , i.e.—

$$\begin{aligned} Z &= 2.5j & \text{lag of } 90^\circ, \cos \phi = 0, \\ &= 1 + 2.2j & \cos \phi = 0.4, \\ &= 1.5 + 2j & \cos \phi = 0.6, \\ &= 2 + 1.5j & \cos \phi = 0.8, \\ &= 2.5 & \cos \phi = 1.0, \\ &= 2 - 1.5j & \cos \phi = 0.8 \text{ leading,} \\ &\text{etc.} \end{aligned}$$

The results are shown in tabular form in Tables III, IV, and V.

TABLE IV.—Effective values.

Cos ϕ	Main Circuit		Branch 1		Branch 2	
	Volts	Amperes	Amperes	Watts $\times 1,000$	Amperes	Watts $\times 1,000$
0	432	173	90.5	13.55	94	-13.25
0.4	432	173	99.5	28.05	83.5	-1.57
0.6	442	177	107	37.3	79	10.35

TABLE V.—Synchronizing Current, etc.

Main Current		Synchronizing Current	
Cos ϕ	Amperes	Watt Component Amperes	Syn. Watts $\times 1,000$
0	173	26.8	13.4
0.4	173	27.2	13.6
0.6	177	27.6	13.8
0.8	181	28.4	14.2
1.0	196.5	30.5	15.3
0.8	218	34.2	17.1
0.6	228	35.5	17.8
0.4	237	36.2	18.1
0	238	37.2	18.6

The curves (Fig. 2) show the manner in which the currents, etc., depend upon the power factor of the load.

It will be noted that the effective values of the currents in the two branches are widely different except at low power factors. The influence of the nature of the load upon the synchronizing watts is clearly shown. For a load current of 200 amperes the synchronizing watts are from 30 to 40 per cent greater at zero power factor leading than at zero power factor lagging.

EXPERIMENTAL RESULTS.

In order to check the above calculations a series of experiments was carried out by the author. In the first

series of experiments 100-volt 50-cycle mains were connected in parallel with the secondary of a 1:1 transformer fed by the same mains, impedance being included in the circuit as is shown in Fig. 3. The main impedance was obtained from the readings of the main ammeter, voltmeter, and wattmeter. The impedances of the branches B C and D C were obtained by means of a voltmeter and an ammeter, and their resistances by similar means with

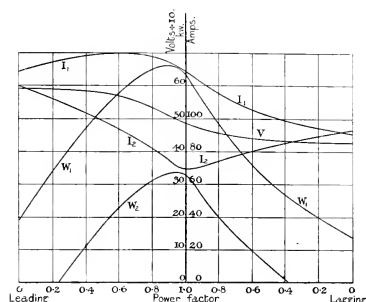

FIG. 2.

continuous currents. The reactances in the paths B C and D C consisted of choking coils having iron cores, but the error due to omitting the iron losses in the cores is insignificant. The instruments used were ordinary switchboard instruments, and the agreement between the test figures and the calculated figures was exceedingly good.

In order to obtain a phase displacement between the

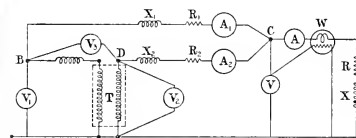

FIG. 3.

pressures, a small choking coil was introduced in the primary circuit of the transformer. This produced a secondary E.M.F. smaller than and displaced from the potential difference between the mains.

To obtain the value of the phase displacement, readings of the pressures E_1 , E_2 , and $E_1 - E_2$, were obtained, and the triangle of voltages was constructed (see Fig. 4).

A few only of the test results are shown in Table VI. It will be noted that the difference between the observed and the calculated figures is insignificant.

In the second series of experiments a double-current generator with 6 slip-rings for 1-, 2-, or 3-phase current was used.

$$\begin{aligned}\text{Current } I_1 &= \frac{E_1}{Z_1 + 2Z} + \frac{j a E_1 Z}{Z_1(Z_1 + 2Z)} \\ &= \frac{E_1}{Z_1 + 2Z} \left(1 + j a \frac{Z}{Z_1} \right).\end{aligned}$$

$$\begin{aligned}\text{Current } I_2 &= \frac{E_2}{Z_2 + 2Z} - \frac{j a E_1 Z}{Z_1(Z_1 + 2Z)} \\ &= \frac{E_2 - j a E_1}{Z_2 + 2Z} - \frac{j a E_1 Z}{Z_1(Z_1 + 2Z)} \\ &= \frac{E_2}{Z_2 + 2Z} \left[1 - j a \left(1 + \frac{Z}{Z_1} \right) \right].\end{aligned}$$

$$\text{Main current } I = \frac{E_1}{Z_1 + 2Z} (2 - ja).$$

The calculation of the distribution of the load between two similar machines is thus reduced to very simple equations.

So far we have calculated the distribution of the currents for a given load impedance. It is frequently desirable to calculate the manner in which a given load current is shared by the two machines.

$$\begin{aligned}\text{We have} \quad E_1 &= I_1 Z_1 + I Z, \\ E_2 &= I_2 Z_2 + I Z, \\ \text{and} \quad I_1 + I_2 &= I.\end{aligned}$$

$$\begin{aligned}\text{Whence } E_1 - E_2 &= I_1 Z_1 - (I - I_1) Z_2; \\ I_1 &= I \frac{Z_2}{Z_1 + Z_2} + \frac{E_1 - E_2}{Z_1 + Z_2};\end{aligned}$$

$$\text{and} \quad I_2 = I \frac{Z_1}{Z_1 + Z_2} - \frac{E_1 - E_2}{Z_1 + Z_2}.$$

Expressed in this form it is extremely simple to calculate the characteristic curves. The term $(E_1 - E_2)/(Z_1 + Z_2)$ is the value of the synchronizing current at no load.

Table VIII below gives the results of such calculations.

$$E_1 = 500, E_2 = 500 - 50j, Z_1 = 0.018 + 0.72j, Z_2 = 0.012 + 0.48j,$$

$$\frac{Z_1}{Z_1 + Z_2} = \frac{3}{5}, \frac{E_1 - E_2}{Z_1 + Z_2} = \frac{50j}{0.03 + 1.2j} = 41.5 - 1j.$$

TABLE VIII.

I	I_1	I_2
0	41.5 + 1j	-41.5 - 1j
50	61.5 + 1j	-11.5 - 1j
100	81.5 + 1j	8.5 - 1j
150	101.5 + 1j	28.5 - 1j
200	121.5 + 1j	48.5 - 1j
250	141.5 + 1j	68.5 - 1j
300	161.5 + 1j	88.5 - 1j
350	181.5 + 1j	108.5 - 1j
400	201.5 + 1j	128.5 - 1j

The calculations for other values of I out of phase with E_1 are quite similar.

DETERMINATION OF THE PHASE DISPLACEMENT BETWEEN TWO ALTERNATORS WORKING IN PARALLEL.

In actual practice alternators do not work with a fixed mechanical phase displacement. With two machines working in parallel the manner in which they share the

load (watt component) depends entirely upon the engine characteristics. The mechanical displacement between the machines adjusts itself automatically so that each engine has to deal with its proper load. The wattless component of the main current is shared by the machines according to their relative excitations, the machine with the larger excitation contributing the greater part of the wattless current. It is necessary then to be able to calculate the phase displacement between the machines. From the engine speed-output characteristics the manner in which the two machines divide the load can be determined with fair accuracy (see Fig. 6). Hence we know also to a close approximation the ratio W_1/W_2 of the watt outputs of the alternators.

We have already obtained expressions for the values of the various currents; from these expressions we can obtain

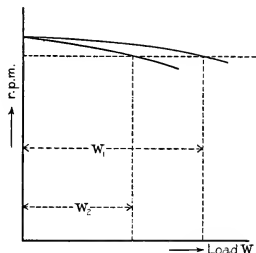

FIG. 6.

the values of the power developed by the two machines, from which we find for machines similarly excited—

Phase displacement α

$$= \frac{R(W_1 X_1 - W_2 X_2)}{(W_1 + W_2)[R^2 + X^2 + X(X_1 X_2)/(X_1 + X_2)]}.$$

The proof of this formula is given in the Appendix.

The author proposes to check the formula by referring back to Table IV, where several cases have been calculated for two machines having a phase displacement of one-tenth of an electrical radian.

$$X_1 = X_2 = 0.8$$

CASE 1.—Unity power factor. $Z = 2.5$; $R = 2.5$; $W_1 = 63,750$; $W_2 = 33,600$.

$$a = \frac{2.5 \times 0.8 (30,150)}{97,350 \times 0.25} = 0.099.$$

CASE 2.—Power factor 0.4 lagging. $R = 1$; $X = 2.29$; $W_1 = 28,650$; $W_2 = 15,700$.

$$a = \frac{0.8 \times 27,100}{30,200 (6.25 - 2.29 \times 0.4)} = 0.100.$$

CASE 3.—Power factor 0.6 leading. $R = 1.5$; $X = -2$; $W_1 = 56,750$; $W_2 = 21,500$.

$$a = \frac{1.5 \times 0.8 \times 35,250}{78,250 (6.25 + 0.8)} = 0.099.$$

Thus the angle of phase displacement between two alternators can readily be calculated provided that the engine characteristics and the equivalent reactances of the two windings are given.

THREE ALTERNATORS IN PARALLEL.

We have—

$$\begin{aligned} E_1 &= I_1 Z_1 + (I_1 + I_2 + I_3) Z_0 \\ E_2 &= I_2 Z_2 + (I_1 + I_2 + I_3) Z_0 \\ E_3 &= I_3 Z_3 + (I_1 + I_2 + I_3) Z_0 \end{aligned}$$

Solving these equations we obtain—

$$I_1 = \frac{E_1 Z_2 Z_3 + Z_1' (E_2 - E_3) Z_3 + (E_1 - E_3) Z_2'}{Z_1 Z_2 Z_3 (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3)};$$

and similar expressions for I_2 and I_3 .

The load component of the current I_1

$$\begin{aligned} &= \frac{E_1}{Z Z_1 (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3)} \\ &= \frac{E_1}{Z_1 + Z (Y_1 + Y_2 + Y_3) Y_1} \end{aligned}$$

The synchronizing component of the current I_1 is obtained from—

$$\begin{aligned} I_{s1} &= \frac{E_1 - E_2}{Z_1 Z_2 (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3) + Z_2 Z_3 (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3)} \\ &= \frac{E_1 - E_2}{(Z_1 + Z_2) + Z_2 Z_3 (1/Z + 1/Z_3)} + \frac{E_1 - E_3}{(Z_3 + Z_1) + Z_1 Z_3 (1/Z + 1/Z_2)} \end{aligned}$$

and similar expressions for I_{s2} and I_{s3} .

$$\begin{aligned} \text{The total current } I &= \frac{1}{Z} \sum \frac{E_i}{Z_i (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3)} \\ &= \frac{1}{Z (1/Z + 1/Z_1 + 1/Z_2 + 1/Z_3)} \sum \frac{E_i}{Z_i} \end{aligned}$$

The problem is thus completely solved as in the case of two machines in parallel, and similar deductions can be obtained from the equations.

DETERMINATION OF THE PHASE DIFFERENCE BETWEEN THE INDUCED E.M.F. AND THE TERMINAL VOLTAGE.

Actually the value of the real induced E.M.F. will not be that obtained from the vector diagram, since the armature reaction reduces its value. The value used in the vector diagram is the total E.M.F. induced on open circuit with the same excitation as on full load.

In the vector diagram, Fig. 7, ωL_s is the true reactance of the winding, ωL_a is that equivalent to the armature reaction. OE is the true induced E.M.F., OE' is the fictitious value and is equal to the open-circuit E.M.F. The total lag of the terminal pressure behind the machine vector is equal to the angle EO'V, of which E'O'E is due to the distorting effects of the armature reaction, and EO'V is due to the true reactance of the winding.

Let θ = angle E'O'E, and take the reference vector in phase with the terminal pressure. Then the expression for the E.M.F. is given by—

$$\begin{aligned} \text{OE}' &= E_1 (\cos \theta + j \sin \theta), \\ &= E_1 \cos \theta + E_1 j \sin \theta. \end{aligned}$$

$$\text{Hence } E_1 \cos \theta + E_1 j \sin \theta = V + I_1 Z_1.$$

The output of the machine = real part of $I_1 V$, i.e. of

$$(E_1 \cos \theta + E_1 j \sin \theta - V) V.$$

$$W_1 = E_1 V X_1 \sin \theta + R_1 (E_1 V \cos \theta - V^2) - \frac{R_1^2 + X_1^2}{2}$$

$R_1^2 + X_1^2 = X_1^2$ for all practical purposes, hence—

$$W_1 = \frac{E_1 V \sin \theta}{X_1} + \frac{R_1 V}{X_1^2} (E_1 \cos \theta - V).$$

The second term is exceedingly small, R_1/X_1^2 being of the order of $1/250$ and $E_1 \cos \theta$ being nearly equal to V . Hence to a close approximation—

$$\sin \theta_1 = \frac{W_1 X_1}{E_1 V}.$$

Similarly for another machine feeding into the same busbars—

$$\sin \theta_2 = \frac{W_2 X_2}{E_2 V}.$$

$$\text{Hence } \sin \theta_1 - \sin \theta_2 = \frac{W_1 X_1}{E_1 V} - \frac{W_2 X_2}{E_2 V}.$$

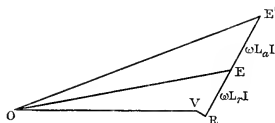

FIG. 7.

and for the small angles obtaining in practice—

$$\alpha = \theta_1 - \theta_2 = \frac{W_1 X_1}{E_1 V} - \frac{W_2 X_2}{E_2 V}.$$

For equally excited machines—

$$\alpha = \theta_1 - \theta_2 = \frac{W_1 X_1 - W_2 X_2}{E_1 V}.$$

The value α is the phase displacement between the two machines. Expressed in this form the formula is perhaps more suitable for calculations than the one given earlier, for all cases when the busbar potential difference is given. In the Appendix the two expressions are shown to be equivalent.

MANY ALTERNATORS IN PARALLEL.

When dealing with the parallel operation of more than two alternators the calculations are simplified by the fact that the potential difference between the busbars can now be taken as known.

Taking the reference vector in phase with V , we then have $E_i \cos \theta + j E_i \sin \theta = V + I_i Z_i$; and for the values of θ obtaining in practice, neglecting the alternator resistance—

$$E_i + j E_i \theta = V + j I_i X_i,$$

$$\text{where } I_i = E_i \theta / X_i - j (E_i - V) / X_i,$$

$$\text{where } I_i = W_i / V - j (E_i - V) / X_i,$$

$$\text{since } \sin \theta = W_i X_i / E_i V.$$

Of this the watt component is the real term W_i/V , and the wattless component is $(E_i - V) X_i$.

TRANSFORMERS IN PARALLEL.

For convenience the author will first deal with the case in which the transformation ratio is unity. It is well known that such a transformer can be replaced by the equivalent circuit shown in Fig. 8.

Let I_m be the magnetizing current of the transformer, Z_1' and Z_2'' be the primary and secondary leakage impedances,

and Z_1 be the equivalent impedance on open circuit.

$$Z_1 = \text{the total leakage impedance} = Z_1' + Z_1''.$$

$$\begin{aligned} E &= (I_1 + I_m)Z_1' + I_1Z_1'' + IZ_1 \\ &= I_mZ_1' + I_1(Z_1' + Z_1'') + IZ_1 \\ &= I_mZ_1' + I_1Z_1 + IZ_1. \end{aligned}$$

$$\text{Whence} \quad E - I_mZ_1' = I_1Z_1 + IZ_1 \dots \dots (1)$$

Similarly for the second transformer working in parallel with the first—

$$E - I_2Z_2' = I_2Z_2 + IZ_2 \dots \dots (2)$$

$$\text{and} \quad I = I_1 + I_2 \dots \dots (3)$$

Solving these equations, we get—

$$I_1 = \frac{(E - I_mZ_1')Z_2}{Z_1Z_2 + Z(Z_1 + Z_2)} + \frac{(I_mZ_2' - I_mZ_1')Z_1}{Z_1Z_2 + Z(Z_1 + Z_2)};$$

$$I_2 = \frac{(E - I_mZ_2')Z_1}{Z_1Z_2 + Z(Z_1 + Z_2)} - \frac{(I_mZ_1' - I_mZ_2')Z_2}{Z_1Z_2 + Z(Z_1 + Z_2)};$$

$$I = \frac{(E - I_mZ_1')Z_2 + (E - I_mZ_2')Z_1}{Z_1Z_2 + Z(Z_1 + Z_2)}.$$

In general the second terms in the expressions for I_1 and I_2 can be omitted, and we have—

$$I_1 = \frac{(E - I_mZ_1')Z_2}{Z_1Z_2 + Z(Z_1 + Z_2)}; \quad I_2 = \frac{(E - I_mZ_2')Z_1}{Z_1Z_2 + Z(Z_1 + Z_2)} \quad (4)$$

For the secondary potential difference we have—

$$V = E - I_mZ_1' - I_1Z_1.$$

In the majority of cases the effect of the magnetizing current can be neglected—

$$I_1 = \frac{EZ_2}{Z_1Z_2 + Z(Z_1 + Z_2)}; \quad I_2 = \frac{EZ_1}{Z_1Z_2 + Z(Z_1 + Z_2)};$$

and

$$I = \frac{E(Z_1 + Z_2)}{Z_1Z_2 + Z(Z_1 + Z_2)};$$

i.e. the same expressions as for equally excited alternators in phase. These expressions are sufficiently accurate for

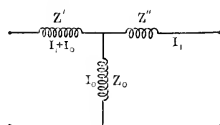

FIG. 8.

ordinary purposes. For more exact purposes the expressions (4) may be used.

The terms I_m , I_1 , and I_2 give the values of the secondary currents. To obtain the primary currents we have—

$$\text{Primary current (1)} = I_m + I_1,$$

$$\text{Primary current (2)} = I_m + I_2.$$

EXPERIMENTAL RESULTS.

To check the above, experiments have been carried out on two Berry transformers, the primaries of which consisted of two windings in parallel. By using these two windings as primary and secondary respectively, a 1:1 transformer was obtained. The two transformers being similar, a reactance coil was introduced in the secondary

$$I_m = 5 \text{ amps.}; \quad I_2 = 4 \text{ amps.}$$

circuit of one of them as shown in the diagram of connections (Fig. 3). The effect is obviously the same as increasing the secondary leakage. The actual leakage between the two windings was very small and the transformers being worked at one-half the normal frequency the reactance was so small as to be much less than the resistance. In order to obtain relatively large magnetizing currents the working pressure was about 60 per cent above the normal. The test figures are given in Table IX and it will be noted that the results are in agreement with the calculated theoretical values.

In the case where the secondary E.M.F.'s are not exactly equal, it is best to work in terms of the actual secondary E.M.F.'s on open circuit, and reduce the primary impedances in terms of the secondaries in the usual manner. The difference in E.M.F. will give rise to a circulating current equal to $\frac{(E_1 - E_2) Z}{Z_1 Z_2 + Z_1 (Z_1 + Z_2)}$, which, for a transformer, where Z_1 and Z_2 are small compared with Z , is practically constant and equal to $\frac{E_1 - E_2}{Z_1 + Z_2}$. The equations for this case are the same as for two alternators in phase but with different excitations.

RÉSUMÉ.

By the aid of the symbolic method due to Steinmetz problems connected with the parallel operation of sources of alternating currents can be solved as readily as similar problems connected with continuous currents.

In the method given by the author the equations deduced in their general terms would hold good for both continuous and alternating currents.

The whole method is based upon sine functions, although if necessary with non-sinusoidal E.M.F.'s each harmonic can be considered separately. In addition, in the case of alternators, it is based upon an equivalent reactance due to the combined effects of reaction and reactance. A method of obtaining a correct value for this equivalent reactance has been given by the author in the *Electrician*.²

APPENDIX.

TO DETERMINE THE MECHANICAL LAG BETWEEN TWO MACHINES.

The manner in which the machines divide the total watt output is determined by the engine characteristics. The present calculations will therefore assume equally excited

* *Electrician*, vol. 73, p. 90, 1914.

machines, and the alternator resistances will be neglected. We have—

$$I_1 = \frac{j E_1 X_2 + j a E_2 (R + j X)}{-X_1 X_2 + (R + j X_1)(j X_2 + j X)}, \text{ say } A + j B.$$

To obtain the mean watts we multiply the above by the symbolic expression for the E.M.F., or say $(C + j D)$, and we have the mean watts = $A C - j^2 B D = A C + B D$.

$$I_2 = \frac{j E_2 X_1 - j a E_1 X_2 - j a E_2 (R + j X)}{-X_1 X_2 + (R + j X_1)(j X_2 + j X)},$$

Proceeding as indicated above we obtain for the ratio of the total power developed by the two machines—

$$\begin{aligned} W_1 &= \frac{R(X_1 + X_2)(X_2 + aR) + aX[X_1 X_2 + X_2(X_1 + X_2)]}{R(X_1 + X_2)(X_1 - aR - aX_1) - aX[X_1 X_2 + X_2(X_1 + X_2)]} \text{ approx.} \\ W_2 &= \frac{R X_2 + a R^2 + a X^2 + a X X_2 X_2 / (X_1 + X_2)}{R X_1 + a R^2 - a X^2 - a X X_1 X_2 / (X_1 + X_2)} \text{ approx.} \end{aligned}$$

whence—

$$a [R^2 + X^2 + XX_2 X_2 / (X_1 + X_2)] (W_1 + W_2) = R(W_1 X_1 - W_2 X_2),$$

and—

$$a = \frac{R(W_1 X_1 - W_2 X_2)}{(W_1 + W_2) [R^2 + X^2 + XX_2 X_2 / (X_1 + X_2)]}.$$

This may also be written—

$$a = \frac{W_1 X_1 - W_2 X_2}{(W_1 + W_2) \left(\frac{R^2 + X^2}{R} + \frac{XX_2}{R} \right)},$$

where X' is the equivalent reactance of the two alternators in parallel, i.e. X' equals $X_1 X_2 / (X_1 + X_2)$. Hence—

$$\begin{aligned} a &= \frac{W_1 X_1 - W_2 X_2}{V^2 + (W_1 + W_2) (X X' / R)} \\ &= \frac{W_1 X_1 - W_2 X_2}{V^2 + (I V \sin \phi) X'}, \end{aligned}$$

where ϕ = angle of lag of the main current.

$$\therefore a = \frac{W_1 X_1 - W_2 X_2}{V(V + I X' \sin \phi)}.$$

($I \sin \phi$) X' is approximately equal to $E - V$; hence—

$$a = \frac{W_1 X_1 - W_2 X_2}{V(E - V)}.$$

as obtained previously.

For unity power factor $X = 0$, and—

$$a = \frac{W_1 X_1 - W_2 X_2}{(W_1 + W_2) R}.$$

STATIC TRANSFORMERS FOR THE SIMULTANEOUS CHANGING OF FREQUENCY AND PRESSURE OF ALTERNATING CURRENTS.

By A. M. TAYLOR, Member.

(Paper first received 23rd September, 1913, and in final form 5th May, 1914; read before the BIRMINGHAM LOCAL SECTION 20th April, 1914.)

SYNOPSIS.

Historical—the frequency changers of Joly, Vallauri, Spinelli, and Taylor.

Principle of Taylor's frequency changer.

Regulation.

Efficiency.

Uses of the apparatus.

Wireless telegraphy—ratios of 9 : 1 and 27 : 1 in one operation.

Appendix—explanation of the operation of the apparatus.

The object of the present paper is primarily to describe the method of employing static transformers for changing the frequency of alternating currents for power and lighting. In the latter part of the paper allusion will be made to the use of similar apparatus in connection with wireless telegraphy. In this direction, however, the author is not so familiar with what has been done as he is in the applications relating to power. It is therefore hoped that any incompleteness in the way of references to the work of other experimenters in the wireless field will be overlooked, in view of what is hoped will prove interesting matter relating to the frequency changer that the author has devised.

HISTORICAL.

The earliest public announcement of the invention of a frequency changer, as far as the author is aware, was made by the late M. Maurice Joly, and was communicated to the Académie des Sciences early in 1911. Two other inventors have also entered the field, both of them Italians, namely, Signor Vallauri, who, the author understands, has invented a frequency changer for doubling the frequency, and Signor Spinelli, who has invented an arrangement for trebling the frequency.

M. Joly's invention covered both forms of apparatus, namely, apparatus for taking a single phase of the supply and producing from it another single-phase supply either at double or treble the frequency. The first result was obtained by employing a continuous current to excite the static frequency changer. A very similar arrangement was independently worked out by the author. Whatever may be its advantages for wireless telegraphy, the fact of continuous current having to be used for excitation is rather a drawback as regards its application for power or lighting, and therefore the theory of this apparatus will not be discussed in this paper in detail as regards doubling the frequency. Those interested may find some valuable information in *La Lumière Électrique*¹ in a description of M. Maurice Joly's invention.

As regards trebling the frequency (the second form of apparatus), the principle of M. Joly's invention was

essentially as follows:—He started with the idea that a sine wave can be split up, as shown in Fig. 1, into two waves—one of which is in the nature of a flat-topped wave with a steep front and end, and the other a somewhat peaky wave, the front and end of which have a very easy gradient. The difference between these two waves, or $\phi_1 - \phi_2$, gives a triple-frequency wave, as shown in the diagram. M. Joly suggested that by taking two transformers (A C and B D), of which the primary coils were A and B respectively, and the secondary coils C and D, and by applying a sine-wave electromotive force across the two primary coils A and B in series, waves of flux of the desired form would be obtained if one of the transformer cores (A) were saturated and the other (B) unsaturated. Further, he said that, considering the electromotive forces

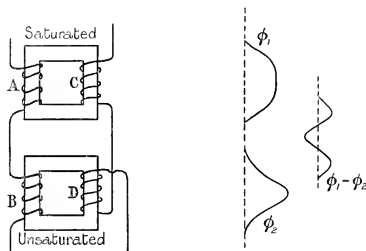

FIG. 1.—Joly's Arrangement.

from the secondary windings (which correspond with the differentiation of these waves of flux), by reversing one secondary winding so that its E.M.F. wave was opposed to that of the other secondary winding, a resultant effect would be obtained in the secondary circuit due to the difference of the two waves. In other words, one would get a triple-frequency electromotive force in the secondary circuit.

It will be seen at once from an investigation of the author's arrangement given later that this relation between the fluxes in the two cores is quite natural under particular conditions and exists in an aggravated form in his arrangement. The essential difference between M. Joly's arrangement and that devised by the author is that whereas in M. Joly's arrangement the secondary coils are wound both on the saturated and on the unsaturated cores and connected in series, this is not the case in the author's

¹ *Lumière Électrique*, vol. 14, p. 195, 1911.

arrangement, only one secondary coil being used, which is placed on the unsaturated core.

The difference in the operation of the two arrangements is also apparent, since in M. Joly's arrangement, owing to the fundamental condition of employing two secondary coils in series, it is necessary that the two half-waves should be distorted to exactly the right amount, and therefore the apparatus only works at its best efficiency under the conditions of a particular flux density in the saturated transformer and a particular value of the demagnetizing action in the unsaturated transformer; whereas in the author's arrangement the two flux densities can be varied quite independently and the induction can be raised to any desired degree in either, or the load varied to any desired amount in the working transformer. The magnetizing current itself can also be carried to very high limits and a large output thereby obtained from a given transformer. The author's arrangement, however, as will be seen from the description given later, generates an incomplete wave of electromotive force in any one phase, but the electromotive forces received from the three phases of the supply are so combined as to give a properly balanced single-phase wave of supply at the triple frequency.

To sum up, therefore, the essential difference between M. Joly's arrangement and that of the author is that whereas M. Joly takes a single phase of the supply and resolves a half-wave into three half-waves of electromotive force of triple the frequency, the author, on the other hand, takes a three-phase supply and from each individual phase of that supply, and from each half-wave of each phase, abstracts two incompletely formed half-waves of triple the frequency, supplementing these by other half-waves from the other two phases and delivering to the triple-frequency circuit a single-phase triple-frequency current. The author's arrangement, in fact, only works when transforming from three phases to a single phase. This statement does not apply, however, to his arrangement for obtaining a step-up of the frequency in the ratio of one to two.

As regards Signor Vallauri's invention, the author believes this to be substantially the same as that of M. Joly—but with some interesting developments—in that it transforms one phase of the supply into single-phase current at double the frequency. This method has been described in a paper read before the *Associazione Elettrotecnica Italiana*.²

The invention of Signor Spinelli differs from those of Vallauri and Joly in that it takes a three-phase supply and combines the three phases in such a way as to obtain a single-phase supply of triple frequency from the secondary coil. This frequency changer has been described by Signor Spinelli in a paper read before the Italian Society.³

In that paper Signor Spinelli pointed out that the arrangement should be particularly well adapted for use on three-phase railways (of which there are many in Italy) for the purpose of lighting railway stations, the frequency of the supply to the railway motors being only of the order of 15 periods per second, which periodicity is of course quite unsuitable for giving satisfactory lighting with incandescent lamps: whereas the frequency obtained (viz. 48 cycles per second) by increasing the fundamental frequency three-fold is eminently suitable for incandescent lighting.

² *Atti della Associazione Elettrotecnica Italiana*, vol. 15, p. 391, 1911; and *Electrician*, vol. 70, p. 382, 1912.

³ *Elettropista*, vol. 1 (Ser. 3), p. 215, 1912; and *Electrician*, vol. 70, p. 97, 1912.

Signor Spinelli's arrangement is shown in principle in Fig. 2, and consists in taking three single-phase transformers and coupling their primary windings in star and their secondary windings all in series, and impressing on the primary windings an electromotive force from a three-phase supply of such a value that the primary cores are highly saturated. The author believes that the operation of this transformer may correctly be said to depend upon the fact that at a particular instant the current in one of the three limbs is double that in either of the other two, and consequently that the first-mentioned limb may be magnetically saturated at the moment that the other two are not so saturated; thus the electromotive forces generated in the three limbs no longer follow a true sine wave, as they do when the cores are entirely unsaturated. It will at once be granted that if they did follow a true sine wave, and the secondary windings were connected in delta, the resultant electromotive force in the

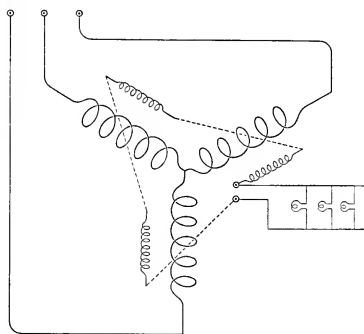

FIG. 2—Spinelli's Arrangement.

secondary circuit would be zero. Hence it follows that the only electromotive force generated in the secondary circuit is that due to departure from a sine wave: in other words, the two coils that are in parallel at any moment act in a precisely similar way to the unsaturated transformer coils which the author employs in series with his saturated choking coil, the saturated choking coil in Signor Spinelli's apparatus being the coil which is in series at any moment with the other two.

The author understands that Signor Spinelli has obtained an efficiency of 60 per cent, so that evidently the method possesses possibilities, though this is hardly a sufficiently high efficiency to admit of its entering into serious competition with motor-generators in sub-stations for general lighting supply.

TAYLOR'S FREQUENCY CHANGER (HISTORICAL).

Before M. Joly, in France, had evolved his frequency changer, the author of the present paper had, without at first appreciating it, arrived at an arrangement giving a

three-fold change of frequency and converting from three-phase to single-phase supply in one operation.

The germ of this idea was evolved in the summer of 1909. The author was at that time considering a means of deforming the E.M.F. wave of an alternating-current supply, by flattening it at the commencement and end of the half-wave (with a view to facilitating the commutation in changing from alternating current to continuous current with a rotating rectifier). He proposed to draw current from the alternating-current mains, pass this current through a transformer wound on a saturated core, thus tending to give the wave of current a very sharp peak in a way that is well known (see Fig. 3, Curve C), and then to pass this deformed wave of current through an unsaturated choking coil in which the flux responded to the deformed wave of current so received, and in which in consequence two impulses of back electromotive force

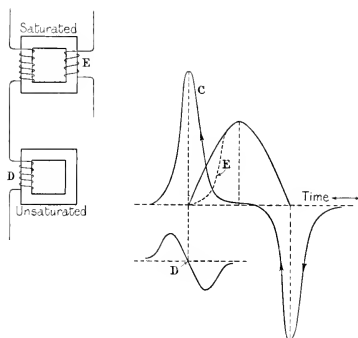

FIG. 3.

(see Fig. 3, Curve D) were generated, one at the commencement and end of each half-cycle of the fundamental electromotive force, thereby absorbing part of the electromotive force received from the mains at this instant and leaving a deformed E.M.F. wave generated in the saturated-core transformer, as shown in Fig. 3 (curve E).

It occurred to the author that it would be practicable, by winding a secondary coil on the unsaturated-core choking coil (D), to generate an E.M.F. wave of partially-complete triple frequency; and shortly after this he thought of employing a three-phase current and making up the missing parts of the E.M.F. wave from the other two phases. This led at once to the present invention.

PRINCIPLE OF TAYLOR'S FREQUENCY CHANGER.

The principle of the present invention will be clearly understood by reference to the accompanying figures. In Fig. 4 the connections are shown that would obtain if the arrangement were single-phase; this arrangement, however, is not practicable, owing to the triple-frequency impulses received being incomplete, and their having one

half-wave missing in every series corresponding to a half-cycle of fundamental frequency.

It will be easiest to consider first what would happen in the choking coil if the primary winding of the working

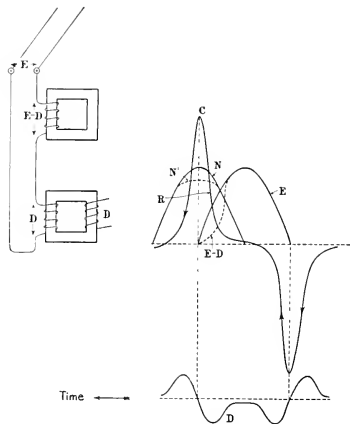

FIG. 4.—Principle of Taylor's Arrangement.

transformer were short-circuited; i.e., in fact, the condition that would obtain if the saturated choking coil were connected direct to the supply mains.

The wave-form of the current which would then flow is

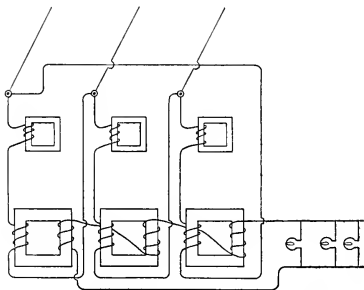

FIG. 5.—Connections of Taylor's Frequency Changer.

shown by Curve C in Fig. 4. It will be seen at once that if the current took this form the portion of the curve marked R would be that on which the rate of change of current was very rapid; and in consequence if the

current undergoing this change could be passed through the primary coil of a transformer winding, on an unsaturated core, so that the flux virtually followed the current wave, the electromotive force in the secondary-coil windings on the core of this transformer would have the wave-form marked D at the bottom of the figure. This, however,

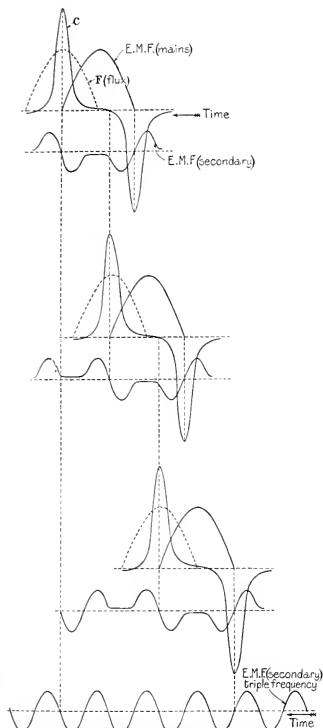

FIG. 6.—Principle of combining Three Phases to form a Single Phase (Taylor's Arrangement).

would leave a large period of the fundamental cycle in which no useful work was being done in the secondary coil of the transformer, and would be an unsatisfactory arrangement. Another disadvantage would be that the half-waves of electromotive force would not be exactly symmetrical, because the ascending and descending sides of the peak of the current are not exactly symmetrical

about the axis. If, however, the arrangement is repeated on the three phases as shown in Fig. 5, these two difficulties disappear, the blank spaces being filled in by the impulses received from the other phases, and the dissymmetry of the positive and negative half-waves of electromotive force being nullified by corresponding impulses from other phases, in the manner indicated by Fig. 6.

A further investigation of the wave-form obtained in the secondary circuit (Fig. 6) shows that at any instant only two out of the three transformers are active, and the question then arises whether it is expedient to couple the secondary coils in series or in parallel. The author decided, and he believes rightly, that it would be better to couple them in parallel than in series, because if in

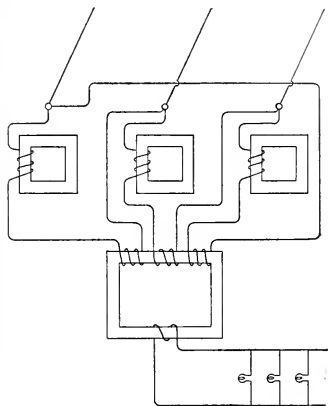

FIG. 7.—Present Form of Taylor's Arrangement.

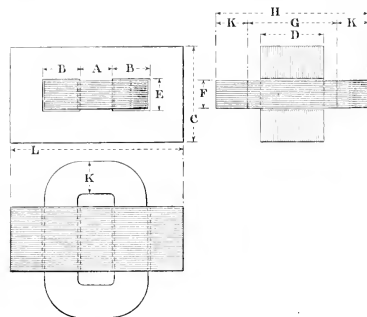

parallel the idle winding merely receives a small magnetizing current from the other two windings; whereas if they are in series the whole of the electromotive force of one winding is absorbed in driving the current through the impedance of the idle winding, leaving virtually only one winding effective. The author has confirmed this deduction experimentally.

In Fig. 6 the currents in the primary windings and the secondary electromotive forces in the three circuits are plotted in relation to one another on a time basis, and the way in which they combine in the secondary circuit can be easily seen.

An obvious deduction from what has already been stated is that it would be desirable to avoid difficulties with the idle current in the third phase by having a single-winding in the secondary, and by employing a common magnetized core, which is magnetized by the three primary currents having peaked wave-forms, as received from their respective choking coils. This is shown in Fig. 7.

REGULATION.

It will be unnecessary to refer to the records of the early experiments, and the author will therefore come directly to the results obtained with the apparatus shown

TRANSFORMERS			CHOKING COILS

All dimensions are in inches

Fig. 8.

in Fig. 7. The dimensions of the apparatus are given in Fig. 8, and the curve of regulation for the secondary load in Fig. 9. It will be noticed that the load can be carried up to 7 kw. without the drop of pressure exceeding 8 per

EFFICIENCY.

The author has analysed carefully the losses obtaining in the experimental 7-kw. set, both by wattmeter and by calculation from the measured currents, etc., and he has got out a design for a 28-kw. transformer which has an estimated efficiency of approximately 86-88 per cent. This set is now being constructed. On a 100-kw. size the author would certainly expect to get an efficiency of over 90 per cent, and on a 500-kw. transformer 95 per cent.

The dimensions for a 28-kw. set are shown in Fig. 8.

USES OF THE APPARATUS.

One use of the apparatus would be the conversion of three-phase current, on systems having a frequency of 25 periods per second, to single-phase triple-frequency currents having a frequency of 75 periods, for lighting work.

The apparatus lends itself in such a case to competition with rotary-converter sub-stations. Instead of supplying continuous-current lighting from the latter, it would be possible in any town where there is a large network of high-tension three-phase mains to install kiosks, or small static "exploitation" sub-stations, at various points along the route, with transformers to reduce the pressure and increase the frequency. The current delivered in the secondary circuit of the frequency changer is single-phase current, but this is actually advantageous for such work, in that it only requires the low-tension main to be run as a single-phase main, and the wiring of consumers' premises may also be single-phase wiring without any question of unbalancing the supply. The transformers being also entirely self-regulating (there being no automatic apparatus to look after), the frequency changers are eminently suitable for fixing in kiosks, where they will have to work without attention for perhaps a month or more at a time.

Another use for this apparatus would be for those power consumers who obtain current at 25 periods on specially cheap terms for lighting purposes and have their power supply in the form of an extra-high-tension supply. In this case it would only be necessary for them to take a supply of low-tension current from the secondaries of their power transformers, lead this through the frequency changer, and use it for the lighting of their buildings at 75 periods. In some trades where bright illumination is required and very fine work has to be done, the eyes get tried even where a frequency of 25 per second is used, and

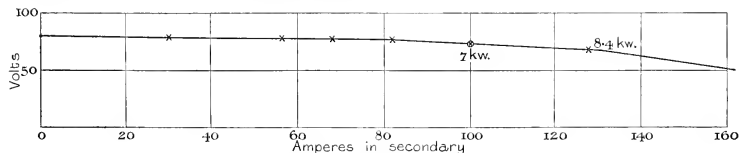

Fig. 9.—Regulation of Frequency Changer (Taylor's).

cent (i.e. 4 per cent up or down). There are means of improving this; but the value given suited the requirements for the present, and further experiments in this direction were deferred.

on the premises of such consumers the frequency changer would prove a most useful adjunct in ensuring a satisfactory supply for lighting purposes.

For electric welding purposes, and possibly also in con-

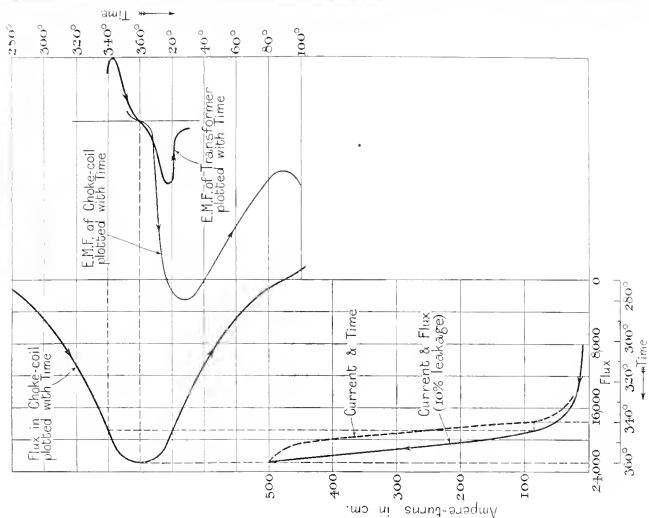

FIG. 11. Nine-fold Step-up.

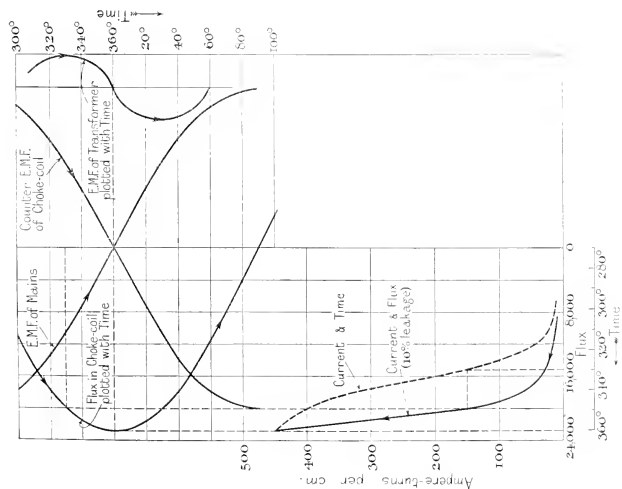

FIG. 10.—Three-fold Step-up.

nection with single-phase electric furnaces, the frequency changer may find a useful field of application, its special feature being that any load (even a complete short-circuit) may be put upon the secondary winding without disturbing the "balance" of the power on a three-phase supply. In the case of certain three-phase furnaces the author is advised that the short-circuiting of the poles on any one phase may introduce extremely severe demands upon a single phase of the three-phase high-tension mains, upsetting the regulation and disturbing the supply to other consumers. It seems to him that here there should be a useful field for the frequency changer.

Another field in which the frequency changer may find a large sphere of usefulness is in connection with three-phase low-periodicity railway work, where it would be specially suitable for taking a supply from the mains at, say, 16 periods per second, and changing this to a supply for lighting at 48 periods per second for use in lighting the stations along the line.

The author anticipates that with a small modification the apparatus can be made reversible; for instance, 16½ cycles might be obtained from 50 cycles. If so, this would open up the possibility of existing power concerns supplying current for electric furnaces or perhaps for railway work. The author has not yet had time, however, to experiment far in this direction; but he hopes to be able to give a demonstration of this on the occasion of the reading of this paper.

WIRELESS TELEGRAPHY.

A brief consideration of Fig. 6 will lead to the conclusion that if we were to have nine phases of supply instead of three, and nine choking coils and working transformers (or nine choking coils and one "common" working transformer), the electromotive forces in the various secondary windings would combine in a similar way to give a current of nine times the primary frequency. The only condition that would be lacking would be that the durations of the secondary electromotive forces would be too long, and they would therefore overlap and partly nullify one another. This defect can be avoided by the simple expedient of generating an E.M.F. wave in the primary generator which is not a true sine wave.

Fig. 10 shows the natural period of time existing between the commencement of the rush of current through the choking coil and the crest of the current wave, where the choking coil is placed directly across the mains and a sine wave of electromotive force is applied. This can be employed for a three-fold step-up in the frequency.

Fig. 11 shows how by a very trifling alteration in the E.M.F. wave of the generator the above period has been shortened from about 50 electrical degrees to 20 degrees; this latter corresponding with a nine-fold step-up in the frequency. In a similar way the step-up in the frequency might be increased to 27-fold.

The author has not yet been able to make an experiment on the 27-fold step-up, but he has successfully made one on the nine-fold.

It will be understood that the apparatus tends to give the same multiple of the frequency whatever the original frequency may be. At the very high frequencies obtaining in wireless telegraphy, however, the eddy currents set up

in the iron react upon the flux passing through the molecule and tend to demagnetize it.

E. F. Alexanderson of America has investigated this effect very carefully, carrying his experiments up to 200,000 cycles per second, and from the tabulated results the author finds that the extra ampere-turns required on the primary of a choking coil for a frequency changer stepping up to 100,000 periods per second are not at all prohibitive, provided that the iron is put in as thin as possible.

Using the 9:1 step-up arrangement the proposal would therefore be to build a generator having a wave-form approximately similar to the curve marked "E.M.F. of choke coil" in Fig. 11, and a periodicity of, say, 11,000 per second, which will give 99,000 periods on the high-tension winding of the frequency changer.

If it is found practicable to step up 27 times in one transformation, the generator need only be built for 3,666 periods in order to obtain 99,000 periods.

In conclusion, the author believes that he has been the first to show a practical application of the principle of employing as many phases of the supply as it is desired that the final frequency shall be a multiple of the original frequency, and combining all these independent waves of electromotive force into a common wave of electromotive force of the same number of times the original frequency that there are phases of supply.

APPENDIX.

A SIMPLE EXPLANATION OF THE OPERATION OF THE APPARATUS.

A few further notes as to the operation of the apparatus may not be out of place.

Referring to Fig. 4, it will be noticed that the curve of flux (N') is flat on the top, due to the back electromotive force (D) in the primary winding of the working transformer leaving the electromotive force (E-D) to be taken up by the choking coil instead of the electromotive force (E) of the mains. Now, when the electromotive force (E) is at its maximum, the rate of change of flux in the choking coil is also at its maximum, though the current in the choking coil is nearly zero. Again, when the electromotive force (E) is at its minimum, the rate of change of flux is also at its minimum, though the current in the choking coil (drawn from the mains) is at its maximum.

In other words, we may look upon the choking coil as a kind of valve which keeps out the electromotive force (E) of the mains from the primary coil of the working transformer at the time when the electromotive force of the mains is at its maximum, and lets it through on to the working transformer for about 60 electrical degrees on either side of the point of zero electromotive force in the mains.

We can also consider that by altering the shape of the electromotive force wave received from the mains the "valve" may be opened or closed for a longer or shorter period during each half-cycle of the supply, as is indicated by the relative time-values for the "current rush" in Figs. 10 and 11.

POWER FACTOR.

The question of power factor has not been touched upon in this paper, for the reason that at the time of writing the paper the author was anticipating that he would be able very considerably to improve the power factor of his apparatus, and in fact to make it comparable with the power factor of other apparatus. Up to the present, however, he has been unable to experiment in this direction, and it therefore becomes important to consider how the low power factor, which is only of the order of 0.2, can be compensated for.

In the first place it is proposed to consider the question of improving the power factor by fitting phase advancers to the motors installed on consumers' premises. It must, however, be postulated that although this would be practicable in the case of those consumers whose plants are already installed, and who are therefore not likely to introduce phase advancers on any large scale under present conditions, yet things may be different in the near future, so that it would be necessary in that case to find other means of compensation. In a large system, however, of say 30,000 kw. size, there will no doubt be large motors aggregating perhaps 15,000 kw., or say 50 per cent of the aggregate power of the system, upon which it would pay to introduce phase advancers for the above purpose.

The author is advised that where the frequency is as low as 25 periods certain phase advancers which are already on the market could be applied at a cost of not much more than 5s. per kilowatt of the rating of the motors under consideration. The question then arises as to how far it would be practicable to introduce a lighting load on such a system, through the medium of frequency changers compensated by phase advancers.

Referring to Fig. 12 it will be seen that if there is an existing motor load of 100 kw. at a power factor of 0.70 lagging, and if by means of phase advancers this is improved to 0.95 leading and a 40 kw. lighting load at 0.2 power factor is then superimposed on the system, the resultant power factor will be 0.77; this is a decided improvement, and the power consumer will gain considerably, his power factor being raised from 0.7 lagging to 0.95 leading. From this it will be seen that for every 100 kw. of motor load no less than 40 kw. of lighting load can be introduced by means of phase advancers on the existing motors of consumers. That is to say, on a 15,000 kw. motor load—the figure taken above—6,000 kw. of lighting load could be introduced by means of phase advancers; and the cost of the maintenance of these phase advancers, together with the interest and sinking fund on the same, works out at something like 0.06d. per unit, even if a load factor as low as 7 per cent is taken.

If, instead of a lighting load, we were considering, say, a furnace load and the use of phase advancers which step down the frequency, the additional cost on a probable load factor of something like 25 per cent would only be of the order of 0.02d. per unit, which would certainly not hamper in any way the selling price of the energy to such consumers. It should also be noted that this figure and the one previously given (0.06d.) include a fair margin for contingencies. It would thus appear to be profitable for the supply company themselves to install the phase advancers on consumers' premises without unduly hamper-

ing the consumer by the charge which would have to be made for this phase rectification.

PHASE RECTIFICATION FROM ROTARY CONVERTER SUB-STATIONS.

An alternative method of phase compensation, which, however, would only carry the compensation as far as the sub-station, would be the insertion of motor-generators in the sub-stations. These machines would be of sufficient rating to introduce a leading wattless component of current on the system. The author is alluding to rotary-converter sub-stations supplying a considerable continuous-current load, such as there are in most large

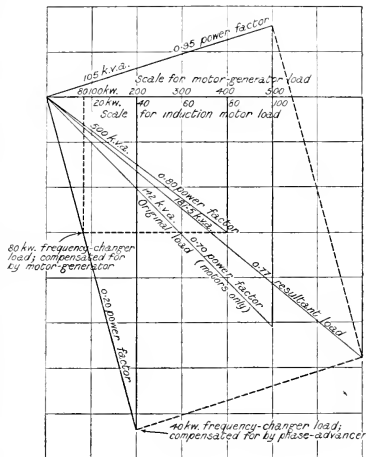

FIG. 12.

towns. It has been shown elsewhere² that if a 500 k.v.a. suitably-excited motor-generator is used to supply a continuous-current load of 375 kw., there could also be drawn from the E.H.T. mains by the alternating-current side of the machine a leading wattless current corresponding with that required by an induction-motor load of 500 k.v.a. having a power factor of 0.80. The vector curves given in Fig. 12 show that in this case the wattless component of the current would be the same as the wattless component for an 80-kw. load at a power factor of 0.2, corresponding with the power factor of the frequency changer on the primary side (the power factor on the secondary side is very nearly unity).

We thus arrive at the conclusion that we can take up an 80-kw. load on the frequency changer for every 375 kw. of load supplied on the continuous-current side of the motor-

² *Electrical Engineer*, vol. 39, p. 266, 1907.

generator, i.e. approximately 20 kw. for every 100 kw. of load on the continuous-current side of the sub-station. Now, the proportion of the copper and iron of the machine used for improving the power factor of the induction-motor load is that represented by 125 kw. (which would otherwise be available for an extra continuous-current load of that amount); and this at, say, £2 per kilowatt represents £250, which is the capital cost of obtaining an additional 80 kw. as a lighting load, or 250/80, i.e. £3.1 per kilowatt of lighting load taken up through the frequency changer.

It may here be remarked that the motors fed from the outgoing feeders on the E.H.T. side of the sub-station could be used to assist further in compensating for the power factor, thus providing for another 40 kw. of lighting load on every 100 kw. of induction-motor load so taken up.

Interest and sinking fund on the above £3.1 per kilowatt at 10 per cent represent approximately 6s. per annum per kilowatt, and at a 6.8 per cent load factor, representing approximately 600 hours' use per annum, this makes the cost per unit = $72/100 \times 0.1 = 0.12d$. So that

if, for instance, energy were sold for lighting purposes at 3d. per unit, the price would have to be raised by only $\frac{1}{4}d$. per unit on account of phase compensation, or by $\frac{1}{4}d$. per unit allowing a 100 per cent margin for other charges and for contingencies. If, however, electric furnaces were being supplied, having a load factor of perhaps 25 per cent, the last-mentioned figure ($\frac{1}{4}d$.) would be reduced to approximately 0.06d. per unit, which should not prove an undue handicap in the case of a charge of 1d. per unit.

Under the above must of course be added the cost of the frequency changer itself, which is of the same order; but, even so, considering that this would bring in an entirely new class of load, the cost would not be at all prohibitive. The distribution costs would, as compared with continuous-current distribution from rotary-converter sub-stations, be saved the heavy expense of the latter and of the continuous-current cable networks from these sub-stations, which would much more than compensate for the cost of the frequency changers. The special field for the scheme would be on the outskirts of the areas fed by the rotary-converter sub-stations.

DISCUSSION.

Mr. R. A. CHATTOCK: I think the author is to be congratulated upon having arrived at results so much superior to those obtained by Joly and Spinelli. Fig. 6 shows a very even wave-form for the triple-frequency current, a very different result from that obtained by the other two experimenters. Of course this wave-form is, I believe, only a calculated one, but I gather that the author has satisfied himself experimentally that it is correct. The one drawback to the apparatus in its present form is the low power factor obtained in the circuit. I understand that it is something like 0.2. The author's suggestion to improve it by installing phase advancers on any large motors that might be connected to the same circuit is undoubtedly a step in the right direction. This method can, however, only apply in those neighbourhoods where there is a large power load in addition to the lighting load that it is proposed to supply at the higher frequency. In most industrial areas the power load is in a different district from the lighting load, and it is therefore doubtful whether it would be possible to correct the lighting load factor in this way to any great extent. The author referred to an actual case of an existing motor load of 100 kw. capacity at a power factor of 0.7 lagging, a lighting load of 40 kw. supplied at the triple frequency and at a power factor of 0.2 being superimposed on the system. With phase advancers coupled to the motors so as to give a leading power factor of 0.95, the resultant power factor would be 0.77 lagging. I should like the author to explain what effect the superimposition of this lighting load on the power load would have on the resultant power factor if phase advancers are not employed. Then, again, if there are no motors or sub-stations in the neighbourhood supplied from the circuit, how would he propose to correct the power factor over a large system of distributing mains supplying current at triple frequency. Unless some correction is made, a large cost would have to be faced in laying down copper to accommodate the wattless component of the current.

Mr. F. W. CARTER: The author's ingenious arrangement is of great interest, but it seems to me that it would not make such good use of the material as is usual in ordinary electrical machinery for power purposes; probably this is in some way connected with the extremely low power factor. Altogether, I consider that the arrangement is more likely to be of use in connection with wireless telegraphy than in ordinary power work.

Mr. A. G. ENGHOLM: I notice that the author claims a very good regulation for his apparatus, and if the latter can be supplied at a low price and the working costs are low there should be a very great field for its use, especially where low frequencies and low voltages are required, such as for electric furnaces, welding, etc. I think it would be interesting if the author could tell us what is the voltage drop in the choking coils used; also how much of the regulation is due to ohmic drop, and how much is due to the self-induction of the transformer.

Dr. J. D. COALES (communicated): In his historical allusions I think that the author must have inadvertently omitted to mention that in investigating this subject he made use of a paper read by myself before this Local Section in 1908.* In that paper the effects of magnetic saturation in transformer cores were very fully discussed and illustrated by oscillograms; and on page 426 of the paper there is the following remark: "This curve marked 'D.C. Amps' shows how the direct current is thrown into ripples by the superposition upon it of an induced alternating current having twice the frequency of the applied voltage." Fig. 1 in the present paper, illustrating Joly's arrangement of 1911, is electrically similar to Fig. 3 of my paper of 1908. The author is to be congratulated on having made a great step in obviating the use of continuous currents in his frequency changer.

Professor E. W. MARCHANT (communicated): The fre-

essor
hant.

quency changer described by the author should be of great use on low-frequency circuits in increasing the frequency for lighting. At the same time the flicker effect at 25 cycles with carbon-filament lamps has, I believe, been much exaggerated. With metal-filament lamps the variation in the light emitted is much greater, but in most cases I doubt whether the flickering is as noticeable as it is sometimes thought to be. With arc lamps the case is different and there is no doubt that the flicker is irritating. The most remarkable feature of the author's device is the high efficiency claimed for it. One would have expected that the high saturation necessary in the cores of the auxiliary choking coil would have entailed a much greater iron loss than that which actually occurs. Possibly this is due to the use of Stalloy for the choking coil and transformer cores. An efficiency of 86 per cent for a small frequency changer is much better than could be obtained with one of the rotating type. The extent to which frequency changers are used in the United States is often overlooked in this country. In connection with the Shawinigan transmission the plant for changing the frequency from 25 to 50 cycles for the lighting of Montreal would fill many of our medium-size central stations. The dimensions of the author's frequency changer for the same power appear to work out at a very much lower figure, and in addition there is the advantage of the diminished wear and tear with stationary plant. One of the most interesting suggestions that the author makes is that his plant might be used for producing high-frequency oscillations for wireless work. There is no physical objection to this. Experiments which I made many years ago, using frequencies up to 50,000 \sim , show that at such frequencies iron has, within the limits of experimental error, the same magnetic properties as it possesses at ordinary supply frequencies. There is some doubt as to whether at still higher frequencies iron possesses the same properties with strong magnetizing forces. The experiments of Alexanderson with small magnetizing forces appear to show, however, that its permeability at frequencies up to 200,000 \sim is the same as it is at low frequencies, but that even with plates of 0.08 mm. thickness the skin effect is so great that the permeability never exceeds an effective value of 1,200. There seems no reason from the point of view of the molecular theory why iron should not behave in the same way with strong magnetizing forces as it does with weak ones. The efficiency of such an arrangement as that suggested by the author would naturally decrease with an increasing number of transformations, and there might be some difficulty in saturating the iron to such a degree as to give the necessary irregularity in the shape of the wave of magnetizing current. The further investigation of this device should prove very interesting, and it is to be hoped that it may result in the production of a new generator of high-frequency currents of practical value in wireless work.

Taylor.

Mr. A. M. TAYLOR (*in reply*): Replying to Mr. Chattock, I would say that in my opinion it is not at all necessary that the power load should be in identically the same area as the lighting load. To emphasize this point I have prepared two diagrams (see Fig. A), the upper of which represents a power load farther out from the generating station than the lighting load, and the lower of which represents the reverse conditions. It is assumed that all lighting loads near the generating station are at present

supplied by rotary-converter sub-stations. Considering Mr. Taylor's first the upper diagram, it will be noticed that the resultant power factor as far as the lighting load is 0.8, or more than 10 per cent higher than it would be in the case of a power load; while beyond the lighting area the power factor is 0.95, or over 30 per cent better. Hence there is a considerable saving in cable to be credited to the scheme. In the lower diagram the power factor as far as the motor load is 0.8, and from there to the lighting load it is 0.2. We may here credit the frequency changer with a saving of 10 per cent on three miles of cable and debit it with the loss on the one mile of cable: which means that a charge of £1 7s. per kilowatt per mile, over and above that of the power load, must be debited to the frequency changer. If, however, the lighting load is situated more than a mile beyond the power load, it might be advisable to step up the pressure, since the frequency changer would do the stepping down. The greater the distance from the generating station at which these power areas are situated, the greater is the saving in cable supplying them with which the new arrangement is to be credited.

The cost of phase compensation by means of phase advancers on induction motors is so very low compared with that of increasing the amount of copper in the cables,

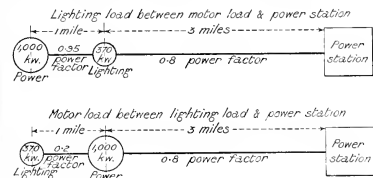

FIG. A.

that if there were a large motor load on one side of the town and a lighting load on the other side it would be possible in many cases considerably to over-compensate for power factor on the motor side; and the saving in cable thus effected would probably balance the extra expense on the lighting side, whilst the power factor of the generator would also be maintained high.

In the case where the supply authority installs its own frequency changers, it would be quite easy to arrange matters in this way, as the cost is thereby distributed over the whole system.

In making the above suggestions I do not wish it to be understood that I have by any means given up hope of improving the power factor of the frequency changer itself, and I only await opportunities of further experimenting in this direction.

Replying to Mr. Chattock's further question, a 10-kw. lighting load through a frequency changer may be superposed upon a 100-kw. motor load of 0.7 power factor, and the resultant power factor would be 0.62 without any compensation being employed. I would not recommend, however, more than 10 per cent being taken up in this way without compensation in some part of the system.

Replying to Mr. Carter, the scheme which I propose should cost considerably less in initial outlay and in main-

Mr. Taylor.

tenance than a scheme involving rotary frequency changers, as accommodation would have to be provided for the latter, a special staff would be necessary to look after their running, and mains would have to be laid, such mains not being so suitable for taking up the power load. My scheme would also enable the existing high-tension power mains to be utilized for lighting purposes where they pass through a district on their way to some more distant district where there is a power demand.

I regret that I am not at the present moment in a position to give publicly the information asked for by Mr. Engholm.

Replying to Dr. J. D. Coales's remarks, I much regret that I did not refer to the valuable work described in his paper before the Birmingham Local Section in 1908. As far as I recollect, however, this work did not give me any clue to the design of the frequency changer, although I was much interested in it as a record of the wave-forms of the currents that flow in the case of saturated cores, upon which subject I was engaged at that time. The sentence quoted by Dr. Coales cannot, I think, have been noticed by me. It shows he appreciated that an induced E.M.F. of double frequency was generated under the conditions of his experiment; but it is, of course, a long way from this to the working out of an effective means of applying this property in a practical manner. For instance, Mr. R. C. Clinker of Rugby has reminded me of some investigations that he carried out in 1905, in which apparently he also pointed out how the triple-frequency currents were gener-

ated and could be obtained, but here again he went no further in the development of the apparatus than to make a suggestion. I regret very much that in this case also no reference was made in the paper to Mr. Clinker's early and valuable work.

I am much indebted to Professor Marchant for pointing out the saving in floor space and efficiency that should be obtained with static frequency changers as compared with rotating ones. Perhaps, however, I may be allowed to question whether the flicker due to 25 periods has been exaggerated. My only reason for making this statement is that it seems to me incredible, knowing the business ability of American engineers, that for these 10 years past they should have been installing hundreds of thousands of pounds' worth of plant every year for the express purpose of converting the lower periodicity into the higher, solely on account of a bogey. With regard to Professor Marchant's statement that the efficiency would naturally decrease with an increasing number of transformations, I may explain that I only employ one transformation whatever number of times the frequency is stepped up. As regards his further statement that "there might be some difficulty in saturating the iron to such a degree as to give the necessary irregularity in the shape of the wave of magnetizing current," I would explain that by the arrangement described in the paper (see Fig. 11) a high degree of saturation is rendered unnecessary, the rate of change of current being obtained with no greater exciting current than that with a three-fold step-up.

PROCEEDINGS OF THE INSTITUTION.

ANNUAL GENERAL MEETING OF THE 21ST MAY, 1914.

Proceedings of the 42nd Annual General Meeting of The Institution of Electrical Engineers, held on Thursday, 21st May, 1914—Mr. W. DUDDLELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on Thursday, 23rd April, 1914, were taken as read, and confirmed.

A vote of condolence with the family of the late Mr. Robert K. Gray, Past President, was passed by the meeting, the members standing in silence.

The President announced that no nominations having been received other than those made by the Council for the offices of President, Vice-Presidents, and Honorary Treasurer, the Council's nominees were, in accordance with Articles 50 and 51 of the Articles of Association, duly elected, and that the scrutineers (Messrs. F. B. O. Hawes, R. W. Hughman, and E. A. Nash) appointed at the meeting of the 23rd April, 1914, to examine the ballot papers for the election of new Ordinary Members of Council, had reported that the following persons had been duly elected as Ordinary Members of Council: Mr. J. Christie, Professor B. Hopkinson, F.R.S., Mr. G. W. Partridge, Mr. W. H. Patchell, Mr. R. J. Wallis-Jones, and Mr. W. B. Woodhouse. The Council for the year 1914-15 would therefore be constituted as follows:—

President.	Ordinary Members of Council.	
J. F. C. SNELL.	A. B. ANDERSON.	A. M. J. OGILVIE, C.B.
The Past Presidents.	F. E. BERRY.	G. W. PARTRIDGE.
Vice-Presidents.	R. A. CHATTOCK.	W. H. PATCHELL.
J. S. HIGHFIELD.	J. CHRISTIE.	DR. A. RUSSELL.
W. JUDD.	E. RUSSELL CLARKE.	W. RUTHERFORD.
C. H. MERZ.	F. GILL.	A. H. SEABROOK.
C. H. WORDINGHAM.	CAPTAIN E. O. HENRICI, R.E.	ROGER T. SMITH.
Honorary Treasurer.	PROFESSOR B. HOPKINSON, F.R.S.	R. J. WALLIS-JONES.
R. HAMMOND.	A. W. MARTIN.	W. B. WOODHOUSE.

The Chairman and the immediate Past-Chairman of each Local Section.

The list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

Mr. A. Home-Morton and Professor J. T. Morris were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

	ELECTIONS.	
<i>Members.</i>	Wilkins, Frederick Hayes.	Shaw, William John.
Juttke, Julius, Ph.D.	Willcox, Francis Wallace.	Sherwin, William Henry.
Laidler, William Cranswick.		Tyler, Arthur Stewart.
McBerty, Frank Robert.	<i>Graduates.</i>	Woodward, Charles Hemiet.
	Alexander, John Wallace.	
<i>Associate Members.</i>	Andrews, William Frederick.	<i>Students.</i>
Ashworth, John.	Bailey, Charles Frederick.	Crampton, Arthur Edward.
Franks, Albert.	Barsdorf, Leonard William.	de Withmann, Henry Marie Sinclair.
Gill, Robert Francis H.	Bestel, Alfred Charles.	Foote, Norman Victor.
Hore, Alfred Thomas S.	Dainty, William Reginald.	Germann, Carl.
Levett, John Victor.	Davies, Felix Carr.	Howarth, Jr., A.
Taylor, Herbert Bardsley, Lieutenant-Commander, R.N.	Hull, Walter.	Kill, Ernest Frederick.
Tipper, Ernest Edward.	Ives, Edward Charles.	Lewis, Hubert John.
	Jones, Reginald Gomer.	Linstow, Frederick Norman.
	Lloyd, John Ambrose.	Ross-Bain, Grant.
	Lythgoe, Joseph.	Seagrave, Harry George.
<i>Associates.</i>	Manly, Edward Harry.	Stone, Herbert John.
Day, William Richard B.	Metcalfe, Henry.	Tabor, Arthur Robert.
Mountain, William John.	Rouse, Horace Frederick M.	Tilson, Herbert Sydney.
Roemer, Charles William von.	Sawtell, Walter Stanley.	Trutch, Charles Joseph Hyde.
	Shand, William Lamont.	Vowell, Christopher.

TRANSFERS.

Rowell, John Periam.

Associate to Associate Member.

Jennings, Edward Jennings.

Student to Associate Member.

Doig, Alexander McLaren.

Donations to the *Library* were announced as having been received from The Canadian Department of Mines (Mines Branch), Messrs. Constable & Co., J. Eck, N. H. Freeman, J. H. Havelock, A. Home-Morton, The Hydro-Electric Power Commission, Ontario, The Institution of Post Office Electrical Engineers, Marconi's Wireless Telegraph Company, C. H. Merz, T. E. Murray, Messrs. E. & F. N. Spon, and A. Stewart; to the *Museum* from the family of the late Sir William H. Preece; to the *Building Fund* from W. McGeoch, and W. M. Mordey; and to the *Benevolent Fund* from The Associated Municipal Electrical Engineers of Greater London, H. C. Silver, J. H. Tonge, and W. B. Woodhouse, to whom the thanks of the meeting were duly accorded.

The PRESIDENT: I move "That the Annual Report as circulated" be received and adopted."

Mr. R. HAMMOND: I have pleasure in seconding that motion.

Mr. F. C. RAPHAEL: I should like to ask whether the Council can offer some explanation of the fact that instead of the membership having increased during the year there has been a decrease of 39. The diminution is small, but I find from last year's Report that the membership in the previous year increased by 547. I should also like to ask in regard to the efficacy of notices which are sent with the *Journal* instead of being distributed separately, as formerly. I think that a very good indication of the effectiveness of the new arrangement would be obtained if we were told, as on a previous occasion, the number of votes given in the ballot for the election of Members of Council.

Mr. W. C. P. TAPPER: I notice that reference is made in the Report to the appointment of a Municipal Loans Committee. I should like to know whether we may have some information as to the composition of that Committee, and whether those who are primarily interested in municipal work can have some assurance that they will be adequately represented on the Committee. I should also like to know whether the Model General Conditions which have recently been issued have received the approval of the British Electrical and Allied Manufacturers' Association and of the Incorporated Municipal Electrical Association.

Mr. R. HAMMOND: The decrease of 39 in the membership must be considered in conjunction with the fact that the present membership totals 508 more than it did two years ago. The very large increase of membership which took place the year before last was due to the Council's intimation that the increase in the subscriptions and the Associate Membership Examination would come into force the following year. The increase in the membership in that particular year was 547, and on deducting the decrease of 39 during the past year we obtain an increase of 508 to our former membership of 6,537, making our present total membership 7,045. It is with that figure of 6,537 that we have to make our comparisons. If the figures were taken over a series of years I feel certain that members would acknowledge that it is very gratifying for the Institution that its membership has increased so much. When, however, one particular year is compared with a year in which there was such an exceptional increase I think it will be admitted that it is only reasonable that there should be a slight decrease. When subscriptions were raised there were those who said that we should lose 20 per cent of our members; when therefore it comes to a decrease of only 39 on a membership of 7,000, I think that those of us who believed that we should maintain our position were sound in that prophecy.

The PRESIDENT: I do not think that the fact that the ballot papers were enclosed with the *Journal* had any appreciable effect, because rather more ballot papers were returned this year than were returned last year, when they were sent out in separate envelopes. Nevertheless, the Council has decided to send out the ballot papers in the future in envelopes. I may also add that approximately 23 per cent of the ballot papers sent out were returned. The Municipal Loans Committee consists of two engineers connected with supply companies, three municipal engineers, and three other members. The Model General Conditions have not yet been formally adopted either by the British Electrical and Allied Manufacturers' Association or by the Incorporated Municipal Electrical Association, but I think that both those Associations are in full agreement with the majority of the clauses.

* See p. 632.

MR. H. HIRST: I should like to make a short statement with regard to the Industrial Committee, the dissolution of which has been mentioned. Although, as a Member of Council, I agree with the wording of the Report, absence abroad prevented me from taking any part in the framing of it, and I am afraid that the Report may be misunderstood by some of the members who are interested in this question. I have no fault to find with the powers that were conferred on the Industrial Committee, so far as the Council could confer powers, but it does not seem to be generally known that the Council considered it essential that the Industrial Committee should not deal with matters which might be construed to have a political bearing. All the Members of Council who were members of the Committee were anxious to respect this wish, but when it is considered that in this country concessions have been granted by Parliament to some 400 municipalities in regard to electricity supply stations, it is very difficult to find subjects connected with municipal electricity supply that do not touch politics. This was also proved by the condition of affairs which arose at the time Dr. Klingenberg read his paper, when the Council had some fears that the paper might lead to a political discussion. The Council had other wishes which do not appear in the constitution of the Committee, but which have been respected by the Committee. The Council considered that questions which were to the detriment of a certain section of its members should not be dealt with, and some members of the Industrial Committee were anxious to respect that wish. Other members of the Committee felt that if a proposition that is for the benefit of the whole industry is brought forward, some section may have to give way or to suffer slightly. The Council having made this ruling, however, it was difficult for the Industrial Committee to choose suitable subjects which were likely to meet with the approval of the Council. Well-known and respected members of the Council thought that the high standard of the Institution might suffer if it lent its name to discussions dealing with money matters, such as finance or trade discounts, that were likely to enter into the discussion of industrial questions. Whilst within those limitations the Industrial Committee had full powers, I think it is due to myself as Chairman and to some of the members who differ from those views, to say that the above were some of the limitations of the constitution which are not referred to in the Report, and which acted against the possibility of the Industrial Committee doing such work as it was hoped could have been done. I do not say this as a complaint or as a reproach, but I think it should be understood by those who take an interest in the question.

The resolution was then put and carried unanimously.

THE PRESIDENT: I shall now call upon the Honorary Treasurer to move the adoption of the Accounts and Balance Sheet for the year ended 31st December, 1913.

MR. R. HAMMOND: As the Accounts have been published in the *Journal** there is no need for me to go into them in detail. I think that the figure which will more particularly be considered satisfactory is the one which appears at the end of the Revenue Account. The unexpended revenue for the year 1913 was £2,832 12s. 3d., compared with £1,237 19s. 5d. for the previous year. The total income of the year was £19,802, compared with £17,606 for the preceding year, and shows an increase of £2,196. On the other hand we have had to increase our staff, so that our total expenditure on Revenue Account and on the Local Sections amounted to £15,410; and as our expenditure on Capital Account amounted to £1,559, the total expenditure amounted to £16,969. The £15,410 expended last year on Revenue Account compares with £14,181 in the previous year, and the expenditure on Capital Account of £1,559 compares with £2,187, the total expenditure being £16,969 for 1913 and £16,368 for 1912, a difference of £601. Our assets this year show an increase of £4,000 compared with those at this time last year. I think there is no other item in the Accounts to which I need draw attention. I have much pleasure in moving "That the Statement of Accounts and Balance Sheet for 1913, as presented, be received and adopted."

THE PRESIDENT: I beg to second that motion.

MR. F. C. RAPHAEL: Can Mr. Hammond explain to us the entry about the Tothill-street property? The cost of the buildings and the site is £19,260; the revenue it brings in, after ground rent, rates, and taxes have been deducted, is £302, that is to say, only about 1½ per cent. There is obviously some explanation of that, and I think we should rather like to know what it is, so that it may be placed on record in the "Proceedings."

MR. R. HAMMOND: We have had under consideration year after year what we should do with the Tothill-street site. We felt that it was very unwise to encourage long tenancies, and of course unless we are prepared to let the buildings on 7, 14, or 21 years' tenancies, we cannot possibly expect to get the full revenue from them. That is what has kept down our revenue from the Tothill-street property; it has been a question of policy. The Council feel—and so far the members have supported them in their policy—that it is advisable to keep that site in such a condition that if a favourable

* See p. 640.

offer came along they could realize it. In order to be able to do that our revenue has certainly suffered somewhat. I am glad to say, however, that since these Accounts were published the vacant offices on the property have been let, so that at the present moment the Council are able to report that the revenue from the Tothill-street property is the largest that we have ever obtained. It represents about £886 per annum, as against about £550 in previous years.

The resolution was put and carried unanimously.

MR. ROGER T. SMITH : I have to propose "That the best thanks of the Institution be given to the Honorary Secretaries of the Local Sections and the Local Honorary Secretaries and Treasurers abroad for their kind services during the past year." We are all conversant with the excellent work that the Honorary Secretaries do in this country, and with the obligations that they place the Institution under for the responsible and arduous work which they carry out. The gentlemen who take up this work abroad collect the subscriptions of members, so that our thanks to them are by no means merely formal. I have much pleasure in proposing the resolution.

MR. A. H. PREECE : I have pleasure in seconding that resolution.

The resolution was put and carried unanimously.

MR. J. S. HIGHFIELD : I have great pleasure in proposing "That the best thanks of the Institution be given to Mr. Robert Hammond in recognition of the valuable services rendered by him as Honorary Treasurer of the Institution during the past year." I think it is unnecessary for me to say very much on the subject of this vote of thanks. We know the valuable work that Mr. Hammond has done for this Institution in looking after its accounts for so many years, and it is satisfactory to know that he has increased the balances so largely during the past year.

MR. H. HIRST : I have much pleasure in seconding that resolution.

The resolution was put and carried with acclamation.

MR. A. H. SEABROOK : Before proposing the vote of thanks entrusted to my care, I should like to say as Vice-Chairman of the defunct Industrial Committee that I regret that the Council cannot see its way to make itself the centre of the electrical industry, not only from the point of view of technical and scientific matters but also with regard to industrial and commercial questions. After all, whether we are professional or business men, we are all dependent on £ s. d., and whether our interests are technical and scientific or industrial and commercial, the financial factor is an essential one in our existence not only as an Institution but as individual members of the electrical industry. In my opinion it is regrettable that the Articles of Association do not seem to allow the Council to take a full share in these industrial and commercial matters. It is evident from the attendance here to-day, and the complacent attitude of the audience, that members are perfectly satisfied, unlike myself, that the Institution should confine itself entirely to the aims for which it was originally constituted. I do not wish to make any protest or complaint ; I merely give expression to my own regret in regard to the matter. I should now like to propose "That the best thanks of the Institution be accorded to the Honorary Auditors, Mr. H. Alabaster and Mr. Sidney Sharp, for their kind services during the past year."

MR. K. EDGUMBE : I have much pleasure in seconding the motion.

The resolution was put and carried unanimously.

MR. W. M. MORDEY : May I also say a word that has nothing whatever to do with the resolution entrusted to me? I am one of those people who think that the influence, dignity, and usefulness of this Institution will be best maintained and increased by following the example that we have always had before us, of giving our attention to the scientific and engineering foundations of the electrical industry, rather than by attempting in any way to make it a trade association. This principle, from which the growth and strength of the Institution have sprung, is, I think, in the long run, actually the best and most helpful to the electrical industry and trade. With these remarks I should like to propose "That the best thanks of the Institution be tendered to Messrs. Bristows, Cooke, and Carpmal, for their kind services in the capacity of Honorary Solicitors to the Institution during the past year." This is a resolution which is formal in the sense that it is brought up every year, but it is not formal in any other sense. We are truly thankful to these professional gentlemen for giving us their time and their services in helping us in any matters of a legal character that come before the Institution.

MR. E. A. NASH : I have much pleasure in seconding the resolution.

The resolution was put and carried unanimously.

THE PRESIDENT : The next matter is the appointment of two Honorary Auditors. I move "That Mr. H. Alabaster and Mr. Sidney Sharp be elected Honorary Auditors for the year 1914-15."

The resolution was put and carried unanimously, and the meeting then adjourned.

INSTITUTION ANNOUNCEMENTS.

ASSOCIATE MEMBERSHIP EXAMINATION,
MAY, 1914.

EXAMINERS :

English Essay ...	C. C. Hawkins, M.A.
Translation from French ...	H. Borns, Ph.D.
Applied Mechanics ...	Prof. A. W. Porter, B.Sc., F.R.S.
Physics ...	Prof. H. Jackson, F.C.S.
Chemistry ...	J. F. C. Snell.
Electricity Supply ...	Roger T. Smith.
Electric Lighting and Power ...	Major W. A. J. O'Meara, C.M.G.
Electric Traction ...	M. B. Field
Design of Electrical Machinery and Apparatus ...	J. S. Peck.

PASS LIST.

Binyon, Basil.
Damania, Ishwarlal Bhogilal.
Goddard, Leslie Ward.
Price, Howard.
Rodwell, James Theodore.
Smith, William Balfour.
Woodward, Charles Hemlet.

BENEVOLENT FUND.

REPORT OF THE COMMITTEE OF MANAGEMENT FOR THE YEAR 1913.

CAPITAL.

The Capital Account stood on 31st December last at £4,642 3s. od., all of which is invested.

INCOME.

The Statement of Accounts (see page 639) shows that the total receipts during 1913 were as follows:—

	£	s.	d.
Dividend on Investments...	...	15	4
Interest on Deposit	8	19
Annual Subscriptions	54	0
Donations of £5 and over	95	9
" under £5	4	0
	£316	9	2

Contributions were received during the year from G. F. Allom, A. B. Anderson, I. Braby, M. S. Chambers, R. A. Chattock, W. C. Clinton, The Committee for the Protection of Electrical Interests, V. K. Cornish, B. Davies, Sir A. Denny, Bart., J. Devonshire, H. C. Donovan, B. M. Drake, C. V. Drysdale, D.Sc., W. Duddell, F.R.S., K. Edgecombe, The Electrical Engineers' Ball Committee, S. Evershed, F. Gill, Dr. R. T. Glazebrook, C.B., F.R.S., B. B. Granger, F. E. Gripper, C. C. Hawkins, M.A., K. Hedges, D. Henriques, J. S. Highfield, H. W. Kille, A. E. Levin, C. H. Merz, The Midlands Electrical Engineers' Ball Committee, L. B. Miller, W. M. Mordey, E. Parry, The Hon. Sir C. A. Parsons, K.C.B., F.R.S., W. H. Patchell, A. H. Preece, W. L. Preece, Sir W. H. Preece, K.C.B., F.R.S., W. R. Rawlings, T. Rich, R. Robertson, B.Sc., S. K. Roget, B.A., R. M. Sayers, S. Sharp, A. Siemens, C. P. Sparks, The Stearn Electric Lamp Company, A. D. Stevenson, A. Strohl, A. J. Stubbs, W. C. P. Tapper, A. P. Trotter, B.A., The "Twenty-five" Club, T. C. T. Walrond, H. W. L. Ward, J. G. Wilson-Dickson, and C. H. Wordingham.

The Committee of Management desire to acknowledge their indebtedness to the generosity of the donors and subscribers who have supported the Fund.

GRANTS.

Eleven applications for assistance were received in 1913, and the Committee, after due investigation, made grants in all the cases. Five grants were made of £10 each, four of £8, and three of £5, a total of £92 for the year.

WILDE BENEVOLENT FUND.

The Capital Account stood on 31st December last at £1,846 4s. 6d., the whole of which is invested and brings in an annual revenue of £55 17s. od.

The Balance standing to the credit of the Income Account at the end of 1913 was £304 6s. 11d.

No grant from this Fund was made during the year.

APPEAL FOR CONTRIBUTIONS.

The Committee of Management desire to call the attention of members of the Institution to the Benevolent Fund, which was formed to assist necessitous members (of all classes) or the families of deceased members. The Fund has been established nearly 25 years and the amount standing to the credit of the Capital Account is only £4,642 3s. od.

The Committee feel certain that the existence of this Fund is overlooked by a large number of the members, and they trust that it will commend itself more widely as worthy of their support.

The Committee make a special appeal to the members to put the Fund upon a substantial basis, and they specially invite them to contribute regular annual amounts.

In future it is proposed to include in the Annual Report a list of the subscriptions received during the year.

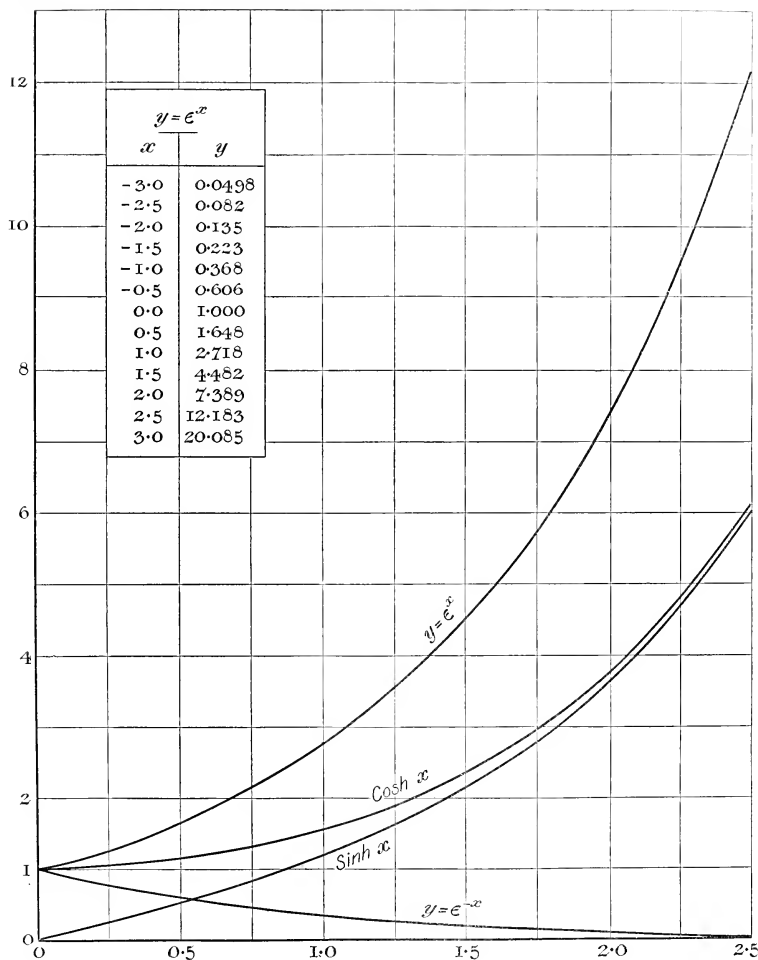

FIG 2.

vector admittance Ad , or $P = \sqrt{Im} \cdot \sqrt{Ad}$, while the line characteristic or impedance Z is the quotient of the same quantities, or $Z = \sqrt{Im} / \sqrt{Ad}$.

Returning then to the unit length of the circuit we can express the drop in voltage and current as follows:—

$$\begin{aligned}\text{Drop in voltage} &= Im \times \text{Mean current in it.} \\ \text{Drop in current} &= Ad \times \text{Mean voltage across it.}\end{aligned}$$

Hence the drop in the drop in voltage, or as it may be called the (drop)² in the voltage, is given by the equation—

$$\begin{aligned}\text{Drop in the drop in voltage} \\ = Im \times Ad \times \text{Mean voltage across it.}\end{aligned}$$

Let us consider how this can be graphically represented.

If we draw an exponential or logarithmic curve, that is a curve whose equation is $y = e^{Px}$, where e is the base of the Napierian logarithms, it is clear that the slope of the curve at any point is proportional to the ordinate, or is equal to $P \cdot y$. Also the slope of the slope or rate of change of slope is proportional to the ordinate and equal to $P^2 y$. Accordingly it is evident that if an alternating E.M.F., V_n , is applied at any point in an infinitely long cable the voltage V at any other point at a distance x will be represented by the exponential expression $V = V_n e^{-Px}$. In practice, however, all our cables are of finite length, and we have moreover to take into account the effect of the receiving instrument at the end.

Consider then a cable of length l having a receiving instrument of impedance $R_2 + j\beta L_2$ placed at the receiving end, and an impressed electromotive force V_1 applied at the sending end. We may consider that the cable is laid out straight (see Fig. 1) and that the applied E.M.F. is represented by a positive potential at one point and an equal negative potential at another point placed at a distance $2l$ in an infinite cable. The receiving instrument is represented by the coil placed in the centre. Then each potential falls along the cable according to an exponential law, and the potential V at any distance x from the sending end is seen to be the algebraic sum of two factors, or—

$$V = A e^{-Px} + B e^{+Px} \quad \dots \quad (1)$$

It is now convenient to substitute for these exponential expressions their equivalent in hyperbolic functions.

If we draw two exponential curves, one rising and the other falling and both starting from an ordinate $y = 1$ at $x = 0$, these curves have ordinates $y = e^x$ and $y = e^{-x}$ at any abscissa x (see Fig. 2). If we take half the sum and half the difference of the ordinates at any abscissa, these values are called respectively the hyperbolic cosine and the hyperbolic sine, and are represented by—

$$\cosh x = \frac{1}{2} (e^x + e^{-x}) \quad \dots \quad (2)$$

and—

$$\sinh x = \frac{1}{2} (e^x - e^{-x}) \quad \dots \quad (3)$$

Hence—

$$e^x = \cosh x + \sinh x \quad \dots \quad (4)$$

$$e^{-x} = \cosh x - \sinh x \quad \dots \quad (5)$$

Substituting these functions for e^{+Px} and e^{-Px} in (1), we have—

$$V = (A + B) \cosh Px - (A - B) \sinh Px \quad \dots \quad (6)$$

It is clear that when $x = 0$ we have $V = V_1$, and also $\cosh Px = 1$ and $\sinh Px = 0$; therefore we have $V_1 = A + B$.

Again the current I in any unit of length of the cable is obtained by dividing the drop in potential along it by the vector impedance of the unit.

Hence we have—

$$I = \frac{P}{K + j\beta L} \{A e^{-Px} - B e^{+Px}\} \quad \dots \quad (7)$$

$$I = \frac{1}{Z} \{ (A - B) \cosh Px - (A + B) \sinh Px \} \quad \dots \quad (8)$$

and when $x = 0$ we have $I = I_1$; therefore $Z I_1 = A - B$.

Substituting the values $A + B = V_1$ and $A - B = Z I_1$ in Equations (6) and (8), and also bearing in mind that the receiving instrument impedance $Z_2 = V_2 / I_2$, where V_2 and I_2 are the voltage and current at the receiving end at which $x = l$, it is easy to see that we obtain the equations—

$$V_2 = V_1 \cosh Pl - I_1 Z \sinh Pl \quad \dots \quad (9)$$

$$I_2 = I_1 \cosh Pl - \frac{V_1}{Z} \sinh Pl \quad \dots \quad (10)$$

Separating the variables and putting $V_2 = I_2 Z_2$, we obtain the final equations—

$$V_1 = V_2 (\cosh Pl + \frac{Z}{Z_2} \sinh Pl) \quad \dots \quad (11)$$

$$I_1 = I_2 (\cosh Pl + \frac{Z}{Z_2} \sinh Pl) \quad \dots \quad (12)$$

These last equations enable us to find the values of V_2 and I_2 from those of V_1 and I_1 when we know the value of the complex factor in the bracket.

In applying the above formulæ (11) and (12) in numerical calculations in any given case the chief difficulty which arises is that the addition, multiplication, and division to be carried out in reckoning the factor in the bracket are vector operations, and the quantities themselves, viz. Z_2 , Z , $\cosh Pl$, and $\sinh Pl$, are complex quantities. If two complex quantities are given in the form $a + jb$, $c + jd$, it is an easy matter to add them, for their sum is $(a + c) + j(b + d)$. If, however, we have to divide or multiply them they have to be converted first to the equivalent forms—

$$\sqrt{a^2 + b^2} \angle \tan^{-1} \frac{b}{a} \quad \text{and} \quad \sqrt{c^2 + d^2} \angle \tan^{-1} \frac{d}{c}.$$

These are troublesome arithmetical operations and require also a table of natural tangents. To facilitate this transformation the author has devised a vector calculating rule made as follows:—

Two boxwood scales about 1·5 metres long have their edges divided into centimetres and millimetres, and are hinged together at the zero ends. A quadrant protractor is attached to one rule so as to show at a glance the angle which the inner edges make with each other when the rule is opened (see Fig. 3). A T-square having one edge graduated in centimetres and millimetres slides along one of the rules. Hence if we are given a complex quantity in the form $300 + j400$ we can slide the T-square along so as

to set off on one rule an intercept of 300 mm. We then open the rule so that the other arm sets off an intercept of 300 mm, on the T-square edge, and we see at once that the hypotenuse of the triangle is 500 mm, and the slope of the rule is $\tan^{-1} \frac{4}{3} = 53^\circ 7'$.

By the aid of the rule we can then convert the expressions for vectors in the form $a + j b$ and $\sqrt{a^2 + b^2} / \tan^{-1} \frac{b}{a}$ into one another numerically with great ease.

To obtain the square root of a complex quantity given in the form $\sqrt{R + j \beta L}$ we have to convert $R + j \beta L$ to the

$C = 0.05$ microfarad, $S = 5 \times 10^{-6}$ mho, all per loop mile, and if $p = 2\pi n = 5,000$, we find at once—

$$Im = 88 + j 5 = 88.1 / 3^\circ 15';$$

and—

$$Ad = \frac{5}{10^9} + j \frac{250}{10^6} = \frac{1}{4010} / 88^\circ 51'.$$

Hence—

$$Z = \sqrt{Im} / Ad = 593 / 42^\circ 48'.$$

In these calculations, if one of the above-described vector calculating rules is not at hand, a single four-figure

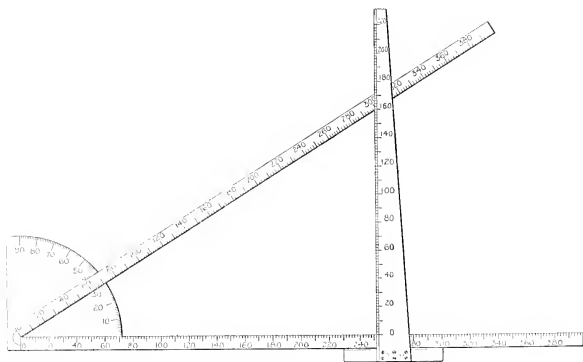

FIG. 3.—Vector Calculating Rule. (Fleming)

form $\sqrt{R^2 + \beta^2 L^2} / \tan^{-1} \frac{\beta L}{R}$, and then to take the square root of the size and halve the angle. Hence—

$$\sqrt{R + j \beta L} = (R^2 + \beta^2 L^2)^{\frac{1}{4}} / \frac{1}{2} \tan^{-1} \frac{\beta L}{R}.$$

Accordingly when we are given the primary constants of a cable, viz. R , L , S , and C , and also p ($= 2\pi \times \text{frequency, } n$), we can calculate the value of the line impedance, $Z = \sqrt{R + j \beta L} / \sqrt{S + j \beta C}$, by finding the vector expressions for \sqrt{Im} and \sqrt{Ad} as above and then dividing the size of the first by that of the second and subtracting the phase angles. The arithmetical operations consist in finding the numerical value of $Z = \sqrt{Im} / \sqrt{Ad}$ or of $\sqrt{R + j \beta L} / \sqrt{S + j \beta C}$ and its slope, which is equal to $(\frac{R^2 + \beta^2 L^2}{S^2 + \beta^2 C^2})^{\frac{1}{4}} / \frac{1}{2} \tan^{-1} \beta L / R - \frac{1}{2} \tan^{-1} \beta C / S$. This is vastly facilitated by the use of the above rule when only a moderate degree of accuracy is required.

Thus, if we are given the line constants of a standard telephone cable for which $R = 88$ ohms, $L = 0.001$ henry,

table of squares and square roots and a table of natural tangents, such as that of J. T. Bottomley, will be found of great assistance.

It is therefore quite easy to find the vector value of Z , or Z 's reciprocal, when we are given the impedance of the receiving instrument and the constants of the line.

In the next place we have to find the value of $\cosh Pl$ and $\sinh Pl$. Since $P = \sqrt{Im} / \sqrt{Ad}$, we can obtain the value of P at once in the form S / θ , and by the aid of the rule convert it to the form $P = a + j \beta$. Thus, for the same standard cable $P = \sqrt{Im} / \sqrt{Ad}$, or—

$$P = \sqrt{\frac{88.1}{4000} / 46^\circ 3' 30''} = 0.148 / 46^\circ 3' 30''.$$

Converting this back into the form $a + j \beta$ by the aid of the vector rule, we find it is equal to $0.103 + j 0.104$. Hence $a = 0.1$ and $\beta = 0.1$ nearly. If then the length of the cable is given, say 20 miles, we have $Pl = 2 + j 2$.

We have in the next place to find the value of $\cosh Pl$ and $\sinh Pl$. These quantities are both vectors because $Pl = a + j \beta l$ is a vector.

4.9	—0.98245	0.18649	67.1412	67.1486					

Bearing in mind the exponential values of $\cosh x$ and $\sinh x$ and $\cos x$ and $\sin x$ as follows:—

$$\begin{aligned}\cosh x &= e^{x/2} + e^{-x/2}, & \sinh x &= e^{x/2} - e^{-x/2}, \\ \cos x &= e^{jx/2} + e^{-jx/2}, & \sin x &= e^{jx/2} - e^{-jx/2}j,\end{aligned}$$

it is easy to show that—

$$\begin{aligned}\cosh (a l + j \beta l) &= \cosh a l \cosh \beta l + j \sinh a l \sinh \beta l, \\ \sinh (a l + j \beta l) &= \sinh a l \cosh \beta l + j \cosh a l \sinh \beta l.\end{aligned}$$

If then we are given the values of $a l$ and βl it is a simple matter to find the values of $\cosh P l$ and $\sinh P l$ from curves delineated in the chart (Fig. 4) at the end of this paper.

In these curves the author has graphically represented the circular and hyperbolic sine and cosine curves plotted in terms of radians as horizontal abscissae set off along a base line. To distinguish the positive from the negative values of the circular sine and cosine the parts of the curves which have negative values of the ordinates are shown as dotted lines. The values from which the curves are plotted are given in the Table on the opposite page. The hyperbolic sine and cosine are also plotted to the same arguments from the calculated values in the same Table.

Since, however, these last curves rise up continuously, it is convenient to divide the ordinates by 10 as soon as the first branch of the curve reaches the top of the paper. When the second branch rises to a similar height we divide again by 100, and in a third branch by 1,000. In this way we can plot curves for $\cosh x$ and $\sinh x$ up as high as $\cosh 9$ and $\sinh 9$ on squared paper of moderate size.

The curves as actually shown in Fig. 4 are on rather too small a scale to enable values to be read off with much accuracy. The reader can, however, easily re-draw the curves on good squared paper divided into centimetres and millimetres on a larger scale, taking the calculated values from the Table and drawing the curves in the manner shown in Fig. 4. This large scale chart will then enable the values of the functions to be read off to an accuracy of the second or third place of decimals.

Suppose, then, we require the value of $\cosh (2 + j 2)$. We look out on these curves the value of $\cosh 2$, $\sinh 2$,

$\cos 2$, and $\sin 2$, which are the respective ordinates of the four curves to argument 2. We find $\sinh 2 = 3.763$, $\cosh 2 = 3.777$, $\sin 2 = 0.901$, and $\cos 2 = -0.42$. Hence—

$$\begin{aligned}\cosh (2 + j 2) &= -1.583 + j 3.303, \\ \sinh (2 + j 2) &= -1.525 + j 3.431.\end{aligned}$$

The vector rule shows us at once that—

$$-1.525 + j 3.431 = 3.74 \angle 113^\circ 45'.$$

If, then, the receiving instrument at the end of the line is a 60-ohm Bell telephone, for which—

$$Z_r = 134 + j 91 = 162 \angle 34^\circ 15',$$

we find immediately that for 20 miles of this standard telephone cable Equation (11) becomes—

$$\frac{V_1}{V_2} = (-1.583 + j 3.303) + \frac{593 \angle 42^\circ 48'}{162 \angle 34^\circ 15'} = 3.74 \angle 113^\circ 45'.$$

Now $593 \times 3.74 \angle 162 = 13.7$, and—

$$113^\circ 45' - 42^\circ 48' - 34^\circ 15' = 36^\circ 42',$$

and $13.7 \angle 36^\circ 42' = 11.0 + j 8.2$.

Hence $V_1/V_2 = 9.5 + j 11.5 = 14.9 \angle 50^\circ 30'.$

Accordingly if 10 volts were applied at the sending end, the voltage V_2 at the receiver terminals would be $10/14.9 = 0.66$ volt. The current through the telephone would be 0.66 divided by the telephone impedance, which is 162 ohms. Hence $I_2 = 660/162 = 4$ milliamperes. It will be seen, therefore, that for approximate calculations, such as may be necessary in getting out general specifications or predeterminations for proposed telephone lines, the vector rule and curves here described will prove very useful. When greater accuracy is required tables of hyperbolic functions of complex arguments, such as those recently published by Dr. A. E. Kennelly, through the Harvard University Press, will be requisite.

For preliminary rough calculations the use of the above described vector rule in conjunction with a slide rule immensely economizes time. The author has arranged with Messrs. W. F. Stanley & Co., of Holborn, London, to make and supply this vector calculating rule.

THE BONECOURT BOILER.

By C. D. McCOURT.

(Paper first received 25th March, and in final form 27th May, 1914; read before the YORKSHIRE LOCAL SECTION 8th April, 1914.)

It is a recognized fact that gas-fired boilers as a class are less efficient than boilers which are fired with solid fuel. The advent of the Bonecourt boiler reversed this state of affairs, this type of boiler being more efficient than any coal-fired boiler hitherto constructed. In order to show to what this is due, the author proposes to consider first of all the operation of ordinary or flame-fired boilers contrasted with that of the Bonecourt boiler.

Gas-fired boilers of the ordinary type might be described as steam generators which are flame-fired, while a Bonecourt boiler is a steam generator which is fired with fuel in a fluid state in such a manner that little or no flame is produced during the combustion. This difference is a fundamental and important one. In the flame-fired boiler a considerable free space is required for the proper development of the flame. If the flame, consisting as it does of a succession of gaseous envelopes of various oxygen contents, comes into contact prematurely with a water-cooled surface, combustion is hindered and products of incomplete combustion arise. In flame-fired boilers, therefore, it is necessary so to arrange the construction that a sufficiently large space is provided for the free development of flame.

In the Bonecourt boiler, on the other hand, complete combustion is obtained without the development of flame. Combustible gas and air in the proportions theoretically required for complete combustion are intimately mixed together so as to produce a homogeneous gaseous medium, and this gaseous medium, containing in itself all the elements required for complete self-combustion, is delivered at a high speed into a bed of refractory material, on the surface of which combustion takes place flamelessly. Such a mixture of gas and air is explosive, hence the necessity for supplying the mixture to the granular bed at a high speed—a speed, in fact, which is greater than the speed at which the mixture will ignite in a backward direction. The bed is maintained incandescent by the continued combustion of the gaseous mixture, and complete combustion of the gas employed is ensured by the incandescence of the bed into which the mixture is passed. It is found that if combustion be brought about in this way the proximity of water-cooled surfaces has no hindering effect on the combustion, and it is possible so to arrange the granular bed in relation to the water space as to obtain the maximum possible proximity of the water to the heat zone. It will be seen that we have here the elements of construction which are required for designing boilers of high evaporative power.

In applying these principles to the construction of steam generators it is possible to employ either a fire-tube or a water-tube type of design. It is more convenient, however, to pack the interiors of tubes with refractory granules than to surround water-tubes with these granules. Hence, the multitubular type of boiler is the one to which this system has first been applied.

Describing first of all in general terms any typical Bonecourt boiler installation, the boiler consists of a

multitubular drum the tubes of which are fitted with a retractory packing that serves to promote rapid combustion. The combustible gas is delivered to the seat of combustion in the packed tubes in a state of intimate admixture with air. Just so much air is present in the mixture as will suffice for the complete oxidation of the fuel, excess of air being avoided. The author cannot too strongly emphasize the fact that this mixture of gas and air, in the proportions theoretically required for complete combustion, is a homogeneous mixture, containing in itself all the elements necessary for complete combustion. The mixture is delivered at a high speed into boiler tubes packed with refractory material of such a kind as to leave interstices through which the gases can flow. A suitable packing for tubes of relatively small size, 3 in. in bore for example, consists of firebrick crushed and meshed so as to produce fragments of about 1 in. in diameter. These fragments, while being fairly regular in size, are irregular in shape, and leave interstices which in the aggregate amount to the same volume as that of the fragments themselves.

The boiler tubes are closed at their entrance ends by fireclay plugs through holes in which the gaseous mixture passes. These holes are of such cross-section that the speed of flow of the gaseous mixture is greater than the speed of ignition of the mixture. This ensures that combustion does not take place prior to the mixture gaining admission to the granules in the tubes.

In order to cause the gaseous mixture to pass through the apertures in the fireclay plugs with the required speed, and to enable the combustion products to overcome the resistance offered by the refractory packing in the boiler tubes, it is necessary to maintain a certain difference of pressure between the opposite ends of the boiler tubes. The amount of this pressure difference required will depend in the main on the rate of evaporation desired. In general, a pressure difference of 15 in. water gauge will suffice for an evaporation of 20 lb. of water from and at 212° F. per sq. ft. of heating surface per hour. With an increase of the pressure difference the evaporation likewise increases, and it is found that the evaporation produced is proportional to the square root of the pressure difference which is applied.

The necessary pressure difference can be obtained in one of two ways, either by supplying the gaseous mixture to the boiler tubes under a positive pressure, for which purpose a fan for blowing the gas and a fan for blowing the air are required, or by drawing away the products of combustion at the exit ends of the boiler tubes by means of a single fan. In either case the amount of pressure or suction, as the case may be, to produce a given evaporation is the same.

The lantern slide shows a view of a Bonecourt boiler installed at the Skinningrove Iron Works and fed with coke-oven gas. This boiler is worked on the suction principle, a fan at the outlet end of the plant drawing the products of combustion through the system under a suction of about 15 in. water gauge. The plant comprises a boiler shell

10 ft. in diameter and 4 ft. long, a feed-water heater 4 ft. 6 in. in diameter and 18 in. long, and an electrically-driven fan. The boiler shell is provided with 110 tubes, each 4 ft. long and 3 in. in bore, charged with refractory material, while the feed-water heater is furnished with 100 tubes 3 in. in bore and 18 in. long, and similarly charged. The gas is supplied to the boiler under the normal pressure existing in the coke-oven main, namely 2 or 3 in. water gauge, and is drawn under suction through the boiler tubes in a state of intimate admixture with air, which is drawn by the same suction from the surrounding atmosphere.

As a description of this plant and its performance has already appeared in the technical Press⁶ the author does not propose to describe it here, except to say that its performance has fully come up to expectations in every way, an efficiency of 92.7 per cent being obtained when evaporating 14.1 lb. of water from and at 212° F. per sq. ft. of heating surface per hour. That the working of the boiler is deemed satisfactory from a practical point of view by those in the best position to judge is proved by the fact that after the plant was taken over a duplication of the plant was ordered by the purchasers, and the second unit will shortly be in operation.

A plant identical with the Skinningrove plant has been erected at the works of Messrs. Friedrich Krupp & Co. in Germany, and the author understands that the official test, although the results are not yet published, has afforded equally satisfactory figures.

Leaving now the particular case of the plant just described, the author proposes to consider the general case of what takes place in a boiler tube of any Bonecourt boiler. A homogeneous mixture of combustible gas and air passes into the bed of refractory granules with which the tube is charged. Combustion there takes place, and as the mixture which burns is a highly explosive one, combustion is completed for all practical purposes instantaneously, and the granules are maintained incandescent as previously mentioned.

The temperature in the granular packing at the entrance or firing end of the tube will approximate to the calorific intensity of the gas employed. When burning coal-gas or coke-oven gas, the temperature at this point is in the neighbourhood of 1,800° C. It must be understood that this is the temperature in the centre of the cross-section, and that the temperature of the granules in contact with the tube surface is very much lower. The temperature of the inner surface of the tube itself is only some 20° C. higher than that of the surface in contact with the water. The granular packing, then, is red-hot or white-hot at the firing end, but its temperature decreases very rapidly along the tube. In the centre the temperature is a dull red heat, while at the exit end the temperature is about 250° C.

It is necessary to form a clear picture of the functions performed by the granular packing. In the first place, the red-hot granules serve to ensure absolute completion of combustion even in the absence of any air in excess of the theoretical requirements. Secondly, they radiate heat to the sides of the containing tube walls, thus largely accounting for the high rate of heat transmission obtained. Thirdly, the granules, even in that part of the tube where the temperature is so low as to prevent heat being communicated to any notable extent by radiation, serve to baffle the com-

bustion products and hurl them repeatedly and with violence against the tube walls. This last phenomenon is one that is often not sufficiently appreciated. If hot gases flow through a water-cooled tube, they communicate their heat to the water very sluggishly. If, however, any device is employed which will cause the hot gases to impinge on the tube surface, heat transmission is greatly increased. To account for this it has been suggested that in normal boiler practice a non-conducting film of cold gases clings tenaciously to the tube surface or boiler plate. If that be so, the effect of the granular packing must be to destroy, by abrasion as it were, this film of cold gases, intimate contact of the hot gases with the tube surface being then obtained.

Considerable latitude is permissible in the design and construction of Bonecourt boilers. A selection can be made as regards the dimensions of the drum and the diameter of the boiler tubes. The length of the tubes (and therefore of the containing drums) can vary from 3 ft. to 12 ft. Messrs. Bonecourt Surface Combustion, Ltd., have installed or are installing boiler plant of which the tubes and shells range within these limits, while they have carried out experiments with tubes 24 ft. long, and it is possible that in some cases tubes even as large as this will be employed in practice.

For a given kind of packing in the tubes, there must be preserved a definite ratio between the length and bore of the tubes in order to obtain sufficient cooling of the combustion gases. Thus, when tubes of 3-in. bore are employed the length is generally 3 ft. or 4 ft. In this case the ratio of length to bore is 12 to 1 or 16 to 1. If it be desired to employ longer tubes of the same bore, this may be done without sacrificing considerations of economy by employing a packing material of a more open nature in the tubes. It is clear that the more closely the refractory material is disposed in the tubes, the steeper will be the temperature gradient from end to end. By suitably selecting the packing for the tubes we have found that we can very effectively employ in boiler construction tubes ranging from 3 in. in bore and 3 ft. long to tubes 12 in. in bore and 24 ft. long. It will be seen that this affords great latitude in boiler design, enabling boiler shells to be made from 3 ft. to 24 ft. in length and of any desired diameter.

It will be gathered from what has already been said that the nature of the packing material in the boiler tubes is a matter of importance. Where a close packing is desired, as for example in tubes in which the ratio of length to bore is relatively small, refractory fragments of about 1 in. in diameter may be employed. Where the ratio of length to bore is greater, larger fragments can be used—for example, up to 3 in. in diameter. If a still more open packing is wanted, the granules may be lengthened until they stretch right across the tube, and arranged in a staggered manner so as to effect the necessary baffling of the gases.

Now with regard to the utilization of the heat developed in a Bonecourt boiler installation. In any form of steam generator the possible losses are:—

1. Loss of heat due to part of the fuel escaping combustion, or being only partially burned.
2. Heat carried away in the form of heated air, being air supplied in excess of the theoretical requirement.
3. Heat carried away in the products of combustion leaving the system.

⁶ *Electrician*, vol. 71, p. 171, 1913.

4. Loss of heat by so-called radiation from the exterior of the system.

Of these four possible sources of loss, Nos. 1 and 2 are for all practical purposes completely eliminated from the Bonecourt system. There is no heat loss due to part of the fuel escaping combustion or being only partially burned. Repeated analyses of the products of combustion from Bonecourt boilers have shown that in every case the combustion is complete so long as sufficient air is admitted to satisfy the theoretical requirement. Neither is there any appreciable heat loss due to air supplied in excess of the theoretical requirement entering the system at a low temperature and leaving it at a higher temperature, because it is found that it is not necessary to supply air in excess of the theoretical requirement in order to ensure complete combustion. This is in striking contrast to the normal practice with regard to coal-fired boilers, where an excess of air amounting to from 50 to 100 per cent of the theoretical requirement is necessitated, failing which there would result a very incomplete combustion of the fuel.

The heat carried away in the products of combustion leaving the system is very nearly proportional, for low temperatures at all events, to the temperature of the products. The specific heats of carbon-dioxide, nitrogen, water vapour, and oxygen being known over a wide range of temperature, the actual heat losses occasioned by gases of known composition leaving the system at a known temperature can be calculated.

Inasmuch as the ratio of air to gas burned in the Bonecourt system can be regulated to a great nicety, so as to correspond almost exactly with the theoretical requirements, and inasmuch as the gas is completely burned, thus avoiding on the one hand any appreciable content of oxygen in the flue gases, and avoiding on the other hand the presence of any carbon-monoxide or other unburned gas in the flue gases, it is possible to construct for any Bonecourt boiler installation a very clean heat balance-sheet, and it is therefore worth while considering the unavoidable losses from the standpoint of theory in order to be in a position to determine how closely the performance of any given installation approaches to the theoretically obtainable ideal.

To this end the author proposes to consider the case in which the gas burned is producer gas made in an ammonia-recovery plant and analysing:—

	Per cent
Carbon-dioxide	17.0
Carbon-monoxide	11.0
Hydrogen	26.0
Methane	2.7
Nitrogen	43.3
	100.0

the net calorific value of this gas being 140 B.Th.U.'s per cubic foot N.T.P.

Assuming that this gas is burned with the theoretical requirement of air, 1 cub. ft. N.T.P. of the gas will yield:—

Carbon-dioxide	0.31 cub. ft. N.T.P.
Water vapour	0.31 " "
Nitrogen	1.33 " "
	1.95 " "

Calculating from the known specific heats of the gaseous constituents, we are able to express the sensible heat (measured from a datum line of 0°C.) of the products of combustion at different temperatures as a percentage of the calorific value of the gas burned. The results obtained are shown in the form of a curve in Fig. 1. By means of this curve it is possible to read

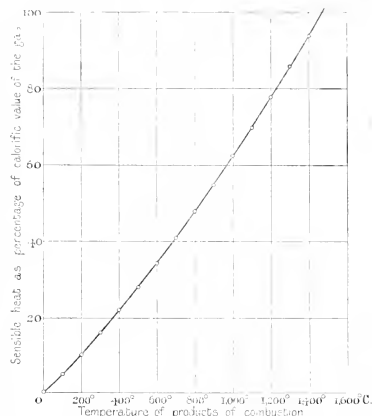

FIG. 1.—Combustion Products of Producer Gas. Curve showing sensible heat measured from 0°C. expressed as a percentage of the net calorific value of the gas.

off at a glance the heat lost in the combustion products from a Bonecourt boiler installation once the temperature of the chimney gases is known. The heat contributed to the system is known in terms of the volume and calorific value of the gas burned, and the heat usefully employed in terms of the weight of water evaporated. The radiation loss from the system is then readily found by the difference.

In a Bonecourt boiler installation the combustion products leave the system at a temperature of about 110°C. where a feed-water heater is employed, and the amount of heat carried away by the waste gases is therefore very small. Owing to the high evaporative power, and therefore the compactness of the plant, the radiation loss only amounts to about 2 per cent, and in some cases is considerably less. It therefore follows that the figures which ought to be obtained, and are obtained from Bonecourt boilers fired with coal-gas or coke-oven gas, yield a heat balance sheet of which the following may be taken as typical:—

	Per cent
Heat utilized in steam generator	95
Heat lost in combustion products	3
Heat lost in radiation	2
Heat originally available in gas burned	100

while in the case of producer gas the expected heat balance-sheet would be:—

	Per cent
Heat utilized in steam generation ...	94
Heat lost in combustion gases ...	4
Heat lost in radiation ...	2
—	
Heat originally available in gas burned ...	100

A battery of three Bonecourt boilers for burning ammonia-recovery producer gas is at present being installed in the works of an important firm in this country, and it is expected that in about two months the plant will be in operation. The steam developed by the boilers is to be used first of all for driving steam turbines, the exhaust from which is to be passed into the gas plant at a gauge pressure of about 3 lb. per square inch. The quantity of steam required will vary in accordance with the demands of the gas plant, but the maximum for the present expectations is at the rate of 22,000 lb. of steam per hour at a gauge pressure of 86 lb.

The boiler-house, which measures internally 38 ft. \times 50 ft., is designed to accommodate three Bonecourt boilers, each with a normal full-load capacity of 11,000 lb. per hour, and all auxiliary apparatus. The general lay-out of this apparatus is shown in Fig. 2. It should be noted in connection

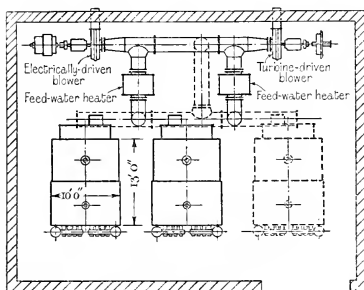

FIG. 2.

with this lay-out that as plenty of space was available for the equipment, generous margins have been allowed and no attempt has been made to place the boiler equipment in the smallest available space. It is interesting to note that, had the necessities of space demanded it, this same steaming capacity could have been condensed into a boiler-house of approximately 24 ft. \times 50 ft., allowing for the inclusion of a third similar boiler unit, as is provided for in the existing boiler-house.

The boilers in question are each 10 ft. diameter \times 12 ft. long between the tube plates, and they each contain 38 tubes of 6-in. internal diameter. The method of developing surface combustion in these tubes and the refractory packing is similar to that employed on the smaller tubes, there being slight modifications which have

been developed as the result of a series of experiments with this particular gas made on a single-tube tank for the purpose of discovering the best arrangement.

The two feed heaters supplied with these boilers have each a capacity equal to the total of two boiler units, so that one feed heater can be put out of action without interrupting the load. The same remark applies to the two power-driven exhausters. One of these is driven by a 440-volt continuous-current motor, and the other by a steam turbine.

Particular interest attaches to this plant, as it represents the first occasion upon which Bonecourt boilers have been used as a link in the system of generating power from coal by means of ammonia-recovery gas producers. The tendency of modern engineering to conserve the valuable by-products contained in coal instead of wasting these in coal-fired boilers has been emphasized so frequently at meetings of learned societies that it is very fortunate that an opportunity has been found of demonstrating the important part which it is hoped the Bonecourt system of steam-raising must inevitably play in power undertakings of the future.

It is not often that such an expensive form of fuel as the illuminating gas of London can be advantageously employed for steam generation, but there is one instance of a Bonecourt boiler at work in a large factory in London, the boiler being fired with illuminating gas from the town main and supplying steam to a steam hammer. The boiler is 8 ft. long and 3 ft. 6 in. in diameter, and is provided with five tubes, each of 6-in. bore. The boiler is capable of evaporating about 2,000 lb. of water per hour, but normally it is found sufficient to work it at about half its possible output.

The justification for the use of so expensive a form of fuel in this instance is to be found in the convenience and adaptability of the plant. The readiness with which steam can be raised when wanted for the hammer, and the immediate manner in which the making of steam responds to the turning on and off of the gas, are found to offer a great convenience in work of such an intermittent nature.

A novel type of construction has been adopted for this boiler. The tubes, instead of being of uniform bore throughout, contract sharply at the entrance end, the first 6 in. of the tubes being only of such bore as is required for the supply of the gaseous mixture. By adopting this plan of construction, the use of fireclay plugs for closing the entrance ends of the tubes is dispensed with, and the first part of the tube which conveys the gaseous mixture to the fireclay packing is kept cool by the water in the boiler. This special construction of the tube is shown in Fig. 3.

The use of a granular refractory packing for the purpose of increasing the rate of heat transmission is not limited to boilers which are fed with combustible gas. The same device may be employed for the purpose of increasing heat transmission in so-called waste-heat boilers, where the heating medium consists of products of combustion from a furnace or gas engine. There is no question of surface combustion in the tubes of the boiler in this case, the granular packing serving merely to increase the heat transmission through the walls of the tube by radiating heat from the hot granules and also by

causing the hot gases to impinge repeatedly on the tube walls.

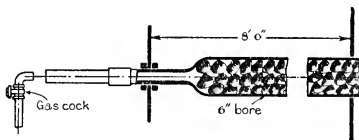

FIG. 3.

A sectional view of a Bonecourt waste-heat boiler that has been supplied for utilizing the exhaust gases of a gas engine is shown in Fig. 4. The boiler consists of a shell 5 ft. 6 in. in diameter and 3 ft. long, provided with 35 tubes of 3-in. bore, giving a total heating surface of 1009 sq. ft. During a test the load on the engine varied between 70 and 150 h.p., but the boiler is of sufficient capacity to work in conjunction with an engine of 300 h.p., as is proved by the fact that this boiler, with 18 of the tubes purposely plugged with stoppers, thus reducing the heating surface to 54 sq. ft., evaporated 250 lb. of water from and at 212° F. per hour, this amounting to 4.7 lb. of water per sq. ft. of

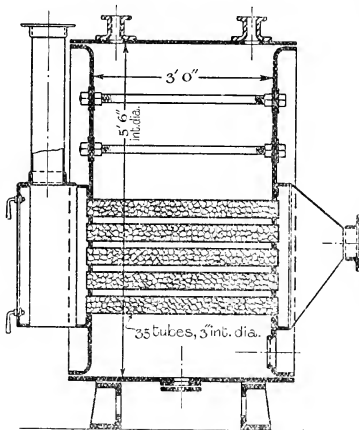

FIG. 4.

heating surface per hour. It was found that 17 tubes afforded sufficient outlet for the gases without putting undue back-pressure on the engine, and we may therefore conclude that in boilers of this class it is sufficient to provide 0.37 sq. ft. of heating surface for each indicated horse-power of the engine. This is a very low ratio of heating surface to work done, and enables waste-heat boiler plant of very compact dimensions to be constructed.

Under the above stated conditions of working, with the heating surface of the boiler reduced by rather more than one-half, the inlet temperature of the gases was 610° C. and the outlet temperature 150° C., with a steam pressure in the boiler of 60 lb. per sq. in.

LIQUID FUEL.

So far the author has dealt with the Bonecourt boiler fired with gaseous fuel or with hot waste gases; and he now proposes to describe recent developments which have resulted in the successful adaptation of the Bonecourt system for firing with liquid fuel.

At first sight there might appear to be something anomalous in the idea of hot surfaces accelerating the combustion of liquid fuel, but when it is considered that the combustion of liquid fuel is only a special case of gaseous combustion, and that when liquid fuel is burned what really burns is the combustible vapour given off by the heated liquid, the possibility of utilizing hot surfaces for accelerating the combustion of liquid fuel appears more feasible.

After many unsuccessful attempts the author has succeeded in devising means for utilizing liquid fuel in Bonecourt boilers. Those who have tried to secure complete combustion of liquid fuel in contact with or in close proximity to water-cooled surfaces will readily appreciate the fact that many difficulties presented themselves in translating the Bonecourt system from a gas proposition into a liquid-fuel proposition. Those difficulties have now been overcome, and a way found whereby results may be obtained with liquid fuel which are quite comparable with the results obtained with gas.

The experiments were carried out in the works of Messrs. Bonecourt Surface Combustion, Ltd., in London, and culminated in the construction of a liquid-fuel-fired boiler, which is now running the works. This boiler is 5 ft. in diameter and 12 ft. long, and is furnished with five boiler tubes each 9 in. in bore. The boiler tubes are packed with refractory material arranged on the staggered plan. The liquid fuel is supplied to the boiler tubes from an overhead tank under a pressure due to a head of about 12 ft. The air required for the combustion is supplied from a fan at a pressure of from 5 to 30 in. water gauge, the oil and air supplies to the boiler tubes being so arranged that the oil is sprayed by the air. A simple arrangement is employed in the entrance of each boiler tube which provides a gasification chamber for the spray of liquid fuel. The arrangement is shown in Fig. 5 and comprises a fireclay sleeve which serves the purpose of conserving heat within the chamber, and a perforated septum which forms the further wall of the chamber.

The process of lighting consists in swinging back the spray device, inserting some lighted oily waste, and turning on the oil and air. In a few seconds the chamber is red-hot, as is seen by inspection through the sight tube, which is fixed in such manner as to give a good view of the middle of the chamber. The chamber being red-hot, it is only necessary to turn on the oil and air to the required extent, the appearance of the glow serving as the indication for determining the correct proportioning of oil and air. All the tubes can be lighted by one man in three minutes, and steam at 110 lb. per sq. in. is obtained in 50 minutes starting with everything cold.

The purpose of the chamber, as has been mentioned, is to gasify, or at all events partially gasify, the liquid fuel. The gasification is brought about by the heat of the chamber and the partial combustion of the liquid fuel, this partial combustion serving to maintain the chamber at the required temperature. The chamber is far too

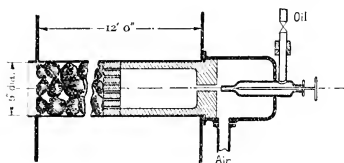

FIG. 5.

small to enable complete combustion of the fuel to take place, and this point has been proved by analysing a sample of the gases drawn through a water-cooled tube of very small bore from a point situated in the fireclay packing immediately after the perforated septum. The gas sample drawn off analysed:—

	Per cent
Carbon-dioxide	11.4
Oxygen	0.3
Carbon-monoxide	11.2
Saturated hydrocarbons equivalent	
to ...	100.0 Methane
Nitrogen	67.1
	100.0

It will be seen that the sample contains a considerable amount of combustible gas, and that at the particular point at which the sample was taken the gaseous medium consisted mainly of combustible gas with the almost complete exclusion of oxygen. A sample of the gaseous medium drawn from a neighbouring point showed a large excess of oxygen, and as analysis of the products of combustion leaving the end of the boiler tube showed the combustion to be complete, it is clear that if samples of the gasified material were taken from a sufficient number of points in the cross-section immediately after leaving the gasification chamber, it would be found that the gaseous medium leaving the gasification chamber consists in the aggregate of combustible gas together with sufficient air to complete its combustion subsequently in contact with the incandescent refractory material in the boiler tube, a certain amount of products of complete combustion being also present.

The following are the results of a test carried out on the oil-fired boiler referred to, which is installed in the London works of the Bonecourt Company, and is in regular operation, supplying the works with power.

Steam gauge pressure (per sq. in.)	110 lb.
Temperature of oil	80° F. (27° C.)
Air pressure	37 in. (water gauge)
Pressure in smoke-box	3 in. "
Temperature of combustion products leaving boiler tubes and entering feed-water heater	608° F. (320° C.)

Temperature of combustion products leaving feed-water heater	275° F. (135° C.)
Temperature of cold feed	43° F. (6° C.)
Temperature of feed from feed-water heater to boiler	110° F. (48° C.)
Duration of test	3 hours
Total water evaporated	7,625 lb.
Water evaporated per hour	2,542 lb.
Water evaporated per hour from and at 212° F.	3,085 lb.
Total tube surface (five tubes 9-in. bore, 12 ft. long)	141 sq. in.
Total heating surface of boiler	123.7 sq. ft.
Steam raised per sq. ft. of heating surface per hour from and at 212° F.	25 lb.
Total oil burned	545 lb.
Oil burned per hour	181.7 lb.
Water evaporated from and at 212° F. per lb. of oil	170 lb.
Net calorific value of oil (per lb.)	17,800 B.Th.U.'s

$$\text{Efficiency} = \frac{7625 \times 1175.0 \times 100}{545 \times 17800} = 92.5 \text{ per cent}$$

FIG. 6.—Admiralty Fuel Oil. Curves showing percentage of heat value of the oil contained in the products of combustion at various temperatures and with various oxygen contents. Measured from 0° C.

A continuous sample of the combustion products was taken during the test, and was found to analyse:—

	Per cent
Carbon-dioxide	12.8
Oxygen	3.4
Carbon-monoxide	0.0
Nitrogen	83.8
	100.0

The oil burned in this boiler is the ordinary class of fuel oil as supplied for the firing of boilers on torpedo-boats and for steam raising and furnace firing generally. Experiments have been made with several kinds of oil, and no difficulty has been experienced in burning any kind of oil that was tried. If the oil contains much bitumen and is so viscous as not to flow readily, it is found advantageous to warm the oil, but for any ordinary kind of fuel oil perfectly satisfactory results have been obtained when the oil has been supplied cold to the boiler.

The points which characterize this boiler may be enumerated as follows:—

1. Complete combustion of the oil, no products of partial combustion being found in the flue gases.
2. The air required for complete combustion of the oil is only slightly in excess of the theoretical requirement.
3. Entire absence of smoke when once the boiler has been started up, and practically no smoke while starting.
4. The oil is supplied to the boiler cold and at a very low pressure, the air supplied for the combustion being sufficient to effect the necessary spraying of the oil.

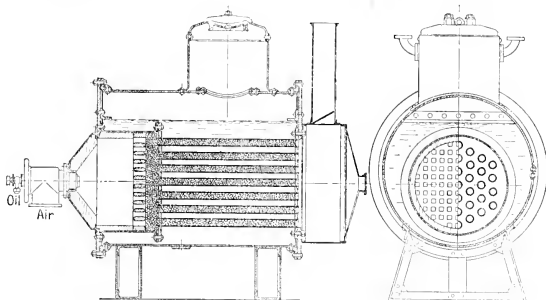

FIG. 7.

5. The combustion products are cooled down to a point below which further cooling would scarcely be practicable or economical.
6. An evaporation of 25 lb. of water per sq. ft. of heating surface per hour.
7. The effective transmission to the water in the boiler of 92.5 per cent of the net heat available in the oil burned, even when evaporating at the above stated high rate.
8. Exact and immediate regulation of steam production.

In order that we may be in a position to examine critically the utilization of heat in this boiler system, the author gives in Fig. 6 some curves showing the heat content of the combustion products at different temperatures and with different percentages of oxygen, such heat contents being measured from a datum line of 0° C. and expressed as a percentage of the net calorific value of the fuel. From inspection of this curve it will be seen that the products of combustion of liquid fuel at 135° C. and containing 3.4 per cent of oxygen contain as sensible heat 5.2 per cent of the heat originally available in the oil burned, while on comparing the temperatures of the feed-

water on entering and leaving the feed-water heater it will be seen that the 92.5 per cent of the heat utilized is divided into 83.7 per cent transmitted through the boiler tubes and 8.8 per cent transmitted through the tubes of the feed-water heater. We thus obtain as the distribution of heat utilized and lost:—

Heat transmitted through boiler tubes	83.7 %	Heat utilized	92.5
Heat transmitted through tubes of feed-water heater	8.8 %		
Heat lost in products of combustion at 135° C.	5.2		
Balance, being radiation loss	2.3		
Total heat available in oil burned	100.0		

As a check on the above estimate of radiation loss, a careful measurement of actual radiation loss from the boiler shell was made by observing the fall in steam pressure when the boiler was laid off with an initial steam pressure of 99 lb. per sq. in., the figure obtained being 2.1 per cent, which agrees very closely with the above.

It is well to note in passing that this radiation loss amounts to 226 B.Th.U.'s per hour per sq. ft. of exterior surface of lagging for a mean boiler pressure of 90 lb. per sq. in., the thickness of the lagging being 2 in.

Although this system of oil firing has only recently been evolved, another boiler has been built and supplied to a customer. The products of combustion after leaving the boiler tubes are returned through a tube in the steam space, in which are disposed steam coils for the purpose of superheating, the products of combustion after leaving the superheater passing to a feed-water heater consisting of the usual drum traversed by packed tubes. The boiler has been in operation for a month or two and is giving entire satisfaction.

This method of oil firing has been taken up in Germany by the Berlin Anhaltische Maschinenbau Aktiengesellschaft, who are developing the subject of surface combustion in collaboration with the Bonecourt Company. With the object of testing an alternative mode of construction they have built a boiler following the same

general principles, but in which one combustion chamber supplies a number of small boiler tubes. This boiler is shown in Fig. 7. It comprises a boiler shell provided with packed tubes of 3-in. bore and a feed-water heater furnished with similar tubes. The author is informed that good results have also been obtained from this boiler, and it would appear that the plan of construction involved may afford a useful alternative.

SOLID FUEL.

The author has discussed in this paper the use of gaseous fuel with the Bonecourt boiler, and has also shown how such boilers may be fired with liquid fuel. There remains therefore only to apply the system if possible to solid fuel—the largest field of all. This field of investigation has already been attacked, and although a Bonecourt boiler fired direct with solid fuel is not yet a *fait accompli*, the attempts which have so far been made in this direction afford hope of a very useful result being obtained at no distant date. The experiments which have already been carried out have produced remarkable results: in a small apparatus fired with solid fuel, evaporating 334 lb. of water per hour from and at 212° F., complete combustion of the fuel has been obtained, although the amount of air supplied

for the combustion was practically no more than is required by theory, as is shown by the following analysis of the combustion products:—

Carbon dioxide	19.1 per cent
Oxygen	1.4 "
Carbon monoxide	0.0 "
Nitrogen	79.5 "
			<hr/>
			100.0 "

The evaporation amounted to 17.8 lb. of water from and at 212° F. per square foot of heating surface per hour. Such a result is remarkable from the point of view of both a combustion phenomenon and the evaporation performance. This result was communicated by the Bonecourt Company to their German allies, the Berlin Anhaltische Maschinenbau Aktiengesellschaft, who expressed themselves sufficiently impressed with the results to undertake immediately the further development. They have constructed a coal-fired Bonecourt boiler and are about to put it under test. This first construction is naturally of a tentative nature, but it is hoped that it will pave the way for a considerable enlargement of the field of surface combustion as applied to steam generation.

DISCUSSION.

Jockel.

Mr. L. M. JOCKEL: Papers dealing with boiler work are very welcome as it seems that at the present time further improvements in the efficiency of steam plant are more necessary in the boiler house than in the engine-room, especially when one considers that in many up-to-date power stations something like 50 to 70 per cent of the works costs is accounted for in the boiler house. On page 724 the author states that a draught of about 15 in. (water gauge) is required, and that this can be produced either by induction or by forcing. If the latter method is adopted it appears that two fans will be necessary, one for the gas and one for the air; in all probability, however, the induced-draught arrangement will prove in practice the more satisfactory and efficient of the two methods. To produce this pressure difference an appreciable amount of power will be required—possibly some 3 to 4 per cent of the power developed by the boiler—and this fact must be considered when comparing boiler efficiencies. In land practice with water-tube boilers working on induced draught the power required for driving the fan seldom exceeds about 1 per cent of the boiler power. In connection with the driving of the fan the lay-out shown on page 727 represents a duplicate fan plant arranged for both electrical and steam-turbine drive. The latter method might prove very economical, as the heat in the exhaust steam could be utilized for heating the feed water previous to its entering the gas-fired heater or economizer. On the other hand this arrangement might not prove so reliable, as during heavy loads the draught would be largely dependent on the boiler pressure. At such times in a power station one naturally wishes to speed up the auxiliary plant in order to get over any difficulty such as low steam pressure as quickly as possible. The evaporative power of the boiler would appear to be some 3 to 4 times greater than in the case of an ordinary water-tube boiler, and it would be interesting to know whether priming does not occur when working at such high rates—

particularly in view of the fact that nowadays such Mr. Jockel. excellent results of boiler tests are published from time to time. As high superheats are now of great importance it would be of interest if the author could give details of suitable superheaters, as no mention seems to have been made of their application to this type of boiler. The compactness of the boiler should be a valuable feature in many cases, the lay-out shown on page 727 illustrating this point. An ordinary water-tube boiler appears to require about 18 sq. ft. of floor space per 1,000 lb. of water evaporated per hour, whereas a Bonecourt boiler would only require say 14 or 15 sq. ft. of space for the same duty. On page 728 the author mentions in connection with an oil-fired boiler that steam at 110 lb. pressure can be raised from cold water in 50 minutes. In view of expansion troubles this would hardly seem to be good practice with a shell-type boiler, particularly with a multitubular design having a large ratio of diameter to length and flat stayed surfaces. From practical experience with multitubular boilers of the shell type I have always found that there is a certain amount of "dead" water present unless some efficient circulating device is utilized; but perhaps the author gets over this difficulty by placing the fire tubes very low down in the boiler. The maintenance of boilers is an important factor, and it would be interesting if the author in his reply could give some figures in regard to that item, as I understand that some Bonecourt boilers have now been working under practical conditions for over a year. In view of the high evaporative rating, it would seem that scaling would be frequently required unless the feed water is remarkably pure, while unless the gas is carefully cleaned the fire tubes and granules will tend to get clogged. The latter difficulty might possibly be overcome by periodically refluxing the tubes.

Mr. W. M. SELVEY: The Bonecourt system will be of Mr. Selvey. great use to the community when it has found its right

Mr. Selvey. sphere. A suggestion rather than a positive statement is made on page 727 in the paragraph which states that Bonecourt boilers have been used as a link in the system of generating power from coal by means of ammonia-recovery producers. I think that this is not borne out by the circumstances quoted. All that I see in it is a boiler installation for supplying the Mond type of producers with the large quantity of steam which on the one hand is so necessary if a large yield of ammonia is to be obtained, and on the other hand is so detrimental to the heat efficiency. I have no wish here to open up this old controversy; those interested can refer to the discussion on Mr. Humphrey's paper before the Institution of Mechanical Engineers,* but I feel compelled to point out that if Mr. McCourt wishes us seriously to consider this boiler as a link in the chain for obtaining power from coal via a producer, a steam boiler, and a steam turbine, rather than by producer plant and a gas engine, then I must certainly dissent from the balance sheet for the efficiency of his boiler. It is the old question of the producer efficiency being taken on the "gross" or "higher value" of the gas, and the gas-engine efficiency on the "net" or "lower value." I have come to the conclusion that with a Mond type of plant, with a boiler of the highest efficiency that I have personally tested, and with steam supplied to the producer from a mixed-pressure turbine, the amount of coal burnt in the producer-boiler system is 1.43 times that of the same boiler with a modern chain grate. Now this coal-fired boiler had an efficiency of over 85 per cent reckoned on the "higher value," and on the "lower value" it would have had an efficiency of over 88 per cent, so that accepting the author's figure of 95 per cent for this boiler, and deducting 2 per cent for "extra" fan power, we are only 5 per cent better off and the ratio is only reduced from 1.43 to 1.36. Now this chain-grate boiler which I have in mind would burn even the poorest class of coal, whereas the producer to go with this boiler would require a coal not only carefully selected but containing a high percentage of nitrogen. I look for the solution of the problem therefore rather on the lines of the combined coke-oven-waste-heat power station in which this boiler may legitimately find a field. In such cases land is generally cheap and the size of each unit is small. The present boiler is a return to the fire-tube type, which has generally been limited to an evaporation of about 15,000 lb. per hour, whereas our modern large power stations are now being fitted with Babcock and Stirling boilers which can easily evaporate 40,000 lb. of water per hour—indeed, in the United States a number of boilers of the Stirling type have evaporated 100,000 lb. per hour. The Bonecourt boiler, to give an efficiency of 95 per cent, has an economizer that reduces the temperature of the outlet gases almost to the condensation point of the water vapour carried by them. The effect of any such condensation will be known to those who have occasionally run economizers with feed water below 90° F.; a solution of sulphuric acid is produced which plays havoc with the metal-work. I expect that the author has already heard of this. Corrosion would also occur in the suction fan if it were placed in the outlet gases; but I think that this could be remedied by placing the fan between

the boiler and the economizer. It may be news to some members that economizers of the pipe type have already given outlet temperatures lower than those mentioned in the paper, and with a fan power of only 2 in. (water gauge) instead of the 15 in. to 30 in. quoted. The extra power required for this draught as compared with the usual type of fan has not been debited against the 95 per cent efficiency claimed. The outlet temperature from the boiler itself is quite a normal figure for a water-tube boiler, and there is no particular item from the combustion to the temperature of the outlet gases that could not be produced by other means at present available. The fan power is quite a considerable item. The power required for 1,000 cub. ft. of air at a pressure of 20 in. (water gauge) is 304 h.p. Assuming reasonable efficiencies, I find that the power required for the fan for an electrical drive is equivalent to 2.9 per cent of the steam generated—Professor Bone in one of his papers allows 4 per cent. If the steam is provided by a high-pressure turbine and its exhaust is used for feed-water heating, the consumption will not be better than double this figure, which means practically 6 per cent of the total steam. This is nearly as much as the feed water can take up under ordinary conditions, having already the steam from the feed pump, and is enough to prevent the final temperature of the gases from approaching 200° F. The electrical drive is of course dependent on electrical power always being available before the boilers are started up. There are several other points which might be put forward, such as the arrangements for meeting rapidly varying loads and the adjustment of the ratio of the gas and air, on which the author could give us welcome information. I should like to close my remarks with a note of appreciation. The author has produced a boiler situation similar to that in connection with gas engines, in which the small unit is as efficient as the large. He has put forward an exceedingly clever flash boiler on a much larger scale than hitherto, and has provided a means of prolonging the life of many small private plants which are using steam as an alternative to electric power supply from a large company.

Mr. W. A. CHRISTIANSON: The author refers to the possibility of using boilers of the water-tube type worked on the Bonecourt gas combustion system, but he has shown no actual designs. The Bonecourt system of combustion is excellent, and had it been arranged so that it could be adapted to boilers of existing types more progress might have been made. So far, development appears to be confined to boilers of the fire-tube type, and the largest size made up to the present is only of 11,000 lb. per hour evaporative capacity. There is therefore not sufficient inducement for power users to discard their existing boilers for Bonecourt boilers. No reference has been made to the use of blast-furnace gas on the Bonecourt system, and blast-furnace gas is undoubtedly a most important field of gas firing. It seems to me that it would be necessary to clean the gas first, as otherwise the boiler tubes and granules would become badly choked after a short time. Cleaning of blast-furnace gas has made considerable progress in Germany, but not so much in this country, and therefore I think that the Bonecourt system will not be adopted in this sphere. The boilers described by the author supply saturated steam only. For present-

* H. A. HUMPHREY. Power-gas and large gas-engines for central stations. *Institution of Mechanical Engineers, Proceedings*, p. 41, 1901.

day power installations it is essential to have superheated steam, and it would seem to be a matter of some difficulty to arrange for this with a Bonecourt boiler, as the exit flue-gas temperature at the back of the boiler portion is too low for superheating purposes. The high efficiency claimed appears to be to a great extent due to the feed-water section. Reference to one of the author's tests shows the exit temperature from the boiler section to be 608° F., while of the total efficiency of 92.5 per cent, 83.7 per cent is due to the boiler and 8.8 per cent to the heater. The figures corresponding to the boiler are by no means exceptional, and I am of opinion that equally good results are being obtained from coke-oven gas-fired boilers of ordinary make where similar care is taken in the working of the boiler as has been done in these Bonecourt boiler tests. Blast-furnace gas-fired boilers are notoriously inefficient, but the same cannot be said of coke-oven gas-fired boilers. Although figures are not generally published, I think that with reasonable care efficiencies of 85 per cent would be obtained. The high efficiency of the Bonecourt system is further due to the surface combustion with its resulting minimum amount of excess air, and the impinging effect caused by the granules in the tubes. The surface combustion can be initiated in a simple fashion by properly arranged chequered brickwork in the furnace chamber of any water-tube boiler, and as in boilers of this class the impinging principle on the tubes is already fairly well carried out, I am hopeful that such a combination would be equal in practical efficiency to the Bonecourt system—especially so in a boiler of the Stirling type where the back section of tubes is practically an economizer section. The impinging or retardation principle in fire tubes has already been appreciated, as evidenced by occasional attempts to fit retarders to marine boiler tubes. These have generally had to be discarded owing to choking. Coal-fired boilers have generally lower efficiencies than coke-oven gas-fired boilers, and this should be borne in mind when considering the high efficiency claimed for the Bonecourt system. For the present I think that the Bonecourt boiler is suitable only for small plants. Incidental advantages of the system are that the nozzle control allows each burner and tube to be worked at its maximum efficiency throughout a wide range of power, while in case of low water it is possible to shut off the top burners and so prevent damage. A disadvantage is that the boiler is not readily adapted for changing over to coal firing, which is sometimes necessary. With the multiplicity of burners used on gas-fired boilers, there is the possibility that the mixture in each may vary, resulting in a lower efficiency; but this difficulty is satisfactorily overcome in the oil-fired boiler shown in Fig. 7, which has a preliminary mixing chamber. On previous occasions the diaphragm principle of firing gas on the Bonecourt system has been put forward, and I thought that this might have been adapted so that it could be used on existing types of water-tube boilers. Perhaps the author will tell us why no such development has taken place. About twelve months ago I inspected the boiler at Skinningrove and was informed that it was giving very satisfactory results. With regard to the author's statement that the evaporation is proportional to the square root of the difference of pressure between the opposite ends of the boiler tube, I have found that a similar law applies to an ordinary chain-grate coal fire. Perhaps the author will be able to

enlighten us further on several of the points referred to—more especially in regard to adapting his principle to existing makes of boilers for large powers, and in regard to comparisons with existing methods.

Mr. C. D. McCOURT (*in reply*): The following points have been touched upon in the discussion, and I propose to consider them in the order in which they arose, namely:—(1) Power consumption for fan driving; (2) the possibility of priming due to the high rates of evaporation obtained; (3) the provision of superheaters; (4) the possibility of straining a Bonecourt boiler by too rapid starting from cold; (5) the cost of maintenance of the boilers; (6) the necessity for removing scale deposited on the tubes; (7) the possibility of the boiler tubes becoming clogged up internally by dust deposited from gaseous fuel; (8) the cost of generating steam by means of ammonia-recovery producer gas; (9) corrosion of the feed-water heater and fan due to condensation; (10) the suitability of the system for meeting rapidly varying loads; (11) the employment of blast-furnace gas.

Turning first to the question of power consumption for fan driving, it should be remembered that the figures which have been recorded up to the present have been measurements upon fans not expressly constructed to give good efficiency for the duty required. In the case of large installations of Bonecourt boilers it would be possible to use standard fans having efficiencies ranging between 70 and 80 per cent for a considerable variation in load. The results of carefully made tests on exhausters of large capacity, constructed by the De Laval Company of Sweden, show that for large boiler installations the percentage of power necessary for driving the exhausters may be reduced far below the figures mentioned in the discussion; in fact, taking the fan tested, over a considerable variation in load the fan power would be below 2 per cent of the boiler output. With regard to the power required for the fan, it should be recollected that centrifugal fans possess the useful property of giving when driven at a constant speed almost constant suction for very great variations in load.

Careful measurements have been made of the wetness of the steam produced from Bonecourt boilers evaporating at high rates, and in every case the steam has been found to be technically dry. The excellence of the circulation induced by the steep evaporation gradient along the tubes is probably partly responsible for the absence of priming, but a more important factor in this connection is that the boiler in question is a fire-tube boiler and not a water-tube boiler. If a water-tube boiler were to evaporate at the high rates obtaining in a Bonecourt boiler, the steam formed in the tubes might be expected to shoot water into the steam spaces and cause serious priming. Water tubes are known to act spasmodically in the generation of steam, and can be observed acting much in the manner of pop-guns if a suitable model be constructed and operated.

Superheaters can be readily provided in Bonecourt boilers, the boiler tubes being chosen on the short side so as to obtain the necessary temperature of the combustion products, the superheater being located between the boiler and the feed-water heater, and the feed-water heater having to do a little more work by reason of the increased temperature of the entering gases. If a high degree of superheat be required, the boiler can be designed of a short

Mr. Christianson.

Mr. McCourt.

Mr.
McCourt.

length and furnished with an equal number of combustion tubes and return tubes, the superheater being located at the end of the boiler shell and therefore being subject to a surrounding gaseous medium at a temperature of 600 to 900° C.

It has been suggested that if boilers of high steaming power such as the Bonecourt boiler are started quickly, straining will take place owing to unequal heating of the shell. This has not been found to occur, and immunity in this respect is attributable to the vigour of the circulation produced by the steep evaporation gradient along the tubes. The vigorous circulation prevents the formation of "dead" water at the bottom of the boiler, and hence every part of the shell increases in temperature at a nearly uniform rate however quickly steam may be raised starting from cold.

With regard to cost of maintenance of the boilers, the absence of heated joints and the restriction of the heat transmission area to the tube surfaces must make for a low cost. Bonecourt boilers have not as yet been sufficiently long in use commercially to afford data on this head, but they have at all events been sufficiently long in use to show that during two years' operation no necessity for repairs of any kind has been encountered either in the straining of the shell or the burning or impoverishment of the boiler tubes or tube joints.

No trouble has yet arisen with regard to scale formation. The scale formed on the tubes is shed off as soon as it reaches a thickness of about a millimetre. On opening the Bonecourt boiler at Skinningrove after it had been running for some months, no scale thicker than a millimetre was found on the tubes, but in the bottom of the boiler shell was found an accumulation of detached scale, which had evidently been dropped from the tubes after attaining a certain thickness.

Experiments have been made with gases heavily laden with dust, and it is found that very little dust settles in the boiler tubes. The speed of the gases passing through the tubes effectually prevents serious deposition of dust, any dust tending to collect being at once moved on by the violence of the blast.

With regard to the comparison between the relative advantages of Bonecourt boilers and gas engines for the development of power from ammonia-recovery producer gas, it is thought that a discussion of this subject, involving

as it does a full consideration of a great diversity of points, cannot advantageously be entered upon here. It will be evident, however, that the simplicity and low first cost of large turbine sets of say 10,000 to 12,000 kw. offer compensating advantages to set against the lower fuel consumption of gas engines limited to sets of about 2,000 kw.

It has been suggested that the gases in passing through the feed-water heater of a Bonecourt boiler are cooled down to the point at which condensation may take place, and that if this occurs it will be found to cause serious corrosion. This can be obviated by causing part of the hot feed water to circulate back again to the inlet of the feed-water heater, thus preventing such undue cooling of the flue gases as would produce condensation and consequent corrosion.

To meet variations in load, any number of tubes can at a moment's notice be turned off, and when required again can as quickly be lighted up. To do this it is only necessary to manipulate a damper and the necessary valves. By this means any desired output of steam from 1 per cent to 100 per cent of the maximum output can be obtained at any time. A more elastic control of steam generation can scarcely be conceived, the response of the boiler to alterations in the supply of gas being immediate.

Coming finally to the firing of Bonecourt boilers with blast-furnace gas, two large boilers each evaporating 15,000 lb. of water per hour are about to be constructed by a large firm in Belgium for their power station. Preliminary experiments have been carried out at their works, the gas employed possessing a calorific value of 105 B.Th.U.'s per cubic foot, and yielding an evaporation of 20.5 lb. of water from and at 212° F. per square foot of heating surface per hour. The flue gases analysed:—

Carbon dioxide	16.4	per cent
Oxygen	2.6	"
Carbon monoxide	0.0	"
Nitrogen	81.0	"
			100.0	

This composition shows that the combustion is complete even when the amount of excess air employed is almost negligible.

Mr.
McCourt.

THE CONSTRUCTION OF A WIRELESS STATION.

By C. G. ROACH, Associate Member.

(Paper read before the WESTERN LOCAL SECTION 16th March, 1914.)

ABSTRACT.

About four years ago it was decided to spend a large sum on improvements in the ship-to-shore wireless service, and on completion of the scheme there will be 12 stations having the following ratings, viz.:—

	kw.		kw.
Valentia	10	Guernsey	1½
Malin Head	5	Bolt Head	3
Liverpool	2	Land's End	5
Caister	1½	Fishguard	3
North Foreland	2½	Crookhaven	3
Niton	1½	Cullercoats	2

The stations acquired from the Marconi Company at Rosslare and the Lizard have been abandoned, and those at Bolt Head and Guernsey will be maintained for use in emergencies only.

The Land's End station was opened for traffic on the 1st December last. It is situated close to the main road from Penzance to St. Just, and within a mile of the latter town. The station stands 500 ft. above sea-level, and the ground has a gradual fall to the sea, thus affording the best possible conditions for ship-to-shore signalling.

The original scheme was to obtain the electrical energy for working the station from the Cornwall Power Company's 10,000-volt mains, but it was subsequently found necessary to install prime-movers and to generate the electrical energy required.

There are two lattice steel masts each 205 ft. 6 in. in height and fitted with three sets of four stays. Originally it was intended that they should stand on porcelain feet, but owing to the high cost of such massive insulators, which would have had to be specially made, it was decided to substitute reinforced concrete feet. The diameter of each block is 36 in. The blocks stand 18 in. high and are 36 in. in diameter, and there are three for each mast. The stay anchorages are formed of T-shaped blocks of concrete reinforced with ½-in. iron rods. Each block is estimated to weigh 18 tons. Running through the concrete at an angle of 45 degrees is a 1½-in. iron rod, 9 ft. in length, threaded through a 6-ft. length of channel iron 4½ in. × 2 in. × ½ in. at the lower end and fitted with a 6-in. ring at the upper end to take the stay attachments. The stays are made of 2½-in. steel rope. The topgallant stays have three block porcelain insulators, and the topmast and mainmast stays two each. The stays terminate at the ground anchors with a short length of crane chain and a special clamp which admits of a fine adjustment by nuts, and of a coarse adjustment by taking up a half-link or a number of links in the chain.

The masts, which were designed by the Engineer-in-Chief to the Post Office, are of triangular section, and will maintain their stability when subjected to a wind having a velocity of 80 miles per hour. The main members are composed of bent steel plate of uniform thickness, and are

connected end to end by suitable fish-plates. The braces are of 2 in. × 2 in. × ¼ in. angle iron and are fitted to the vertical members by two rivets at each end. Their lengths are for the mainmast 5 ft. 11½ in., topmast 4 ft. 7¾ in., topgallant mast 4 ft. 0¾ in. Owing to the extreme length of the sections, 70 ft. 10 in. main, 65 ft. 7¼ in. topmast, and 66 ft. 5¼ in. topgallant-mast, they were sent down in half-sections, each half-section being nested together for convenience of transport and erection. The moving-derrick method was employed for erecting the first mast, but in the case of the second mast this method was abandoned and treble and quadruple blocks taking a 4-in. manila rope were used instead. The untelescoping was by no means an easy job owing to the extreme lengths to be handled and the small overlap between the sections, but it was carried through in due course and successfully completed. The masts will doubtless do all that is expected of them, but the cost of carriage and erection will probably prevent the perpetuation of that particular design.

The mast erected at Fishguard consists of three sections, the dimensions being as follows:—

Mainmast 65 ft. × 13½ in. square, tapering to 11½ in.
 Topmast 58 ft. × 11¼ in. square, tapering to 9¼ in.
 Topgallant-mast 51 ft. × 9¼ in. square, tapering to 6½ in.

This type of mast is the one usually adopted for coast stations, the timber used being pitch or yellow pine.

The Marconi Company's latest mast is of tubular design built up in sections, each section being about 10 ft. in length. The half-sections are pressed out of sheet steel and flanges are formed at the sides and ends, which are drilled to take the connecting bolts. To facilitate erection a wood spar is fitted inside the tube and gradually raised until the required height is attained. The spar serves to hold the tackle necessary to carry a balcony on which the men work and to raise the half-sections as the work proceeds; finally it supports the antenna above the steel structure. The advantages attending the use of this type of mast are the moderate cost of transport and the ease of erection; against which must be set the increased resistance offered to wind pressure as compared with the lattice-work mast.

The International Convention on Wireless Telegraph Traffic decided that each coast station must be able to work with either a 600-metre or a 300-metre wave. To provide for this at Land's End two separate antennas are used. The 600-metre antenna consists of an inverted triangle, the base being 200 ft. and each of the sides 160 ft. in length. Both the base and the sides are formed of cages of six wires separated by light wooden spreaders with the ends brought together on stout copper rings. The first cages were made of 7/19 S.W.G. hard-drawn copper wire but in future silicon bronze is to be substituted, copper having failed to stand the severe strain.

This aerial is suspended by $1\frac{1}{2}$ -in. flexible steel cables, running over suitable sheaves attached to the top of the masts, and thence to two 5-ton winches which are anchored permanently for raising and lowering the cages. The 300-metre aerial is much lighter and can be easily handled with a set of double-purchase blocks. It consists of two wires, each 1.1 ft. in length, separated by two spreaders. The halyard is a 2-in. hemp rope rigged on the mast standing at the south-west corner of the site. Vulcanized rubber strop insulators are interposed between the aeriads and their halyards. The earth system is of the capacity type and consists of 20 cast-iron plates No. 18 gauge, each plate measuring 6 ft. \times 3 ft. They are arranged on either side of the building in two arcs of 80 ft. radius measured from the centre of the high-tension room. The plates were buried as nearly vertical as possible without having recourse to blasting, and their upper edges are bolted together. To the centre of each plate a copper wire, weighing 100 lb. per mile, is attached and led over a short stake to a rolled-steel frame erected on a platform on the roof of the building, and insulated therefrom by 4 Buller's third-rail insulators. Each of the 20 wires from the earth-plate is clamped to the outside of the frame, and from the inside six wires are led to a Bradfield insulator fixed at the centre of the platform. On either side similar insulators are placed for terminating the two aeriads.

The wave-changing switches are operated by means of a lever switch mounted on the side of the receiving cabinet and acting through flexible steel wires run over rollers. There are six 0.014-mfd. and one 0.016-mfd. condensers.

The motor-alternator carries a 10-in. disc discharger at its free end. The whole of the high-tension apparatus is enclosed by a wire screen provided with two entrance doors, each of which is fitted with a safety switch, so that any person entering the danger zone automatically disconnects the circuit. The conductors used for leads are strips of copper $1\frac{1}{2}$ in. \times $3/32$ in. separated by ebonite strip $3\frac{1}{2}$ in. \times $\frac{1}{2}$ in. The copper strip is shaped to ensure the minimum length, and all joints are riveted and soldered. The leads from the Bradfield insulators are 20-ampere cord flexible. The disc discharger has 12 sparking studs, corresponding to the 12 poles of the alternator.

The leads from the earth discharger to the receiving cabinet are stout copper wires run through the walls on partition insulators. The receiving cabinet is of special design and fulfils two functions: it shuts out the noise of the running machines, and by means of an earthed screen of wire netting built into its walls it shields the receiving apparatus from inductive disturbance. Two detectors are used, the Marconi magnetic and a crystal set. In order that low-resistance telephones may be used with each detector, a step-down transformer is interposed between the crystal and the telephone.

In carrying out tests of the efficiency of the station it was noticed that stronger signals reached Crookhaven than were received at Fishguard. Good signals were exchanged with Bolt Head, but Niton can only be reached occasionally.

The range westward has been proved up to 1,200 miles, and very considerable distances south have been reached. The efficiency to the west is so marked that power has to be reduced in order to avoid interference with Crookhaven. These results go to prove that there is considerable screening to the east, but in all other directions the range is good. In this connection it is interesting to note that the Land's End station was the first to answer the s.s. *City of Philadelphia's* distress call when she recently went ashore at Rame Head, near Plymouth.

The power plant includes two oil-engines, each capable of developing 10 b.h.p. at a speed of 700 revs. per minute. The continuous-current generators are direct-coupled, have shunt-wound field magnets, and are designed for an output of 5 kw. at 100-140 volts with a speed not exceeding 1,000 revs. per min. The motor-alternator set consists of a continuous-current 100-140-volt compound-wound motor coupled to a single-phase alternator which has a stationary field and a revolving armature designed to give a single-phase current at 300 volts and 200 periods per second, with a total output of 5 kw. The normal current is 18 amperes. The armature and field magnet windings of both the alternator and the motor are protected from surges by guard lamps.

The transformer is of the closed-magnetic-circuit type with independent windings, and the secondary is wound in sections, the whole being insulated and cooled by immersion in oil. It raises the voltage from 300 to 8,700, and the test showed an overall efficiency of 93.7 per cent. The high-tension terminals are mounted on large porcelain insulators and are provided with a safety gap and discharging horns. The gap is adjustable so that the maximum voltage shall not exceed 57,000. Two switchboards are provided; the one in the engine-room controls the continuous-current generator, the charge and discharge of the battery, and the supply to the motor-generator, auxiliary motors, and lighting circuits; the other switchboard is installed in the high-tension room and is designed for controlling the motor-alternator from a remote-control fixed in the operating cabinet.

The starting switch and resistance is of the Bray Markham and Reiss type, and is operated by two tumbler switches, one fixed on the power board and the other in the silence cabinet, so that the operator has full control without leaving his seat. A second field-regulating resistance in series with that on the power board is fitted in the silence cabinet to enable the operator to reduce the amount of power if required.

The equipment of the switchboard in the engine-room includes 3 watt-hour meters; No. 1 records the total units generated, No. 2 the energy used for lighting, and No. 3 that expended on signalling. The transmitting key is joined direct in the primary circuit of the transformer and is provided with a second pair of contacts through which the receiving circuit is made when the key is at rest, and broken when the key is depressed. The battery consists of 52 cells with a maximum discharge of 378 ampere-hours at the 9-hour rate.

DISCUSSION ON "A TWO-RATE TARIFF SYSTEM WITHOUT TIME-OPERATED CONTROL."*

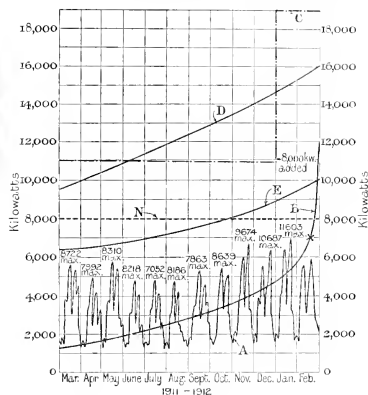

YORKSHIRE LOCAL SECTION, 11TH MARCH, 1914.

Mr. W. E. BURNARD: The object aimed at by the author is obviously to encourage the use for long periods of the small proportion of lamps that the consumer would use if the rate were low enough, and at the same time to obtain the full price during the ordinary dark hours when the load is in the neighbourhood of the maximum. Although it would be rather difficult to explain to the consumer the system in which a low rate per unit is charged for a small consumption and a high rate for a large consumption, I think that there should undoubtedly be a limited field for the device described by the author, and that it will have to some extent the effect of obtaining some revenue that might otherwise be lost. There appear, however, to be two rather serious disadvantages of the author's system, the first being that in common with the maximum-demand and similar systems which give an increased rate on the consumer's periodical demands, it tends to induce economy on the consumer's part, probably several hundred times per year when this is no advantage whatever to the supply authority. The second point is that in common with the telephone and other systems in which the high charge is based upon the lighting consumption, the proposed tariff is not on a very secure foundation, as, owing to the low efficiency of the method of converting electrical energy into light, very great reductions are possible in the future in the consumption of energy for lighting, whilst the same does not apply to anything like the same extent to other electrical apparatus. I think it is reasonable to expect that in a few years' time lighting will cease to be the predominating factor in the cost of electricity supply, and that heating and other uses will take the place now held by the lighting load. Any system that ignores such conditions is bound to give trouble sooner or later as the load factor and the distribution of the load vary from time to time. What is required is a system that automatically adjusts the amount of revenue according to the cost of giving the supply. On page 43 the author states that "the mere granting of a low flat rate for power by many authorities to-day is an admission that the diversity factor is large enough to allow the coincidence of double peaks to be ignored." My opinion is that so far from this coincidence of double peaks being of no importance, it is to-day really the most important factor and is likely to continue to be so for a very long period with the present demand for unprofitable units, that is to say the demand which lasts for so few hours per year that the outlay on the plant required to deal with it is altogether out of proportion to the revenue received.

Apart from this double-peak coincidence, I think that the simplest and most generally satisfactory tariff is one which comprises a simple fixed charge dependent on the character of the service required plus a low rate per unit. The rateable-value system of charging which is so much in vogue at the present time—justified perhaps by its value as a business getter—approximates to this ideal, since,

although the fixed charge is based upon the rateable value of the house, it is recognized that as other uses become more prominent relatively to the lighting load this rateable value will have to be altered. The charge is therefore really based on both the rent of the house and the service demanded, and it will eventually vary more with the character of the service than with the rent or rates. Going back to the question of coincident peaks, the accompanying diagram will, I think, show that the

Mr. Burnard.

importance of this is very much greater than anybody would expect who has not looked somewhat closely into the matter. Curve A, for which I am indebted to Mr. S. E. Fedden, shows the average distribution of the lighting and power load at Sheffield throughout the day for each month of the year 1911. It does not show the maximum variation, but the highest peak observed during each month is marked in figures at the top of each average peak shown in Curve A. By extending this average peak to the maximum and reducing the width so that the curve still encloses the same area, and then adding together all parts of equal height, we get Curve B, which shows the total time per annum during which the load has reached any given value. It should be noted that all these values are taken from ammeter readings, so that these curves represent kilovolt-amperes and not watts. Curve C represents the amount of generating plant installed. As, however, the capital outlay is not confined to the generating plant, the greater proportion of it being due to mains and the distribution system, Curve C hardly corresponds to the capital outlay, which would really more nearly

* Paper by Mr. H. H. Perry (see pp. 42 and 150).

approximate to Curve D. Thus the area enclosed below Curve D shows the total rating of the plant available for the supply, and Curve B the energy actually generated. The difference between the two areas indicates what a large increase in output is possible by improving the load factor and with only a small addition to the capital expenditure. The chief point that I want to bring out, however, is the expensive nature of Curve B above the point marked X (which represents only about 50 hours' use of the plant per annum) due almost entirely to coincident peaks. Supposing that it were possible to control these peaks so that we should be quite certain that with the existing connected load the demand on the supply system would not exceed that represented by the point X, everybody would agree, I suppose, that the plant capacity indicated by Curve E would be sufficient to deal with this load. That shows that the whole of the plant represented by the difference between Curves B and D is required in order to cope with the demand above the point X on Curve B. The difference between Curves D and E is about 5,000 kw., which at £40 per kilowatt (including the generating plant, buildings, mains, and distribution system) represents £200,000, whilst the actual revenue from the current supplied for the period when the demand exceeds the value X is only something like 200,000 units, which at say 2½d. per unit only bring in £2,000. This very unprofitable return could not, of course, be covered by any reasonable increase in the tariff. The best way to deal with this over normal peak load, if feasible, is to get rid of it altogether by obtaining control over the peak load and letting the consumers know when this load is on, so that all unimportant load may be switched off and the load above the point X thereby reduced. By thus keeping down unprofitable plant expenditure obviously a lower charge could be made for the current supplied, with a corresponding increase in the consumption and a better load factor, both of which tend to decrease the cost still further. To prevent repetition of matter already published I would refer any one interested to the discussion on the papers by Mr. A. H. Seabrook* and Mr. W. W. Lackie† and also to an article which I contributed to the *Electrical World*.‡ The only system giving control of the character

proposed over the peak and at present actually in use is that developed by Messrs. Duddell, Dykes, and Handcock. I wish to disclaim, however, any suggestion that this system is in any way the result of suggestions made by myself.

Mr. H. H. PERRY (*in reply*): Mr. Burnand considers that the basis of the system proposed is partially un-sound for two reasons, but I think that the system has at least no greater weakness than there is in those systems hitherto in use; and it must be taken as a maxim that no system can be perfect. If the consumer can be induced to be careful with his supply, it may be taken for granted that he will be a very regular user and unlikely to cause extravagant peaks. I quite agree with Mr. Burnand's view that lighting will cease in a few years' time to be the predominating factor owing to the rapid demand for energy for heating, cooking, and perhaps power for domestic uses. He takes exception to the possibility of double peaks being beneficial in the long run, but if heating and cooking make the headway expected, the peaks due to that load will not be merely double, or two per day, but quadruple; and in this way one must look for a large increase in the load factor, and so fill up many of the gaps shown in his very interesting curves obtained at Sheffield.

The rateable-value system of charging, together with a low rate per unit, is undoubtedly popular, but at its best it is an approximation, and nobody can argue that every consumer is being treated on his merits. It may encourage the very worst consumer whose consumption is low on a high maximum demand, and whose annual bill is altogether too low in proportion. It would seem to be a system which needs a great amount of initial personal adjustment as between the consumer and the supply authority, particularly where different classes of consumers have to be catered for, and it is doubtful whether it readily attracts new business from the small consumer.

It is somewhat difficult to criticize the curves shown and to offer any suggestions as to a suitable tariff to fill up the gap between curves B and C, but it would seem likely that should the lighting load become of secondary importance, the improvement in the load factor must of necessity have become an accomplished fact. At such a stage the price will be very low and the task of selecting a suitable tariff will be made easy—the reversion to a pure flat rate may be the outcome for all-day users.

DISCUSSION ON

"THE SIGNALLING OF A RAPID-TRANSIT RAILWAY."*

NEWCASTLE LOCAL SECTION, 8TH APRIL, 1914.

Mr. E. F. FLEET: This paper contains information that has never been published before in tabular form, although the subject has for many years been considered almost daily by signal engineers. As the paper presupposes certain conditions, and is written to substantiate the occurrence of those conditions, it cannot be criticized. The conditions, however, are those of suburban traffic where all the trains are of practically the same length and run at the same speed. I have been connected with automatic signalling for a considerable time and these problems arose in an acute form about 8 years ago in connection with the automatic signalling on the North-Eastern Railway from Aln to Thirsk. We considered that the overlap should be determined by the traffic conditions. Thus, whilst the lengths considered in the paper are expressed in feet, owing to the different conditions the length of the sections in our case was something like 1,300 yards between signals and the overlap was 400 yards. It was also necessary to consider various speeds from 15 miles per hour up to 60 miles per hour, but the principle was the same as that described in this paper, although the conditions being different we had naturally to deal with the problem somewhat differently. For instance, the author does not refer to a warning signal; he deals with absolute length signalling. That, I am afraid, would not be applicable to the conditions on trunk lines, where the trains may be either a few feet or 400 yards long—or even half a mile long—and we had to do something to meet these conditions. The author mentioned that the overlap was 300 ft., and referred to special overlaps for through trains, but I should like to know what the limit is for through traffic. He also mentioned speed control from the track. I have had considerable experience in the maintenance of track control in connection with the cab-signalling system of Mr. Raven and Mr. Pigg,[†] and I have had to maintain permanent-way ramps for some years. There is of course a great deal of variation owing to the wear and tear of sleepers and owing to various other considerations, so that if speed control is added I am quite sure that it would be impracticable and that a lot of delicate adjustment and tests would be required before it could come into very general use. There is no mention of gradients in the paper because, I take it, of the conditions which the paper sets out to explain. I may say that the system where the signals stand normally in the clear position does not appeal to me: I prefer the old system where the signals stand at danger until the section is cleared. It is a small point to some people, but I think that it is a question of principle and that it should be followed except perhaps where the existing method of block working is entirely dispensed with.

Mr. C. W. PRESCOTT: With reference to the author's remarks on the accumulative effect of delays at stations, I

should like to know if any form of bell or other signal has been used to warn the station staff when a train has exceeded the maximum allowable station stop. This arrangement ought to be fairly simple, and would perhaps check the delays before the margin left between the operating conditions and the theoretical limit of the signalling was exceeded. I was rather surprised that the sighting distance shown on the diagrams is less than the overlap, because I always look upon the overlap as dependent on the emergency braking, and the sighting distance as dependent on the service braking. I notice that the maximum speed taken for the calculations in the paper is 25 miles per hour; this might seem rather low when considered in relation to steam practice and also to express electric trains. It is a rather interesting point that the possible headway is absolutely dependent on the maximum speed with the type of signalling under discussion—that is, with train stops. The distance between two stations is divided up into two overlaps, one sighting distance, and a certain length of time during which the train is running at maximum speed, this length of time being equal to the station stop. There is therefore for a definite spacing of stations an absolutely definite maximum speed which will give unchecked running. If the trains are capable of exceeding this maximum speed they are not being used to the best advantage and energy is being wasted. If they are incapable of attaining this maximum speed, passengers are not being carried as fast as possible. It is a simple matter to plot this relationship as a curve; 25 miles per hour is a suitable maximum where the stations are spaced close together—something of the order of 0·4 mile apart. It is quite probable that in the future when an electrification scheme with stations very close together in the central area and comparatively far apart on outlying lines is being considered, it will be made impossible for the drivers to exceed a certain low maximum speed in the central area, this speed being raised in the outlying area: for instance, for a given set of conditions the maximum speed suitable for a station spacing of 0·4 mile is 30 miles per hour, whereas that for 0·8 mile spacing is 50 miles per hour. I am much interested in what the author says about speed control: it certainly seems as if the ideal system had not yet been developed.

Mr. R. PETERS: What impresses me most in this paper is the graphic method used by the author in arriving at his results. This method may be a commonplace to signal engineers, but to me it appears very ingenious. In connection with the improvement of train timing, the system advocated involves an addition to the number of signals, and consequently an increased risk of drivers mistaking them. It seems to me that cab-signalling will partly solve this problem, probably by means of what may be termed a "wireless" device. It should not be impossible to combine with such a contrivance a form of speed control.

Mr. O. R. WILLIAMS: I take it that this paper deals with services where electric power is employed, and conse-

* Paper by Mr. H. G. Brown (see p. 545).

† J. Pigg. Automatic cab-signalling on locomotives. *Journal I.E.E.*, vol. 40, p. 62, 1908.

quently that, whatever speed is assumed, all the trains would have the same maximum speed, thus justifying the assumptions made. There is one point that I should like to mention in connection with Fig. 3: the resultant delay due to a 10-second stop is shown as 19.45 seconds, which period after the home signal has been passed is sufficient to bring the train into the station section. The time taken for trains to decelerate from, and to accelerate to, a speed of 25 miles per hour is 19.45 seconds, but of course the trains would not enter the platform at such a speed. At some point previous to that the driver of the first train would start to decelerate, and similarly the driver of the second train; therefore I think that the estimate of 19.45 seconds is not strictly accurate when both trains are decelerating in order to stop at the station, and this would seem to have some effect on the resultant delay. Another point is that when working at double the minimum time interval a delay to the first train will not cause a delay to the second train unless such delay is sufficiently long to cause the home signal to go to "danger," which is equivalent to working at something below the minimum time. This again would not delay the train unless train No. 2 was stopped for such a time as to cause it to come within the minimum time again; consequently bunching should only take place with a few trains unless the original delay is considerable.

Mr. H. G. BROWN (*in reply*): The intention of the paper was to explain the principles, and the data given have been taken from railways of the London Underground type. The principles explained can be applied to any railway, being applicable to a line having different data from those given.

Mr. Fleet referred to the necessity of using distant signals. I am strongly of the opinion that, particularly on rapid-transit lines, in practically every instance a repeater or distant signal should be installed to work in conjunction with each stop signal. It is always found in practice that a decrease in the train interval as well as a saving in power is obtained by the addition of repeating signals.

In reference to the normal-clear position for automatic signals, an overwhelming majority of such signals are installed on the normal-clear principle, and when the normal-danger system is preferred for automatic signals the preference is probably due to the precedent established by the normal position of the manually-controlled interlocked signal. The only virtue of a signal is to impart information to the driver of an approaching train. A manually-controlled signal should be normally in the danger position because it is the interpreter of the will of the signalman who is capable of, and must use, selective discretion. The signal is not supposed to indicate the condition of the portion of the line that it governs, but to give

access to that portion of the line when, and only when, the signalman considers it advisable that such access should be given, and it is the will of the signalman that no movement should be made except on his own initiative. An automatic signal should stand normally in the clear position. It interprets the condition of the portion of the line that it governs, and it is not controlled by human agency, being an automatic mechanism and necessarily without discretion. If the section of the line is clear, the signal should indicate that fact; and vice versa. The main arguments against the normal-danger system are as follows: It is illogical, as the signal does not correctly interpret the condition of its section at all times. It costs more to install and maintain, and there is a greater liability of failure, as it requires more instruments and material than its equivalent on the normal-clear system. Any normal-clear system can be changed to a normal-danger system by the addition of apparatus. In the normal-danger system, the circuits must be arranged so that an approaching train sets the signal to the clear position when its section is unoccupied. A normal-danger system therefore becomes a normal-clear system when the traffic increases beyond a certain point, because the signal stands in the clear position an increasing percentage of the time that the section is clear in direct proportion to the increase in the frequency of the trains.

Mr. Prescott asked if it would not be advisable to arrange for a bell to ring when the time allotted for the station stop had expired. As far as I know, this has not been done, and the idea would be worth the consideration of traffic officials.

The sighting distance has been taken as the deceleration distance, which would naturally be the minimum. On railways of the London Underground type it is considered advisable to allow a distance of 600 ft. wherever possible, but the deceleration distance has been given in the paper, as anything beyond this figure is a question of the personal equation of the driver.

Attention has been called to the maximum speed of 25 miles per hour used in the illustrations. While the maximum speed is important, it is not as important as the rate of deceleration and acceleration when the stations are near together. This will be evident when it is remembered that a large proportion of the entire time during which the train is moving is occupied by decelerations and accelerations.

Cab signalling is a very difficult question. Only a few systems now in use are satisfactory, and these are successful because the principles of design are sound, and also because they do not attempt too much. For some time yet cab signalling should be considered as an auxiliary to the existing systems of signalling, and not as a complete system in itself.

COMPARATIVE TESTS ON SINGLE-PHASE ALTERNATING-CURRENT COMMUTATOR MOTORS.

By E. A. RICHARDS, B.Sc.Eng., Graduate, and D. DUNHAM, B.Sc.Eng., Student.

(Paper read before the STUDENTS' SECTION 7th May, 1913.)

The following paper consists mainly of a record of experiments carried out in the laboratories of the City and Guilds Engineering College (London) on alternating-current commutator motors, the object of these tests being to compare the performances of the same machine when running as an Atkinson, Fynn, Latour-Winter-Eichberg, or synchronous motor. The last mentioned is of course a constant-speed machine, and the Atkinson and Fynn motors nearly so, whilst the Latour-Winter-Eichberg motor has a series characteristic.

As in the case of continuous-current motors these machines may be made to have either a series or shunt characteristic. Traction motors are naturally of the series type, and on account of the large demand for this type of motor much work has been done in perfecting them, with the result that they are now established as commercial machines.

Although Mr. Fynn and others have written papers dealing with commercial forms of the alternating-current shunt commutator motor, these motors have only recently come into extended practical use. They are suitable for many classes of work, such as the driving of machines, lifts, etc., where a larger starting torque is required than can be obtained with a single-phase induction motor, and they are particularly valuable in cases where speed regulation is required. For these reasons they should have a wide field of usefulness, in spite of the difficulties which have to be overcome in their design.

With the exception of tests in which the authors assisted Mr. F. Creedy on a motor of his own design, the tests here described were all carried out on a Fynn motor built by the Alioth Company of Basle, and rated at 140 volts 57 amperes at 1,430 r.p.m. The rotor of this machine is an ordinary continuous-current series-wound armature with a commutator of 117 segments. There are also four slip-rings connected to equidistant points in the winding. The commutator carries four sets of brushes displaced 90° electrically from one another. The stator is built up of laminations and carries three distinct windings disposed in slots:—

- (a) A 4-pole partially distributed winding termed in this paper the main or transformer winding, S_1 ;
- (b) A similar but smaller winding displaced half a pole pitch from (a) and termed the auxiliary or starting winding, S_2 ;
- (c) A compensating winding, S_3 , of a few turns only, placed in the same slots as the main winding.

The ends of these windings are brought out to separate terminals, enabling the motor to be connected in various ways, in order to carry out the tests described below.

The motor was first tested as an Atkinson motor, connected as shown in Fig. 1 (a). For simplicity the motor has been considered throughout as a two-pole machine, in

which case the four sets of brushes would be equally spaced round the commutator. The Atkinson motor is not self-starting, and so it is necessary to connect it as a repulsion motor as shown in Fig. 1 (b) to start up, and switch over to the Atkinson connections when running.

At starting, then, the current in the main winding S_1 induces a current in the short-circuit axis AA by transformer action. This secondary current in conjunction with the field due to the winding S_2 produces a torque, the direction of which depends on the direction of connection of S_2 . When the motor is running a back E.M.F. is induced along the AA axis due to the cutting of the lines of the field produced by S_2 by the rotor conductors. This E.M.F. opposes the secondary transformer current and so determines the speed of the motor for any given torque. The repulsion motor has, of course, nearly a series characteristic. The rotor conductors also cut the field due to S_1 , and an E.M.F. is thereby produced at the brushes BB. If these brushes are short-circuited when the motor has attained full speed, a current will flow in the BB axis and produce a field along that axis. The winding S_2 can now be cut out and the motor will continue to run, the motor field being produced by the current in the rotor along the BB axis. In all cases of a field being produced by the rotor, it is important to bear in mind that the axis of the flux coincides with the axis of the brushes, since the magnetic reluctance is practically uniform all round the gap.

The vector diagram of the Atkinson motor is shown in Fig. 1 (c). Starting with the applied voltage V , we have the transformer flux N_1 practically in quadrature with it, and the transformer E.M.F., E_T lagging 90° behind the flux. Due to the rotation of the rotor conductors in this flux we have E_B (the E.M.F. in the BB axis) in phase with N_1 , and causing the current I_B to flow in the B axis. Owing to the high self-induction of the armature along this axis, I_B lags by a large angle behind E_B , and the motor flux N_2 set up by it will be almost in quadrature with E_B . Due to rotation in N_2 we have the back E.M.F., E_A , opposing E_T . The resultant of E_T and E_A is E_R , which is the vectorial sum of 1 R, the drop of pressure due to resistance, and E_s , the inductive drop in the AA axis. The armature current I_A is in phase with 1 R. The resultant of the current I_A and the stator current I_s must be the magnetizing current I_0 which is necessary to produce the flux N_1 along the AA axis; and from the position of the vector I_A the power factor of the stator is necessarily low. It will be seen from the figure that there is a large phase displacement between the armature current I_A and the motor flux N_2 , thus necessitating a large armature current for a small torque and limiting the output of the motor.

The conditions may be somewhat improved by adding self-induction along the BB axis by means of an external choking coil. The effect of this is to make I_B lag still more behind E_B , consequently displacing N_2 still farther

and decreasing the angle between the motor flux N_2 and the armature current I_A . It will be noticed also that by displacing N_2 still further back E_A is also moved, and this brings I_A still more into phase with N_2 . By adding inductance in this manner I_B is necessarily reduced, and consequently the field N_2 is weakened and the speed increased. This method can be used to a limited extent for speed control.

Fig. 2 shows the curves of performance of this motor both with and without added self-induction in the BB axis. It will be observed that the output is small, the maximum being about 3 h.p. without, and 4 h.p. with, additional self-induction. The efficiency in the first case only reaches 51 per cent, and the power factor 0.5. These are increased to 58 per cent and 0.62 respectively by adding self-induction. It will be noticed that the current in the AA axis reaches about 100 amperes in each case, and that it is increasing very rapidly. It is obvious that

and flux should be in phase at full load although the power factor is thereby somewhat reduced. This point is further discussed in connection with the curves of performance of the motor. The compensating E.M.F. is in phase with E_A , and can therefore be induced directly by transformer action from the main stator winding. A winding, S_2 , consisting of a few turns is placed in the same slots as the main winding, and is connected across the brushes BB in place of the short-circuit used in the Atkinson connection.

The connections of this motor are shown in Fig. 3. At starting the windings S_1 and S_2 are connected in series by means of the switch H, the BB brushes being open-circuited. The machine starts up as a repulsion motor as previously explained. When up to speed the resistance R in the BB circuit is cut out, and at the same time the switch H is moved over the stops, cutting out the winding S_2 in three steps. To reverse the direction of

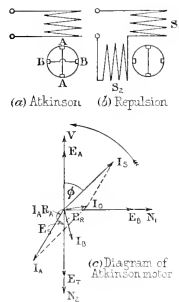

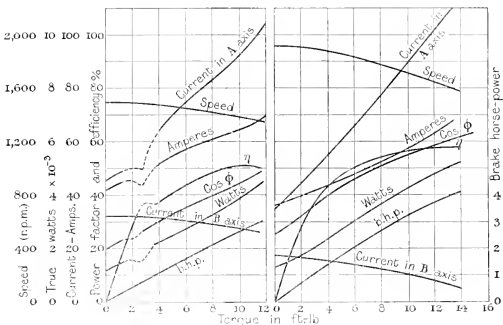

FIG. 1.

(1) Atkinson Motor.

(2) Atkinson Motor, with extra self-induction in BB axis.

in this form the motor cannot be considered as a commercial machine. The performance of the motor is, however, greatly improved by the addition of the compensating device invented by Mr. Fynn, and described by him in a paper read before the Institution in 1906.²

The method adopted is to add a small E.M.F., E_C , in the BB axis in quadrature with E_B . Referring to Fig. 3, the result is to shift E_B to E_B' . The consequent displacement of N_2 and E_A causes N_2 to lag in phase behind I_A , and since the stator current I_A must always be determined by the resultant of I_A and I_B , it is now brought nearly into phase with the applied voltage. By suitably choosing the amount of compensation the power factor may be increased to unity at any particular load. This result is only possible, however, if there is a phase displacement between the flux N_2 and the current I_A ; and as this current practically limits the output of the motor it is very desirable that this current

rotation, the connections to S_2 , and also to the compensating winding S_1 , are reversed.

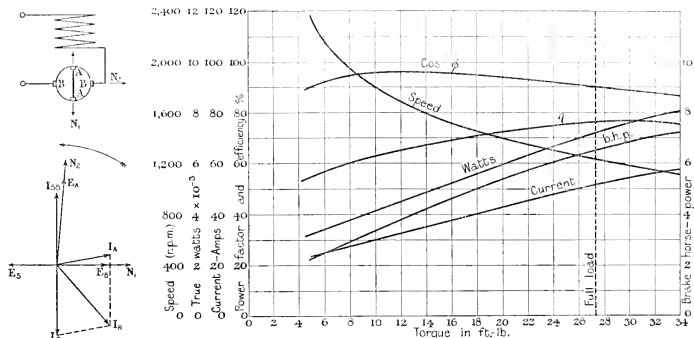

Fig. 4 gives the result of a constant-voltage test on the motor thus connected, and it illustrates the striking improvement effected by the use of the compensating winding; for the same armature current the torque is doubled. The full-load efficiency has risen to 75 per cent, and the output of the motor is correspondingly increased. At no-load the stator current leads on the voltage, but as the load increases the phase displacement becomes less, the power factor being nearly unity at about half full load and then decreasing, although not very rapidly. As explained above, the power factor at any load depends entirely on the magnitude of the compensating E.M.F. and not on the dispersion coefficient as in the ordinary induction motor. Complete compensation can, however, only be attained at the expense of increased copper loss in the rotor. It will be observed that the current in the BB axis and therefore the motor flux N_2 are nearly

* V. F. Fynn. A new single-phase commutator motor. *Journal I.E.E.*, vol. 50, p. 324, 1906.

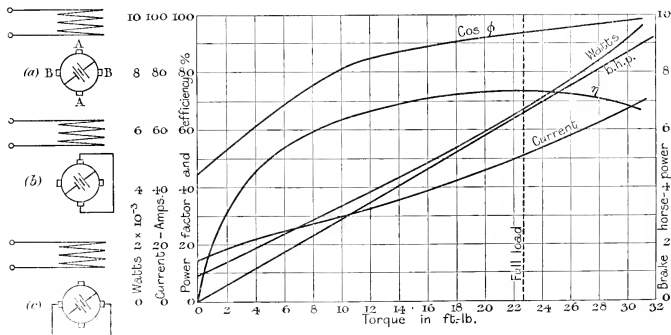

corresponds to the B B axis of the Atkinson motor, and raises the power factor to unity at some particular load. On account of the magnetizing current of the transformer, the power factor of the whole motor is somewhat lower than unity, reaching about 0.91 at full load. The motor having been designed especially for lift work has a

65 amperes. This current can be somewhat reduced by varying the amount of compensation, but the power factor suffers in consequence. In fact, by adjustment of the compensation the motor may be given any characteristic intermediate between shunt and series.

For the sake of comparison the original Fynn motor was

FIGS. 7 AND 8.—Latour-Winter-Eichberg Motor.

FIGS. 9 AND 10.—Synchronous Motor.

very high starting torque—starting being effected by switching the motor straight on to the mains, thus simplifying the external connections.

The performance curves of this motor are shown in Fig. 6. The efficiency at full load is about 74 per cent and the power factor 0.91. The starting torque at 220 volts—the working voltage of the motor—is about 75 lb.-ft., $2\frac{1}{2}$ times full-load torque, with a current of

next tested as a Latour-Winter-Eichberg motor. The connections and vector diagram are shown in Fig. 7. The latter is taken from a paper read by Messrs. Page and Scott before the Students' Section,³ in which this motor is fully dealt with. The authors therefore do not

* G. W. P. PAGE and G. J. SCOTT. Single-phase commutator motors, especially the Latour-Winter-Eichberg type. *Journal I.E.E.*, vol. 47, p. 779, 1911.

propose to deal here with this type in detail. The performance curves are given in Fig. 8. This motor having a series characteristic the speed decreases rapidly as the load increases. At about synchronous speed the motor has its maximum power factor of 0.97. The efficiency at full load reaches 76 per cent at a power factor of 0.90.

It has been previously mentioned that the motor is provided with slip-rings connected to equidistant points

as the slip-ring connections passed under the brushes, a choking coil was connected in series with the continuous-current source of supply.

It was hoped that by running the machine as a synchronous motor a greater efficiency would be obtained, as the iron losses are a minimum at synchronous speed; but owing to the necessity for short-circuiting the A A axis, and the consequent heavy I²R losses in the rotor, no improve-

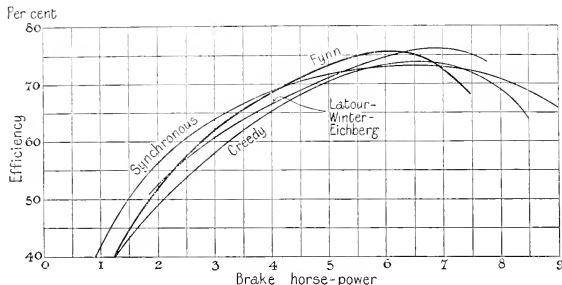

FIG. 11.—Efficiencies.

in the armature. Brushes were fitted to two rings connected to diametrically opposite points, and the machine was run as a synchronous motor, continuous current being led into the rotor by means of these rings to form the field-magnet system. Connections were first made as shown in Fig. 9 (a). Starting was effected as a repulsion motor, and when synchronous speed was reached the

ment was effected in this direction. The experiment has some interest, however, as an example of a self-starting synchronous motor. The power factor can of course be varied at will by altering the amount of the continuous-current excitation. The motor was also tried with the B B axis short-circuited, the idea being that this would act as a compensating winding and prevent the phase-swinging of

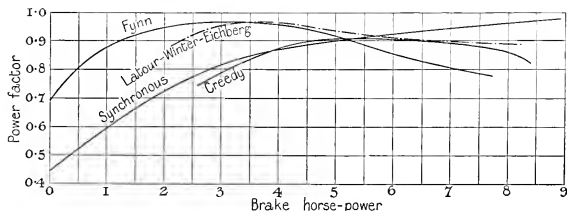

FIG. 12.—Power Factors.

continuous current was switched on to the rotor and the auxiliary winding cut out through a resistance. It was found to be impossible to load the motor to any extent without pulling it out of step owing to the high reactance of the stator. The A A axis was therefore short-circuited as shown in Fig. 9 (b) to reduce the stator impedance. In this way satisfactory running was obtained up to well above full-load output. In order to prevent any ill-effects from the short-circuiting of the continuous-current excita-

tion the flux. This was unsatisfactory as the motor pulled out of step in the same way as when there was no short-circuit. Excessive sparking prevented the running of the motor with both axes short-circuited.

The performance curves of the synchronous motor with the A A axis short-circuited are shown in Fig. 10. To obtain the necessary torque at heavy loads the motor was over-excited and so a leading power factor was obtained, viz. 0.45 at no load, rising to 0.93 at full load and nearly

unity at 40 per cent overload. The efficiency reached 73 per cent at full load.

In Fig. 11 the efficiencies of the Fynn, Latour-Winter-Eichberg, synchronous, and Creedy motors are shown together, plotted with the brake horse-power as abscissa. It will be seen that the efficiencies in each case are nearly the same, varying from 73 per cent to 75 per cent at full load, which figures compare fairly favourably with those of single-phase induction motors of the same horse-power. Efficiencies of about 85 per cent are obtained with Fynn and Creedy motors of 30 to 50 h.p.

The power factors are compared in the same way in Fig. 12 and range from 0.85 to 0.92 at full load, the figures for the Fynn and Latour-Winter-Eichberg motors being somewhat higher at about half load. The synchronous motor, as explained before, was taking a leading current, as was also undoubtedly the case with the Fynn and Latour-Winter-Eichberg motors at light loads. Of course the synchronous motor could be adjusted to give nearly unity power factor at all loads, the curve given referring

The losses occurring in the motor may be classified as follows:—(a) Resistance losses in stator and rotor; (b) brush contact and resistance losses; (c) friction and windage losses; (d) eddy current and hysteresis losses, including under the former title the losses due to currents circulating in the coils short-circuited under the brushes.

The losses under heading (a) merely resolve themselves into accurate determinations of the resistances of the various circuits and the currents flowing in them, and therefore require no special consideration.

(b) The brush losses were experimentally determined in the following manner:—The Fynn machine was driven by means of a belt from an adjustable-speed continuous-current motor. A pair of brushes on the same spindle were used for the test, one brush-holder being in contact with the spindle and the other insulated from it. A measured continuous current was led in at one brush, along the commutator segments, and out at the other brush, and the drop of potential in the two brushes in

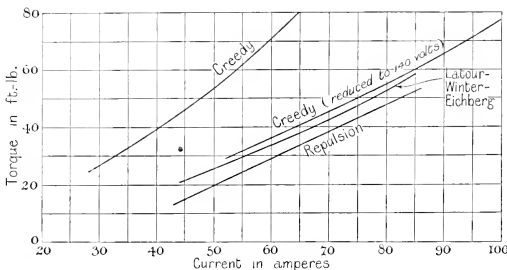

FIG. 13.—Starting Torques.

only to the case where the excitation is kept constant throughout.

The starting performances of the Fynn, Latour-Winter-Eichberg, and Creedy motors are shown in Fig. 13, the Fynn motor starting as a plain repulsion motor. The Creedy motor being a 220-volt machine, the equivalent currents at a pressure of 140 volts are plotted in this case. The starting torque is plotted with the values of the current as abscissa. It will be seen that with the Latour-Winter-Eichberg connection a considerably higher torque is obtained for the same current than with the repulsion-motor connections. This is merely a question of the relative strengths of the two flux components in the repulsion motor, and, of course, leakage is less in the Latour-Winter-Eichberg machine as the field is produced directly by the rotor. The latter gives twice full-load torque with about $\frac{1}{3}$ times full-load current. The Creedy motor gives about $\frac{2}{3}$ times full-load torque with twice full-load current.

Experiments were carried out to determine the proportion of the various losses in the Fynn motor when connected according to the different methods described.

series was measured with a voltmeter. In this way a series of readings was taken at various speeds for a number of constant values of the current. As the segments pass under the brushes the resistance varies, so that the current as measured on an oscillograph would appear like a continuous current with a high-frequency alternating current superposed on it, and the voltage would follow the same variations. Moving-coil instruments read the average values of the current and voltage, and therefore the product differs from the true power. To eliminate this source of error a choking coil was connected in series with the continuous-current supply, thus damping out the high-frequency oscillations in the current. The curves showing the brush loss are given in Fig. 14; and from these curves the losses per pair of brushes at any required speed and current can be read off. The losses increase very rapidly at high speeds, probably owing to the increase of the contact-resistance due to mechanical vibration.

(c) To determine the friction and windage losses a continuous-current motor was calibrated for various speeds and was used to drive the Fynn motor by means of a light canvas belt. Readings were taken of the input

to the motor when driving the Fynn motor at various speeds, and the difference between the power under these conditions and that required to drive the continuous-current motor light gives the total windage and friction losses fairly accurately. Brush friction was also separated by taking readings with and without the brushes. The friction loss curves are shown in Fig. 15.

(d) The exact determination of the separate components of the iron loss in these motors is extremely difficult, as

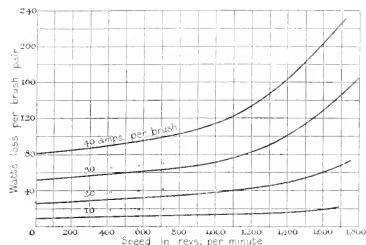

FIG. 14.—Brush Contact and Resistance Losses.

there are so many factors to be considered. With the Atkinson or Fynn connections there will be:—(1) Eddy current and hysteresis losses along the AA axis due to the transformer flux N_1 (with a constant applied voltage the stator loss due to this flux will be constant, but the rotor loss depends on the speed). (2) Similar losses along the BB axis caused by the motor flux N_2 (these losses are a function of the speed). (3) Losses in the rotor caused by

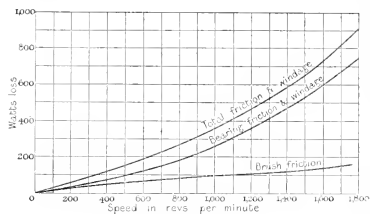

FIG. 15.—Friction and Windage Losses.

the cutting of these fluxes at all speeds except synchronous speed. The fluxes N_1 and N_2 being nearly at right angles in time relation as well as in space, may be considered as forming a rotating field, which will be elliptical except at synchronous speed. At the latter speed the two fluxes are practically equal, and the rotating field will therefore be circular. Now this field always rotates at the speed corresponding to the supply frequency, and consequently if the rotor is running below synchronism there will be a hysteric drag in the direction of rotation, whilst above

that speed this torque is reversed. The rotor iron losses depend on the relative speed of the rotor and the rotating field, so that at synchronous speed they should be nearly zero. In addition to the above there are also the pulsation losses in the stator and rotor teeth, so that it will be seen that an accurate separation of the losses would be exceedingly difficult. For comparative purposes it will be sufficient if the total iron losses are known at any speed.

In order to determine these losses, the motor was driven as in the friction and windage test, and the power supplied to the driving motor was measured. An alternating current at 50 \sim was led into the AA axis of the Fynn rotor through the current coil of a wattmeter W_1 . The pressure coil of this instrument was connected to the terminals of the stator winding S_1 on this axis, and the current in this axis was maintained constant at a fixed value for each test. Under these conditions the wattmeter reads the power supplied minus the copper losses in the AA axis, for the voltage differs in phase by 90° from the flux, since it is induced by the change of the latter.

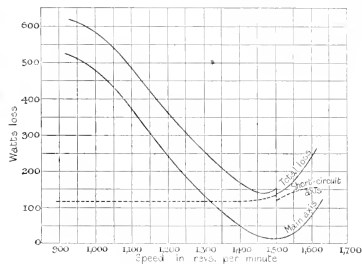

FIG. 16.—Iron Losses.

If the flux were in phase with the current the wattmeter reading would therefore be zero, but since the iron losses cause the flux to lag behind the current the wattmeter measures these losses. The readings have of course to be multiplied by the ratio of the number of secondary to primary turns. It was verified experimentally that the circulating currents in the short-circuited coils also alter the phase of the flux, so that these losses are also measured by the wattmeter. In a similar way the wattmeter W_2 measures the losses along the BB axis. The driving motor supplies the power necessary to overcome the resistance and iron losses in the BB axis, and also the pulsation losses.

The results of these tests are shown in Fig. 16. The total loss is taken as the sum of W_1 and W_2 . As a check, the total power supplied to the Fynn motor, i.e. the reading of W_1 and the input to the driving motor above that required to drive the Fynn machine unexcited, must be equal to the total iron losses and the resistance loss in the BB axis. The values obtained in this way were found to agree well with those obtained by the first method. At constant voltage the stator iron loss along the AA axis is practically constant, whilst in the BB axis it increases

with the speed, since the flux in this axis depends on the speed. The rotor losses, however, are practically zero at synchronous speed, but increase very rapidly on either side of this speed. This is due to the fact that the rotor losses are largely due to the circulating currents in the short-circuited coils, and therefore for constant density vary as the square of the frequency, the latter being the difference between the synchronous speed and the actual speed.

The accompanying table shows the actual losses in the

available for the tests, and this makes the losses somewhat higher than they would otherwise have been. Friction and windage account for about 40 per cent of the losses. The brush friction forms about one-third of the total friction and windage loss in each case.

Single-phase commutator motors may be put to practically the same uses as small continuous-current motors, their only serious rival for small outputs being the single-phase induction motor. Their lower efficiency and higher cost are somewhat of a disadvantage, but their high

various circuits, etc., of the motor when running as an Atkinson, Fynn, Latour-Winter-Eichberg, or synchronous motor, and also the separate losses as a percentage of the total losses in each case. Except for the Atkinson connection, in which the maximum output was 3 b.h.p., these are calculated for an output of 6 b.h.p., which is about the normal full load of the motor. In the last three cases it is interesting to observe that the efficiencies are nearly the same, although the losses are made up in rather different ways. In all cases the brush losses form a very considerable proportion of the total, owing to the heavy rotor currents and high speed. The motor should have four brushes per spindle on the AA axis, but only three were

starting torque gives them a decided advantage for crane and lift work and for driving machinery where high starting torques are required, and they are being manufactured in increasing numbers for these purposes. They are practically the only single-phase motors which can be used for traction work, the plain series type and the Latour-Winter-Eichberg being favoured for this use.

Another great advantage of this type of motor is that it lends itself readily to speed regulation, the speed not being practically restricted to synchronism as is the case with the induction motor. There are several methods of varying the speed of these motors, one of them being to connect an inductance in circuit with the BB axis. The

effect of this is to weaken the motor field, and the machine must therefore run faster in order that the back E.M.F. due to rotation in this flux may attain a sufficient value to restore the equilibrium of E.M.F.'s in the rotor. This method is illustrated in the second test on the Atkinson motor, where the additional inductance in the B B axis caused the speed to rise from 1,500 to 1,900 r.p.m. A resistance cannot be used for this purpose as the current in the B B axis must lag by nearly 90° behind the voltage for satisfactory working, and any additional resistance would naturally decrease this angle. Another method is to supply an extra voltage to the A A axis either by means of a tapping on the stator winding or an auxiliary transformer. This method is analogous to increasing the voltage applied to the armature of a continuous-current motor. A third method is to place an extra coil on the B B axis, connected in series with the brushes on this axis, the coil being connected so that the flux produced by it opposes the motor flux, the effect being similar to that produced by the first method. All these devices tend to raise the speed above synchronism and have been used in practice with good results, but it is more difficult to lower the speed. Any departure from synchronous speed, however, increases the losses in the rotor as the circulating currents and iron losses increase rapidly.

Among the chief disadvantages of these commutator motors are their higher initial and running costs—the commutator of course requiring a certain amount of attention—and their liability to sparking troubles. Sparking on the Fynn motor was noticeable at starting and at heavy loads, probably owing to the fact that soft graphite brushes are used, which although reducing the brush friction and contact losses tend to increase the circulating currents and the amount of sparking; but under normal loads the machine was as sparkless as the average continuous-current motor. The Creedy motor, provided with hard carbon brushes, ran sparklessly at all loads, starting under twice full-load torque with no sign of sparking.

Since the experiments described were made, the authors have assisted in testing a Creedy motor with a variable-speed shunt characteristic, the range of speed being from 600 to 900 r.p.m. This motor is one of a batch designed for the driving of printing presses, but considerations of time prevent the inclusion of the results in this paper.

In conclusion the authors desire to express their thanks to Professor T. Mather of the City and Guilds College for permission to carry out the tests in the laboratories of the College, and to Mr. Creedy for allowing them to publish the results of the tests on his motors.

APPENDIX.

DETAILS OF CONSTRUCTION, ETC., OF FYNN SINGLE-PHASE COMMUTATOR MOTOR, 140 VOLTS, 57 AMPERES, 50 \sim , 1,430 R.P.M.

Rotor.

4-pole series-wound. Number of slots = 39.
 Number of segments = 117. Six conductors per slot.
 Number of conductors = 234. Size of conductors = 0.15×1 cm.
 Circumference of rotor = 81 cm. Diameter = 25.8 cm.
 Axial length = 12.8 cm.
 Laminations per cm. = 21.
 Diameter of commutator = 19.3 cm.
 Size of slots = 1×2.75 cm.
 Opening of slots = 0.3 cm.
 Gap length = 0.1 cm.

Stator.

Bore = 26 cm. External diameter = 42 cm.
 Number of stator slots = 36.
 Size of slots = 1.7×2.3 cm.
 Slot opening = 0.36 cm.
 Axial length = 12.8 cm.
 Brushes 15.3 cm. apart, measured on arc.

Resistances of windings.

Main stator winding S_1 = 0.103 ohm.
 Auxiliary stator winding S_2 = 0.084 ohm.
 Compensating stator winding S_3 = 0.022 ohm.
 Armature under brushes = 0.025 ohm.
 Impedance of B B axis = 2.26 ohm, with a current of 35 amps.
 Power factor of B B axis = 0.101, with a current of 35 amps.

Ratios of turns.

Main winding = 10
 Compensating winding = 1
 Main winding = 1.9
 Rotor along A A axis = 1
 Auxiliary winding = 1.04
 Rotor along B B axis = 1

THE ELECTRICAL EQUIPMENT OF COLLIERIES.

By H. S. RIPLEY, Student.

(Abstract of Paper read before the NEWCASTLE STUDENTS' SECTION 5th January, 1914.)

In the light of previous experience the tendency of present-day practice is towards the adoption of the 3-phase high-tension system as being more economical in working and, with proper precautions, safer and more efficient than a low-tension system.

The author proposes to consider briefly the various branches of the subject under their respective headings.

SWITCHGEAR.

The introduction of electricity into coal mines presents three dangers, namely:—

- (a) Danger of shock to persons through contact with "live" metal.
- (b) Danger of injury to persons and property through the ignition of explosive gases.
- (c) Danger of fire.

The recent colliery disasters seem to show that fire involves the greatest danger to human life. To reduce this to a minimum, all gear should where necessary be explosion-proof and fireproof, and in addition to this, automatic means should be provided for immediately cutting off the supply should a leak occur.

The danger of shock to persons through contact with "live" metal may be eliminated by efficiently insulating all current-carrying conductors, and also protecting the same with a metallic covering efficiently earthed.

With the new Home Office Rules now in force it is perhaps not very easy to go astray in regard to switchgear, but it will not be out of place to consider the more important rules which should govern the choice of any particular make of gear:—

- (1) There should be a minimum amount of cleaning necessary to maintain the gear in good order.
- (2) The insulation should be capable of withstanding any abnormal pressure that is likely to arise.
- (3) All circuits should be broken under oil.
- (4) The switch should be of substantial construction.
- (5) All conductors and contact areas should be of ample current-carrying capacity, and all joints and terminals should be electrically and mechanically sound.

Now the type of gear which best meets the above requirements is the totally enclosed or ironclad type. In this apparatus all the live conductors are enclosed in flame-proof compartments. Flame-proof does not necessarily mean gas-tight. As a matter of fact the joints between the different covers are plain metal to metal, the theory being that should an explosion occur inside the casing the flame becomes effectively cooled by passing through the minute openings left by the machine marks on the face of the joint. The most essential point as regards this switchgear is that it shall be of extremely substantial construction, as the treatment which it will receive in

erection and afterwards in operation will be most severe. Provision should be made for completely isolating and locking the switch from the busbars, in order to obviate the danger of its being accidentally closed whilst men are working on that section. The cases containing parts which have to be removed for adjustment or inspection should be so interlocked as to prevent their being removed whilst the parts inside are "live." This point cannot be too strongly emphasized, as fatal accidents have occurred due to its being neglected.

All switches should be fitted with a "free" handle attachment in order that the trip gear may operate irrespective of the handle being held in the closed position, in case the switch should be closed on a heavy overload or short-circuit. Instruments should be avoided as far as possible, especially where these entail the use of potential transformers. An ammeter, preferably of the straight-through type on panels controlling individual motors or transformers, is all that is really required.

CABLES.

Cables have now reached a high degree of perfection, and if properly installed and given a reasonable amount of attention they are very safe and reliable. For 3-phase work all main transmission cables should be of the 3-core armoured type. Of these there are several varieties, but, generally speaking, the most suitable is the paper-insulated and lead-covered. It must be mentioned, however, that on account of the absorbent nature of the paper insulation this type of cable requires very careful handling by cable jointers in order to ensure a satisfactory installation.

Rubber-insulated cables are out of the question on account of their cost.

Bitumen-sheathed cables should be used where lead-covered cables would be unsuitable owing to the presence of impurities in the water.

With regard to the lowering of shaft cables, although in reality a very simple matter this is liable to have disastrous results if not carried out in the proper manner. There are three safe methods of procedure:—

- (a) If the shaft is sufficiently large the cable drum may be slung under the cage and the cable clamped up as the cage is slowly lowered.
- (b) The drum of cable may be mounted about 100 yards from the mouth of the shaft and the cable lowered in several bights by means of a locomotive. It is important to note that a substantial clamp and chain are required when this method is adopted.
- (c) The cable may be lowered by lashing it at frequent intervals to a steam crab rope. The crab engine should of course have good brakes.

Immediately after the cable has been lowered, the permanent clamps should be fitted. These may be made

of any hard wood, and should have sloping roofs in order to shed the water. With regard to the method of securing the cable in the shaft, the cable is usually clamped to the inside of the buntings, as this position affords the greatest protection from damage. Another good method is to secure the cable to old winding ropes, if these are available, and to have these ropes suspended in the shaft and securely fastened to the headgear. This method facilitates the lowering and raising of the cable in case of a fault. As soon as possible after erection both the cable and the clamps should be liberally treated with Stockholm tar.

Wherever possible, inbye cables should be taken in the main intake airways, and should be slung or clamped in a position to afford the greatest security from damage. They should always be fixed on the lower side of girders, and never between the girder and the roof. Where there is a danger of a fall of stone, the cables should be slung on flexible suspenders in order that they may break away readily should a fall occur.

EARTHING.

The most efficient way of safeguarding against persons receiving shocks is, as mentioned previously, to cover all "live" conductors with an earthed metallic covering.

As to the method of obtaining an efficient earth:—Two earth-plates, approximately 3 ft. square and 30 ft. apart, should be sunk at the surface and placed vertically in the ground at a depth of about 6 ft., being well packed on all sides with crushed coke. The plate selected should be as wet as possible. Should the ground be of a very dry nature a wrought-iron pipe should be buried alongside the plate in order that the latter may be occasionally flushed with water. Great care must be taken to ensure a mechanically sound connection to the earth-plate; and brass, not iron, bolts should be used. Too much stress cannot be laid on the importance of having a sound mechanical earth connection at the surface, but in addition to this a further earth-plate should be sunk at the extreme end of the cables' inbye, the connection being securely clamped to the armouring. This tends to ensure the whole of the armouring being at earth potential irrespective of the condition of the intervening ground. Where possible, all motor and controller frames, etc., should be earthed directly on to the armouring of the cable, and the practice of earthing pieces of apparatus in series should be avoided.

A rather interesting comparison between the combined conductivity of the lead sheath and double armouring and the conductivity of the cores, is given below. These figures

Cable	Equivalent Conductivity of Lead and Armouring. Copper = 1
0.025 sq. in. 3-core, 2,875 volts	2.6
0.05 " " " "	1.5
0.1 " " " "	0.8

were obtained from samples of cable recently supplied to a local colliery, and they may be taken as being approximately correct for all makes of cable.

PROTECTIVE GEAR.

On a completely insulated system complete protection can be obtained by having tripping devices in two phases only, as any fault current or overload passing through the third phase must return through the others and therefore through the trip coil. When this system of protection is used it is necessary to install earth detectors in order to indicate at all times the state of the insulation. On low-tension circuits an earth detector consists of a milliammeter connected in series with a high resistance between the line and earth. On 3-phase systems the resistances are star-connected and the earth detector is inserted between the middle point and earth. The scale is usually calibrated to indicate the insulation resistance in ohms, together with the amount of current flowing to earth. On high-tension circuits it is necessary to use a static earth detector. This consists of a differential static voltmeter, the fixed vanes of which are connected to two phases and the movable parts connected to earth. For 3-phase systems two instruments are required, and are usually enclosed in one case. The scales are arranged with the zero mark in the centre; and with no fault on the mains the needles hang vertically. Should a fault occur on one phase, the needle is deflected to the left or right, owing to its being repelled from one or other of the metal vanes.

With the neutral point of the system insulated, it is possible to keep the plant running with a leakage on one phase. It is in this that the danger lies, as although the earth detector may indicate that the insulation is approaching a dangerous condition, there is always the risk of the warning being neglected until the apparatus finally breaks down, with perhaps serious consequences.

On high-tension circuits with the neutral point earthed it is possible by the use of current transformers to obtain independent control of overloads and earths. The method consists of inserting a sensitive relay or trip coil in the return circuit to the three current-transformer secondaries. This relay or trip coil will then operate on all faults to earth. The overload protection may consist of series trip coils in two phases, or a time-limit overload protection worked from the current transformers. A drawback to the use of the sensitive relay is that it requires a separate source of supply to energize the trip coil of the switch. This entails the use of potential transformers, which are by no means desirable in mining switchgear. The alternative, of course, is to allow the actual current induced by a fault to earth to operate directly on the trip coil of the switch. Owing to the fact that quite an appreciable amount of energy is required to trip the switch, the setting will be less sensitive.

With regard to overload protection, series trip coils should be used whenever possible, as they are very simple in operation and give very little trouble. They are now fitted by several manufacturers for voltages up to 3,000, and are usually encased in the hood of the switch. They are generally calibrated between normal load and twice full-load. Should a time-limit device be required, this can be arranged by the use of oil dash-pots. No-volt releases should be avoided. They are very apt to operate on momentary fluctuations in the pressure, causing unnecessary trouble owing to switches tripping at an inopportune moment. Should the pressure decrease to any great extent and suddenly return to its normal value,

the overload gear will be found sufficient to protect the plant from any damage.

MOTORS AND CONTROLLERS.

The ideal motor for underground use would seem to be the squirrel-cage type. Unfortunately, however, most of the operations requiring large power also require a large torque at starting, and for these the squirrel-cage motor is unsuitable. However, a properly designed slip-ring motor usually gives little trouble, and assuming that it is suitably housed and is given a reasonable amount of attention, it is a sound piece of apparatus.

Probably one of the most important points in regard to motors is the bearings, and special attention should be given to these. Preferably they should be of the self-aligning type, with ring lubrication. The more important point, however, is their size, and no motor should be accepted with bearings smaller than $2\frac{1}{2}$ times the diameter of the shaft.

Starting and controlling devices for large motors require to be of very sound mechanical construction. The liquid type is undoubtedly the most suitable, both as regards first cost and operation. Uniform acceleration is obtained, and also an indefinite number of speeds are available between maximum and minimum limits. Several excellent totally enclosed starting switches are now on the market, and as long as attention is given to mechanical details it is not possible to go far wrong.

Controllers for haulages and winders are also made of the liquid type. As a rule the stator reversing switches are fixed on the end of the controller, and the mechanism is such that the reversing switches are interlocked with the rotor control gear and operated from the same shaft. In the smaller sizes the electrodes are operated directly from the driver's lever, but in the larger sizes the masses are too great for hand operation and the design is somewhat different. The apparatus usually consists of two tanks mounted one above the other, the upper tank containing three stationary electrodes and a movable sluice gate, and the lower one the supply of electrolyte. A small motor-driven centrifugal pump raises the electrolyte from the lower tank into the upper, and with the sluice gate in its lowest position the electrolyte immediately returns to the lower tank. When, however, the sluice gate is raised, the liquid is retained in the upper tank and gradually submerges the electrodes, thereby diminishing the resistance between the slip-rings of the motor. It will be seen that as the pump is delivering a constant quantity of water a certain maximum acceleration of the motor cannot be exceeded. It can, however, be adjusted by placing a stop valve in the delivery pipe of the pump and regulating the quantity of water pumped.

LIGHTING.

All underground lighting should preferably be at pressures below 125 volts, as this obviates the necessity of earthing lampholders and fittings. The high pressure may be stepped down directly to the lighting pressure, or if medium pressure is required for small motors an auto-transformer will be suitable for further reducing the pressure. It is essential that one pole of the secondary winding should be earthed in order to avoid the possibility of the lighting wiring becoming charged with a high

pressure, owing to the failure of the insulation between the primary and secondary windings of the transformer.

COAL CUTTING.

The practice of working coal by machinery has grown and will continue to grow more important as time advances, owing to the fact that most of the big coal seams in this country are becoming exhausted, with the result that the thinner seams, in which it is difficult for men to work, are by necessity having to be worked.

Coal-cutters may be driven either by compressed air or by electric motors, but of the two methods motor driving is better adapted for the purpose. The efficiency of compressed-air transmission is low, being from 20 to 25 per cent as against 65 to 75 per cent with electric transmission. Another important factor is the small space required for a motor compared with that required for a compressed-air machine of the same power. Against this, of course, must be put the additional risk attached to the use of electricity at the coal face. Happily, however, suitable gear has been developed, which has reduced this danger to a minimum.

High pressure is, of course, out of the question and it is necessary to install oil-immersed transformers in buildings as near the coal face as possible, there stepping down to medium pressure. From these places the current is transmitted by 3-core armoured cables to a gate-end box, which is situated at the entrance to the seam that is being worked. This box is of flame-proof construction and contains a 3-pole oil switch fitted with fuses or overload coils. The construction of the box is such that it is impossible to remove the cover until the switch is open. From here the current is transmitted by a flexible trailing cable to the starting switch of the motor. Trailing cables are as a rule of the 4-core type, one core of which is used as an earth conductor. Several varieties of trailing cables are on the market, some insulated with rubber and sheathed with bitumen, and others with a very durable quality of rubber known as "cab-type sheathing."

A 4-pin plug connects the trailing cable to the gate-end box and the motor, the earth pin being internally connected to the framework of the box and the motor. An interlocking arrangement is fixed by which the plug cannot be engaged or withdrawn whilst the gate-end switch is closed, also the pins are so constructed as to make it impossible accidentally to push the earth contact into a live socket.

As to the coal-cutter motor itself, this is of the totally enclosed type and drives the cutter through gearing. Motors up to about 30 h.p. are usually of the squirrel-cage type and are controlled by compensators. For larger powers motors with wound rotors are used, and are controlled by rotor resistances of the grid type.

WINDING.

The application of electric power to winding has up to recent years been limited, probably owing to the fact that very expensive and economical steam winders are installed at many collieries, and that the advantages of electric winding over steam winding have not been sufficiently understood to bring about a change. The development of power companies that can supply electrical energy in bulk at very reasonable rates has, however, been

the means of bringing about several changes in different parts of the country, with very gratifying results.

A correct comparison of the advantages of electric over steam winding depends on the various factors and circumstances affecting each case, and the author regrets that the time at his disposal is too short to go into these very fully. It may be said, however, that the main advantages of electric winding are:—

- (1) Ability to run odd trips at any part of the day or night without the necessity of warming up cylinders, etc.
- (2) More even turning moment.
- (3) Regenerative braking possible.
- (4) Simpler and more economical control.

The author proposes to describe briefly the more important systems of winding now in use.

DIRECT-COUPLED SYSTEM.

The first system consists of a 3-phase induction motor, direct coupled or geared to the drum and controlled by switches and resistances in the stator and rotor circuits of the motor. The controller is usually of the liquid type described earlier in this paper. A geared winder has the advantage of allowing a higher-speed motor to be used, which is an important point where the power factor and the first cost of plant are concerned.

The great advantage of this system of winding is its simplicity and also its low first cost. The overall efficiency is also somewhat higher than that of other systems. Against this it may be said that the peak load caused by the starting of large winders of this description only permits them to be connected to systems with plenty of reserve plant; also, the control being effected by varying the rotor resistance entails considerable rheostatic losses.

WESTINGHOUSE CONVERTER EQUALIZER SYSTEM.

This system has been developed by the above company for the purpose of reducing the heavy current taken from the mains when large direct-coupled winders are started. The main equipment is similar to the one previously described. In addition, however, the 3-phase mains are fed through transformers to a rotary converter, the energy of which is supplied to a shunt-wound motor fitted with a heavy flywheel. The field of the continuous-current motor is adjusted by means of an automatic regulator. Under normal conditions with the winder motor at rest the converter set is running at constant speed; when, however, the motor is switched in and begins to move, a heavy current is taken from the mains, causing the automatic regulator to cut out resistance from the field circuit of the continuous-current machine, and the latter to act as a generator and its speed to drop. The kinetic energy of the flywheel now drives it as a generator, and its electrical energy is supplied to the rotary converter; it is here converted into alternating current, which flows through the transformers to the line, helping to supply the winder motor. When the load falls below the average the action is reversed and the regulator inserts resistance into the field circuit of the continuous-current machine, which then acts as a motor and, driven by the rotary converter, brings the flywheel back to its normal speed. The auto-

matic regulator is fed by series transformers in the main leads to the winder motor, and it will thus be seen that by suitably arranging these transformers the energy taken by the winder from the generating station can be kept at an average value.

The advantages of this system of equalizing are that a breakdown of the converter does not necessitate a stoppage of the winding plant, and also that the rotary converter being a synchronous machine can be made to operate at leading power factor and so compensate for the lagging component of the induction motor.

WARD LEONARD AND ILLNER SYSTEMS.

In these systems instead of the winder motor being directly connected to the supply mains, there is interposed between the two a motor-generator, the motor taking energy from the mains and the generator supplying energy to the winder motor. The field magnets of the winder motor are separately excited and the field is of fixed direction. The field magnets of the generator are also separately excited, but with a long-range rheostat in circuit, by which the magnetism can be raised from zero to a maximum and reduced again to zero, or it can be reversed and raised to a maximum in the opposite direction. On starting, the voltage of the generator is raised until sufficient torque has been exerted by the winder motor to overcome the load. As the winder motor accelerates, the voltage of the generator is raised further, so as to maintain the full current as long as may be desired. The turning moment can with equal ease be reduced by lowering the voltage of the generator, and a reversal of rotation is obtained by reversing the direction of the generator field.

In order to equalize the load the motor-generator is fitted with a heavy flywheel. This comprises the Illner system of winding.

At the start of a wind the power required to start and accelerate is considerably more than is required when the motor-generator is running light. The demand upon it causes its speed to drop, the flywheel immediately giving up part of its kinetic energy and assisting to drive the generator. When, however, the load falls, the kinetic energy of the winder, drum, etc., begins to drive the motor, which becomes for the time being a generator and returns current to the motor-generator, causing the generator to act as a motor and to bring the flywheel back to its normal speed.

The chief advantage of this system is the ease and economy of control. Any speed from inching to full speed can be obtained by simply varying the field strength of the generator. The disadvantages are the higher first cost, due to three machines being installed instead of one, and also the lower overall efficiency.

THE C.M.B. CONVERTER SYSTEM.

In this system the method of control is similar to the Ward Leonard, but embodies certain modifications. The equipment consists of a rotary converter and a variable-voltage generator coupled on one shaft, and also a main winding motor. The generator is connected in series with the rotary armature and may be excited so as to oppose or assist its voltage. It is also provided with a

special series winding in opposition to the shunt field winding, and by this arrangement the resultant field of the generator bears a relation to the current supplied to the winder motor, which is thereby limited.

The heavy torque required by the winder motor at starting is obtained by employing two shunt windings, one of which is constant, whilst the other varies with the speed of the motor. The gear is controlled by means of a regulator in the field circuit of the generator and by a reversing switch in the motor circuit. Whilst running light, the voltage of the generator opposes that of the rotary converter. On starting, the main switch is closed and the regulating switch is operated, by which the field of the generator is reversed. As the winder motor is accelerating, the combined voltage of the rotary converter and generator is building up, and a current is supplied to the motor, which, in conjunction with its strong field,

causes the motor to exert a heavy torque until the field of the generator is reduced.

CONCLUSION.

In conclusion, it is hardly necessary to emphasize the necessity of using the best possible gear that can be obtained, as everybody will admit that a coal mine is the very last place in which imperfect gear should be installed. Simplicity of design and mechanical strength are the main features of good equipment, and complicated apparatus should be avoided. As regards the maintenance of the plant, cleanliness is of course the chief point, and a system of routine inspection work should be established. It must be rigorously carried out there should be very little trouble due to breakdowns, and the reputation of electricity as being the most efficient method of transmitting power in collieries will be maintained.

DISEASES OF TRANSFORMERS.

By J. L. THOMPSON, M.Sc., Student.

(Abstract of Paper read before the MANCHESTER STUDENTS' SECTION 17th March, 1914.)

Although transformers are the most reliable of electrical machines there are several causes from which troubles may arise. The major troubles are:—(1) Absorption of moisture; (2) excessive heating; (3) short-circuits; (4) abnormal voltage strains.

ABSORPTION OF MOISTURE.

Before putting transformers of 6,000-volt rating and over into service it is essential that they should be dry and that the oil in which they are immersed should also be dry. The state of dryness can only be roughly estimated, and that by an intimate knowledge of its history. The insulation resistance of a transformer will give an approximate indication of its state of dryness, but any values obtained should be taken with reserve.

If drying out is considered necessary, the insulation resistance values taken at different stages of the heating and plotted against the temperature will give a very valuable indication as to when the transformer is in a safe condition. As the temperature of the transformer rises the insulation resistance will fall, as shown by (a) in Fig. 1. This drop will continue until the temperature reaches 90–95° C. After this drop, the resistance will remain constant for a period of time, short or long according to the quantity of moisture that is present. When most of the moisture has been removed the resistance again drops, as shown by (b) in Fig. 1, but it rapidly rises again as shown by (c). At any point a moderate way up on section (c) the transformer may be said to be dry.

Due to breathing action moisture may be absorbed by transformers in climates where there is a great variation in temperature or where steam is prevalent in the atmosphere. This trouble can be eliminated by using air-tight tanks, or by fitting the tank with breathing apparatus. In general when moisture-proof transformers are required the first

alternative is followed, a tank constructed of boiler iron with welded seams being used.

Water-cooled transformers will accumulate moisture by

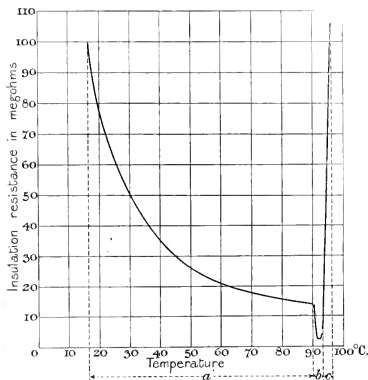

Fig. 1.—Insulation Resistance Characteristic with Temperature.

the condensation of any moisture in the atmosphere on the copper cooling coils (owing to the high heat conductivity of copper) down to the level of the oil. This can be guarded against by lagging the pipes down to the level of

the oil, or by sealing the spaces round the pipes where they enter the tank. Periodic examination of the cooling coils should be made in case corrosion has taken place due to acid impurities in the water. Seamless tubes should be used as they are less likely to develop faults than welded tubes.

With force-cooled transformers moisture troubles are rare, since such transformers are in general air-tight and the oil is forced through the cooling apparatus under pressure.

Samples of oil, drawn from the bottom of the tank, should be taken periodically from transformers and the breakdown voltage of the oil should be tested. If this voltage falls much below 30,000 across a 0.2-in. gap, the oil should be dried out. Although failures due to moisture are not of frequent occurrence, yet all things being equal, any precautions taken will be repaid by the long life and the continuity of service of the transformers.

EXCESSIVE HEATING.

Oil-immersed, self-cooled transformers are in general designed to give a normal temperature rise of 40-50° C., but this will be materially increased if the room or chamber in which they are installed is not sufficiently ventilated. If there is poor ventilation the transformers will operate as if surrounded with lagging, and before the losses can be dissipated a rise in temperature of 45° C. is necessary above that of the surrounding air, which may be 30-35° C., with a result that the working temperature will be 80-85° C., that is to say near to the danger zone. For efficient cooling, the chambers should be uniformly ventilated about the level of the floor and the roof. If several self-cooled transformers are working in the same room they should be spaced 24-30 in. apart, or they will serve as lagging to one another.

Heavy and frequent overloads result in high temperature rises, and if sufficient time is not allowed between these overloads for the accumulated heat to be dissipated, this high temperature will be maintained.

Water-cooled transformers are used to deal with large outputs and where adequate ventilation cannot be obtained. Since the heat generated is dissipated by external means, the ventilation of the chamber will not affect the working temperature. The thermometers used for temperature indication should be placed well away from the cooling coils, and well down under the oil. This type of transformer should never be operated without water circulating through the cooling coil; even on open circuit the water should not be cut off, as the iron loss in itself is sufficient to raise the temperature of the oil and windings to a dangerous value. The temperature of the entering water should never exceed 25° C., since the transformer is designed with a certain temperature rise above the temperature of the entering water. If the water, when used, can be run to waste, then the initial temperature can be easily kept within the required value. If the quantity of water is limited, the auxiliary chamber must be well ventilated or its temperature will rapidly rise. The quantity of water flowing must be kept up to the specified amount, or overheating will occur.

Decreasing the flow of water increases its temperature rise in inverse ratio, and the transformer temperature is raised half this amount; on the other hand, increasing the

flow decreases its temperature in inverse ratio, and lowers that of the transformer by half this amount. If the flow is increased 50 per cent, the transformer temperature is reduced 5 per cent. If the flow is decreased 50 per cent, the transformer temperature is increased 15 per cent. From this it follows that the cooling coils should be clean inside, so as not to restrict the flow of water. As with self-cooled transformers, excessive overloads are dangerous, since the dissipation of heat depends on the natural circulation of the oil. With large transformers the temperature is kept within the required limits by forced circulation of the oil.

Overheating from whatever cause results in (1) deterioration of the insulation; (2) increase in the copper losses, and therefore increased running cost and lower efficiency; (3) sludging and disintegration of the oil; (4) ageing of the iron, with increased losses and running costs, and lower efficiency; (5) fire risks due to the inflammable nature of oil vapours.

MECHANICAL STRAINS.

The author has dealt so far with diseases of slow growth, and he now passes on to those of instantaneous growth.

The mechanical force exerted on transformer windings under normal conditions is small, and is amply taken care of by the rigidity of the windings. The force exerted on the end coils of a 2,350-k.v.a. 25- \sim single-phase shell-type transformer which came under the author's notice only amounts to 0.24 ton. In a transformer having an impedance of 2½ per cent a current equal to 40 times full-load current will flow in the case of a short-circuit if the full voltage is maintained across the primary windings. This current will result in a force 1,600 times that under normal full load; and as it may amount to hundreds of tons, it is therefore destructive.

The causes of excessive currents are:—(a) Accidental short-circuits; (b) switching.

Accidental short-circuits occur through incorrect connections, the falling-out-of-step of synchronous machines, bad synchronizing, or a flash-over on the continuous-current side of a rotary converter. The magnitude of the short-circuit current is dependent on the total impedance of the short-circuit and on the voltage that can be maintained. If the voltage maintained be only half the line voltage, then the force exerted would be one-quarter of that which would be present with full voltage.

Transformers which can safely withstand a short-circuit at a distance, i.e. with a long transmission line, or a high-reactance machine situated between the fault and the transformer, might be instantly destroyed if the short-circuit had occurred directly across the secondary terminals.

Until recently good regulation was considered essential, and to obtain this transformers were designed with low reactance. However, with the growth of the output of modern supply systems this low reactance has become a danger, since it is now possible to maintain full-line voltage in the event of a short-circuit. The short-circuit current can be limited to a safe value by increasing the reactance internally or externally. With transformers of 1,000 k.v.a. and upwards it is now usual to include 6-8 per cent reactance for protection.

As an example of the reduction of the mechanical forces

on short-circuit due to increased reactance, let us consider the 2,350-k.v.a. transformer already referred to.

A. Coil grouping existing in transformer.

B. " " rearranged to give higher reactance.

A.—L.L.L. H.H.H.H.H. L.L.L.L.L. H.H.H.H.H. L.L.L.

B.—L.L.L.L.L. H.H.H.H.H.H.H.H.H.H. L.L.L.L.L.

	Grouping	Reactance (per cent)			Impedance (per cent)	Max. Force on End Coils (outside core) with Line Volts. at Short-circuit
		Internal	External	Total		
1	A	5'42	—	5'42	5'55	75 tons
2	B	10'25	—	10'25	10'26	24 "
3	A	5'42	4'1	9'52	9'7	24 "
4	A	5'42	8 0	13'42	13'43	12½ "
5	A	5'42	13'83	19'25	19'26	6 "

From the above it will be seen that by using grouping B instead of A the reactance is increased $3\frac{1}{2}$ times, and the mechanical stresses are reduced to less than one-third. If external reactance were used on the primary side, the same reduction would be obtained by increasing the total reactance to 1.8 times its original value, or the forces have been reduced inversely to the (increase in reactance)². If

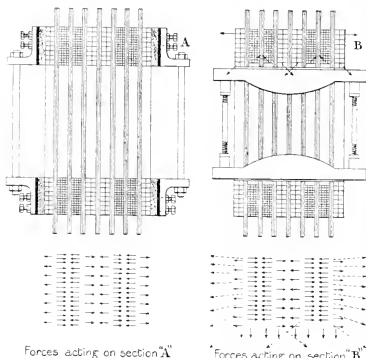

Fig. 2.—Bracing of Transformer Windings.

the external reactance were further increased so that the total equalled that of B, then the forces would be reduced to one-twelfth, as against one-third with B.

(Items 2 and 5.) From these it will be seen that external reactance is more effective and efficient than internal reactance. External reactance, unless inserted in the

primary circuit, will have no effect in allaying destructive forces occurring from breakdowns of the insulation in the windings. Further, the extra capital cost that external reactance necessitates must be balanced against its utility when other means are available for doing the same work though not in such an efficient manner.

Though the current may be limited, the forces still exerted are destructive to the windings if the latter are not

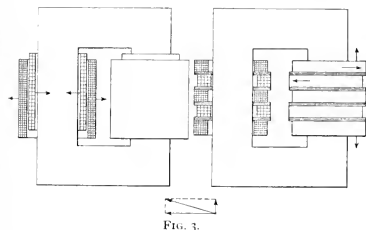

Fig. 3.

mechanically braced. The forces act in two directions: a repulsive force between the coils, and a compressive force in the plane of the coils. These repulsive forces are overcome by the core in shell-type transformers, and by the bracing at the top and bottom of the coils as shown in Fig. 2. The forces in the plane of the coils can be reduced to a large extent by making the sections and lengths of the primary and secondary coils approximately equal. The bracing used for resisting this force is also shown in Fig. 2. With core-type transformers similar forces are experienced.

With concentric windings, if the coils are symmetrical and coaxial, the forces in the axial direction are eliminated, but by reason of tappings, uneven winding, etc., this cannot be attained. The forces in a radial direction are the more effective, and are resisted by clamping the coils at the top and bottom, by taping the windings, by the rigidity of the winding, and by packing out the coils rigidly from the core. Fig. 3 shows these forces acting on a core-type transformer due to eccentricity of the windings.

The following is further proof that external reactances are more effective than internal reactances. Internal reactances can be increased in various ways. If the increase is attained by reducing the number of groups, the forces at short-circuit will not necessarily be within a safe value. This is so because these forces depend inversely on the square of the number of groups, as will be seen from the following equations:—

For equal grouping—

$$\text{Mechanical stress} = \frac{(\text{No. of turns})^2 \times (\text{Current})^2 \times K}{(\text{Length of leakage path})^2 \times (\text{No. of groups})^2}$$

For dissimilar grouping—

$$\text{Mechanical stress} = \frac{(\text{No. of turns})^2 \times (\text{Current})^2 \times K}{(\text{Length of leakage path})^2}$$

where K is a constant.

From the above it will be seen that for low mechanical stress high reactance must be obtained by a large number of groups and a large leakage path, hence an expensive transformer. If, however, the number of groups is kept large, and the current is reduced by external reactance, a low stress will be obtained as in the example.

Magnetic shunts are frequently used for obtaining high reactance for regulation purposes when the transformer is feeding a synchronous converter. This method, however, is of little use for limiting short circuit stresses, since the iron soon becomes saturated and loses its effectiveness.

Excessive currents are sometimes experienced when switching a transformer on to the line, even with the secondary open-circuited. This will occur if the switching occurs at a point where the magnetic field should have considerable value. This current may reach many times full-load current but is not dangerous; it throttles the primary windings, however. This current is dealt with

for instantaneous periods. For higher voltages the end-turns must be reinforced. Fig. 4, which illustrates a section of the top coil of a 60,000-volt transformer, is an example of reinforcement.

The only alternative to reinforcement is the use of a choke coil in series with the primary winding. If this coil has 30 turns, and each has the same choking effect as one transformer turn, then the first transformer turn becomes the 31st turn to receive the voltage, which is $1/31$ of the line voltage. It is advisable to use these coils on overhead transmission systems and not on cable systems, owing to the risk of resonance with the latter.

(2) The same voltage strain exists between the end-turns when transformers experience temporary short-circuits which cause the voltage to fall to zero, the pressure being first withdrawn from the end-turns, then from the last two turns, and finally from the first turn.

Instantaneous short-circuits occur at the instant when a cable of high electrostatic capacity is connected to a trans-

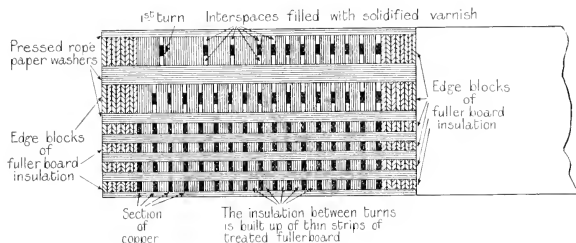

Fig. 4.—Section of Top Coil of a 60,000-volt Transformer.

switching by using a resistance in series until the switch is closed, the resistance then being cut out. The current is thus limited and all instruments on the primary line are protected.

VOLTAGE STRAINS.

With the advent of high voltages, high-tension transformers have to be designed to withstand abnormal voltages as well as the normal pressures. Abnormal voltages result from:—(1) Switching; (2) instantaneous short-circuits; (3) arcing earths; (4) lightning; (5) constant induction.

(1) The maximum pressure rise which can occur under normal switching is limited to twice the normal voltage, and this occurs at the end of the line where the switching impulse adds itself to the line voltage. The result of connecting a "dead" transformer to the line is at the first instant to put full voltage across the end-turn, the pressure being distributed at the next instant over two turns, and so on; thus in successive instants the voltage is distributed over more turns. This impressing of the line volts on the first turns occurs with all transformers; but at pressures up to 3,000 volts it is not dangerous, since the normal insulation between turns is sufficient to withstand this voltage

mission line; the terminal pressure falls to zero, and assumes normal conditions again within $1/1000$ second.

(3) Instantaneous short-circuits are also caused by arcing earths on earthed systems. These earths may occur at insulators on overhead lines due to faulty porcelain, or dirt, ice, or snow, at cable joints with bad connections, at transformer bushings, or at generator coils.

When an arcing earth occurs on one phase of an un-earthed 3-phase system, the arc always takes place at maximum potential, and the potential of the other phases rises from "star" to "delta" potential above earth; and since this earthing is sudden, the voltage will rise to double the normal value. This voltage can only be resisted by designing the insulation to earth to withstand it, and since the usual factor of safety is 4, this insulation may be taken to be sufficient.

Arcing earths, lightning, and switching, all produce high-frequency waves which travel along the transmission system to and from the source of supply. These waves are responsible for many insulation failures on high-voltage transformers, and as they cannot enter into transformer windings unless the windings have a high electrostatic capacity, they are only dangerous to the internal windings of transformers for 50,000 volts and upwards. With lower

voltages they are limited to the end-turns, which are protected by reinforcement.

If the high-frequency travelling wave is due to one impulse, viz. switching, the high voltage will rapidly die down. If, however, successive impulses occur, due to arcing earths or lightning discharges, these successive waves may build up to very high destructive values. This building up of a travelling wave is termed a standing wave, and occurs at a point in the winding which offers direct opposition to the high-frequency wave. An inductance offers a dead resistance to a travelling wave, so that if on the line side of the transformer an inductance or choke coil is inserted in series, the standing wave will form on the line side of that inductance; a horn-gap is placed at this point and the high voltage discharges across it to earth.

This discharge is not allowed to go to earth direct, as it would earth the transmission system, but it is discharged through an energy-absorbing device, known as an electrolytic lightning arrester. Arcing earths at transformer bushings have now been practically eliminated since the adoption of the condenser terminal for high voltages, which

produces a more even electrostatic field to earth and therefore a lower potential gradient.

CONSTANT INDUCTION.

There is always a danger of insulation failures on the low-tension side of high-voltage transformers working on an unearthed system. This danger is due to the fact that the transformer windings have a capacity between each other and also a capacity to earth. If an earth of any kind takes place on the high-tension side of a transformer, then provided the capacity of the low-tension winding to earth is appreciable compared with its capacity to the high-tension winding, the low-tension winding may assume a very high potential above earth, and its insulation from earth may thus be destroyed. To guard against this occurrence the low-tension windings should be earthed direct or through a spark-gap, or else be connected to earth through a condenser having a much higher capacity than that existing between the primary and secondary windings. The same result occurs if one high-tension terminal is disconnected from the high-tension line before the other.

THE POSSIBILITIES OF ELECTRIC TRACTION ON RAILWAYS.

By J. L. MOFFET, B.Sc., Student.

(Abstract of Paper read before the MANCHESTER STUDENTS' SECTION 3rd March, 1914.)

The application of electricity to the haulage of vehicles has been under consideration for many years. In competition with the horse it made rapid progress on tramways, but up to the present it has not been a serious rival of the steam locomotive.

It was only with the introduction of the modern steam turbine that any decided saving in running expenses could be claimed for electric traction, and even now it is only for heavy suburban traffic that it is accepted as a commercial proposition, at any rate in this country.

The main items in which a saving can be effected by electrification are:—

- (1) Fuel per unit of energy.
- (2) Total fuel (owing to the reduction of the weight of the locomotive portion).
- (3) Repairs of locomotives.
- (4) Cleaning of locomotives.

Against these have to be set the increased cost due to:—

- (a) Interest on extra capital expenditure.
- (b) Extra depreciation.
- (c) Extra staff at power station and sub-stations.
- (d) Fuel for extra losses in transmission, converting machinery, track, rheostats, and motors.

In electric traction a smaller amount of fuel is required per unit of energy, since it is not found practicable to construct the steam locomotive to work with a condenser. The difference that this makes is shown in Table 1, which gives the steam consumption per i.h.p.-hour for a

perfect engine when exhausting into the atmosphere and when exhausting into a vacuum of 28 in. A reduction of about 80 per cent is shown in the latter case, which is about the saving effected in practice.

TABLE 1.
Steam Consumption.

		Non-condensing	Condensing
Steam pressure (gauge)	per sq. in.	180 lb.	180 lb.
Superheat	100° F.	100° F.
Vacuum	Nil	28 in.
Perfect plant—			
Steam per h.p.-hour	12.8 lb.	7.1 lb.
Coal per h.p.-hour (13,000 B.Th.U.)	1.1 lb.	0.61 lb.
Actual coal per h.p.-hour (average)	2.5-6 lb.	1.5 lb.
Efficiency	45-18%	41%

It is difficult to estimate the saving in repairs, as so few figures for electric locomotives are available. From Table 2 it will be seen that greatly different values are given, even for the same installation, by various authorities, probably due to different items being included. It would add greatly to the value of most published data if more care were taken in each case to specify exactly what is included in the figures given. In applying American figures to English railways it must be borne in mind

that the repair bill is largely made up of wages, and that these are very much higher in America than they would be here. The repair bill also largely depends on the type of load to which the equipment is subjected. The Lancashire & Yorkshire figure of 1·65d. per mile is for equipment performing one of the heaviest schedules in the world, viz. 30 miles per hour with a stop on an average every $1\frac{1}{2}$ miles. This means that the motors are overloaded to about $1\frac{1}{2}$ times their one-hour rate every two or three minutes, and consequently the wear and tear is very much greater than in the cases subsequently considered in this paper. The number of breakdowns, and therefore also the repair bill, have also been largely reduced

SYSTEM.

It is not the author's object in this paper to discuss the relative advantages of alternating current and continuous current. The values given are based on a high-tension continuous-current system, with a third rail in suburban districts and an overhead conductor on long straight runs in the country. The voltage on the third rail is taken as about 1,500, and on the overhead conductor as 3,000, the motors being run in parallel at 1,500 volts, and two in series in the case of 3,000 volts. If either a single-phase or 3-phase alternating-current system would prove more economical, then it would be so much more to the advantage of electric traction.

in recent years by the use of mica as an insulator in motors, controllers, etc.

From Table 2 a cost of $\frac{3}{4}$ d. per mile would appear to cover the repair costs of a 600-h.p. continuous-current locomotive, but in order to be well on the safe side $1\frac{1}{4}$ d. per mile has been taken in all calculations.

More definite figures are available in the case of the steam locomotive. Table 3 gives the cost of repairs and renewals

TABLE 3.

Repair and Renewal Cost per Loco-mile for Steam Locomotives during Second Half of 1912.

L. & N.W.	G.W.	Midland	N.E.	L. & Y.	G.C.	G.E.
3·1d.	3·9d.	3·8d.	4·8d.	4·45d.	4·7d.	3·9d.

for a few English railways for the second half of 1912. An average figure is 4d. per mile. If the cost of renewals be taken at 4 per cent of the cost of a locomotive, equivalent to an 18 years' life, the cost of renewals works out at 0·9d. per locomotive-mile, assuming the first cost to be £1,900 and the mileage to be 20,000 per annum. The cost of repairs is thus 3·1d. per locomotive-mile, and this has been taken as 3·25d. for goods, 2·75d. for passenger, and 3·25d. for suburban work.

CASES CONSIDERED.

Railway traffic can be divided into three main heads:—

- Express passenger traffic; with which might be classed express goods.
- Goods traffic.
- Suburban or stopping trains.

In order to find with what density of traffic the saving effected in running costs will exceed the cost of interest and depreciation on the extra capital expenditure incurred, a case has been worked out for each class of traffic. The fuel consumption is shown in Table 4, and the energy for each case is calculated from the train resistances given by Mr. Aspinall.² The electric locomotive resistance is based on figures for the New York Central Railroad given by Mr. A. H. Armstrong in the discussion on Professor Carus Wilson's paper on "The Predetermination of Train Resistance."[†] The coal consumptions per i.h.p.-hour in the case of the steam locomotive are based on modern test figures, and are lower than average practice. The figures for the electrical case are based on the steam consumption with modern turbines, on about $\frac{2}{3}$ full load, in combination with boilers having an average efficiency of 70 per cent.

² J. A. F. ASPINALL. President's Address. *Institution of Mechanical Engineers, Proceedings*, p. 474, 1909. Also, Train-resistance. *Minutes of Proceedings of the Institution of Civil Engineers*, vol. 147, p. 166, 1901-2.[†] *Minutes of Proceedings of the Institution of Civil Engineers*, vol. 171, p. 282, 1907-8.

The calculated coal consumption in the case of steam traction is found to come below actual results owing to the effect of side winds and gradients; and to bring the figures into line with working conditions the coal consumption in

weight of train the average draw-bar pull was nearly 17 lb. per ton. The figures taken agree very closely with those given in the "Locomotive Pocket Book," being 45, 60, and 55 lb. of coal per mile, as against the 40, 60, and 50 lb. re-

the steam case, and the energy in the electric case, have been multiplied by the same factor. An example will show that this is justifiable. The train resistance for an express train is taken as 10 lb. per ton, which is the value on the level, while on an actual run with approximately the same

spectively given in that pocket book for similar traffic. That the actual consumption is higher than this can be seen by taking Mr. O'Brien's figure ² of £300,000 per annum for

² H. E. O'BRIEN. Electrification of railways. *Proceedings of the Manchester Association of Engineers*, Session 1911-12, p. 256.

the cost of the coal consumed on the Lancashire & Yorkshire Railway; if the cost per ton be 8s. 6d., this gives 90 lb. per locomotive-mile, assuming 12,300 miles per annum (the 1912 figure), as compared with 45, 60, and 55 lb. in the cases considered. Most of this difference will be due to the coal burnt in lighting up, in inefficient engines, and in engines held up by signals, etc., and would not occur in the electrical case. The figure on the London & North-Western Railway is over 100 lb. per locomotive-mile.

The amount of plant installed in the sub-stations and power station depends largely on the nature of the load. With main-line traffic the load would be much steadier than that experienced on the suburban lines at present electrified, where the rating of the plant installed is usually 2 or 3 times the average load. Table 5 shows the rating of the generating plant per mile of track, and it will be seen that the amount of plant is liberally estimated. In practice, accumulators would probably be installed and

of oil and stores for the electric locomotives and for the power station would equal that for steam locomotives.

The capital cost of the necessary electric locomotives has also been taken to be the same as that of steam locomotives, for although an electric locomotive is somewhat more costly, this is compensated by the extra mileage per annum which could be obtained, owing to the fact that it would not have to be idle for such a large proportion of the year for repairs and shed duties.

Table 7 gives a summary of the costs per train-mile for different types of traffic, and also the fixed annual charges due to electrifying one mile of track. From these two values it is possible to calculate the number of trains that must be run per hour in order that electrification may prove profitable. This will be seen to be 2·2 for express traffic, 1·9 for goods traffic, and 1·2 for suburban traffic. The necessary density of traffic on any railway would depend on the proportions of the various types of traffic. On lines with a large amount of suburban traffic it would

the amount of spare plant would be reduced, the annual charges for these batteries being more than balanced by the saving effected in the amount of plant required and in losses and repairs, to say nothing of the greater reliability of the supply.

Table 6 shows the values that have been assumed for the various items in the cost of generating the electrical energy. The coal cost appears low compared with most of the results that have been obtained, but it must be remembered that in the case considered the station would be equipped with the most up-to-date machinery, running on a very good load factor. That these figures are on a conservative basis can be seen by comparing them with figures published for Carville power station, viz. coal 0·0785d., engine-room wages 0·0223d., maintenance 0·016d.; giving a total of 0·1068d. per unit as against the 0·175d. assumed. Oil and stores have been purposely omitted in both the steam and the electrical cases, as the quantity used with the latter system at the generating station would be very small compared with that used by a large number of steam locomotives. It has been assumed that the cost

approach 1·2 trains per hour, while on lines where through traffic predominates it would approach 1·9 trains per hour.

The number of trains per track-mile for the last half of 1912 varied from 1·2 to 1·8 for English railways, being in most cases nearer the latter figure. When it is remembered that on all railways a large proportion of the total length of track is installed on branch lines with sparse traffic, it will be seen that there is a considerable amount on which the critical density of traffic given in Table 7 would be exceeded, and would profitably stand electrification. Those sections of a railway where the traffic is least dense could be worked for a time by existing steam locomotives; and of course the whole of any railway could not be electrified at one time since the savings brought about by electrification would not be great enough to allow the wholesale scrapping of steam locomotives.

All the figures given are based on results which have been obtained in practice, the tendency having been to take the best steam figures and average electric figures so as to obtain a very safe estimate, which would probably

be improved on in practice. Thus the running costs per mile for the second half of 1912 on the London & North-Western Railway were:

		Cost per train-mile
Wages connected with working of locomotive engines (excluding salaries, office expenses, and general superintendence)		
Coal and coke	4'35d.
Water	5'06d.
Oil, tallow, and other stores	0'17d.
Total	9'99d.

would be materially reduced, the number of breakdowns would be fewer, and compensation for firing crops, buildings, etc., would be eliminated.

In many cases in this country the lines are very congested, and electrification would be a profitable expenditure if undertaken only with the object of increasing the carrying capacity of these lines. Table 8 shows the amount of capital per mile of route for a few English railways; compared with these figures the cost of electrification is insignificant, so that even a small increase in the carrying capacity of a line would pay handsomely for the outlay on electrification.

TABLE 7.
Cost per Mile, Steam and Electric.

	Express		Goods		Suburban	
	Steam	Electric	Steam	Electric	Steam	Electric
A. Variable costs.	d.	d.	d.	d.	d.	d.
Repairs per train-mile	2'75	1'25	3'25	1'25	3'25	1'5
Coal per train-mile	2'42	1'07	3'2	1'4	2'95	0'67
Train crew (Running Dept.) per train-mile	Same		Same		2'0	1'3
Water per train-mile	0'2	—	0'2	—	0'15	—
Cleaners' wages per train-mile	0'5	0'25	0'5	0'25	0'5	0'1
Power station wages per train-mile	—	0'4	—	0'5	—	0'35
Power station and sub-station repairs per train-mile	—	0'45	—	0'7	—	0'42
Total variable costs	5'87	4'22	7'15	5'2	8'85	5'0
Saving per train-mile	—	1'65	—	1'95	—	3'85
Saving per annum per mile of track with one train per hour	—	£61	—	£72	—	£140
B. Fixed costs per annum per mile of track.	£	£	£	£	£	£
Track, interest, and depreciation (8 per cent)	—	72	—	72	—	80
Track repairs (electric)	—	20	—	20	—	20
Feeders, interest, and depreciation (8 per cent)	—	24	—	24	—	40
Sub-station wages	—	20	—	20	—	40
Total fixed costs	—	136	—	136	—	180
Number of trains per hour to pay	—	2'2	—	1'9	—	1'17
Figures above based on—	10s.	8s.	10s.	8s.	10s.	8s.
Price per ton of coal	—	0'04d.	—	0'04d.	—	0'05d.
Power station wages per unit	—	0'05d.	—	0'05d.	—	0'06d.
Repairs per unit	—	15	—	15	—	7'5
Miles between sub-stations	—	£900	—	£900	—	£1,000
Cost of track equipment per mile	—	9'5	—	12'5	—	5'7

These are all considerably above the values taken in Table 7.

No account has been taken of many other savings which would result from electrification, but to which it is difficult to fix a monetary value. The coal at present burnt on locomotives held up by signals, waiting to shunt, etc., amounting to about 150 lb. per locomotive per hour, represents a considerable sum which could be saved. The painting and cleaning bill for both stations and carriages

POSSIBILITIES OF FUTURE IMPROVEMENTS.

Coal consumption.—In Table 9 is shown the efficiency of a perfect steam engine under different conditions.

- (1) Common locomotive practice.
- (2) Common steam-turbine practice.
- (3) Increased superheat.
- (4) Increased boiler pressure.
- (5) Steam re-heated after falling to saturation point.

(2) to (5) indicate that no great increase in the possible efficiency can be obtained without very radical changes in the conditions of working. When it is remembered that some modern turbines work to within 68 per cent of the efficiency possible with a perfect engine under the same conditions, it can be seen that there is little prospect of the amount of coal per unit being very much reduced.

The gas engine has no such limits to its efficiency, and already the latter exceeds that of the steam engine. The results obtained at Accrington* show an overall efficiency of 17·5 per cent against 15 per cent for very good steam plant. In addition to being more efficient, a gas plant produces valuable by-products, for which there is a practically unlimited demand. Thus, according to the published results obtained with the Accrington plant, the

The efficiency of a gas engine does not increase to any extent after a moderate size has been reached, so that there appears to be a future for gas engine plants located at intervals along the line, instead of a central station with sub-stations. This would eliminate sub-stations and feeder costs and the capital cost would work out at about £19 per kilowatt, or at about the same rate as steam plant with sub-stations. There would also be less liability of a complete shut-down.

It is also possible that the locomotive running wages might be considerably reduced by electrification. These amount to 4·35d. per locomotive-mile on the London & North-Western Railway, so that if a second man on the engine could be dispensed with, as would appear possible on a considerable number of trains, a reduction in the

TABLE 8.

Railway Capital per Mile of Route (1912).

Feed water temperature ... ° F.	60	80	80	80	80
Heat utilized per lb. of steam ... B.Th.U.	200	404	460	437	460
Heat supplied per lb. of steam ... "	1,170	1,246	1,342	1,257	1,390
Efficiency of perfect engine ... %	17·0	32·5	34·3	34·8	33·1
Steam per i.h.p.-hour ... lb.	12·8	6·28	5·53	5·8	5·5

following figures per unit are readily obtained: Coal 0·08d., sale of ammonium sulphate 0·13d., sale of tar 0·01d. From this it will be seen that the sale of by-products yields about 1½ times the cost of coal. This is of course not all clear profit, since the recovery of the by-products involves extra expenditure in acid, labour, and capital charges; about one ton of acid is required to produce one ton of ammonium sulphate, so that at the present prices, £2 2s. per ton and £12 per ton respectively, the acid costs only about one-sixth the price obtained for the sulphate. The extra capital charges and labour will vary in each case according to the size of the plant, the load factor, and other conditions, but in no normal conditions will they represent anything like the price obtained for the by-products.

* Science Abstracts, vol. 16, B, No. 1031, 1913.

running costs of 1d. to 2d. per train-mile would result. This would render electrification profitable with only about one train per hour along each track. The double heading of trains without increasing the train crew would still further reduce the running wages.

One of the reasons for the slow progress of electric traction is probably the uncertainty as to which is the best system. Railway directors cannot be expected to sanction large schemes when electrical engineers, both railway and manufacturing, are wrangling as to which is the best system. It would appear that when a little more experience has been obtained with high-tension continuous current, a round-table conference of manufacturing and railway engineers would serve a useful purpose. Such a gathering should be able to settle which system is the best for the average conditions of this country.

THE LAWS OF DIELECTRICS.

By W. S. FLIGHT, Student.

(Abstract of Paper read before the MANCHESTER STUDENTS' SECTION 25th November, 1913.)

GENERAL.

The study of dielectrics is the exact counterpart in electrical engineering to the study of the strength of materials in mechanical engineering, but on account of the great difficulties met with in the study of electrical stresses and strains, our knowledge of the latter is by no means as complete as our knowledge of the former. An attempt is made in this paper to set forth many of the fundamental laws which have been deduced from numerous test results, and references are made to a few points which the author has had an opportunity of investigating. Dielectrics will be considered under three main classes, since the effect of an electrical stress under stated conditions differs for different dielectrics.

I. GASEOUS DIELECTRICS.

When a layer of air at ordinary atmospheric pressure and temperature is subjected to an electrical stress which is gradually increased until the air breaks down, three distinct discharges are observed. As soon as the voltage has reached a certain value a faint glow appears on the electrodes, and the discharge is known as the "glow" discharge. As the voltage is steadily raised, this glow gives place to the "brush" discharge, and at a still higher voltage the brush discharge passes into the arc.

Liquid and solid dielectrics do not show these three discharges in so marked a degree, even under the most favourable circumstances, so that in order to compare the properties of all dielectrics the ultimate breakdown value is adopted and all the figures quoted in this paper refer to this third discharge.

The breakdown voltage of any layer of air is influenced by many factors, of which the following are some of the most important.

(1) *Method of application of the voltage.*—The following are the principal ways in which voltage may be applied to a dielectric: (a) In the form of a regularly increasing voltage; (b) by even steps large or small, the circuit always remaining unbroken; (c) by a sudden application.

The effect upon the breakdown voltage of a definite thickness of air only varies slightly unless the circuit contains capacity and inductance (which may cause surges when the voltage is applied by suddenly closing a switch on either the high-tension or low-tension side). The reason for this may be attributed to the fact that air has practically no time factor until a corona appears, and it can easily dissipate any heat produced.

(2) *Electrostatic fields produced by surrounding objects.*—This has only been extensively studied in the case where one terminal of a testing transformer becomes earthed, when a reduction in the breakdown voltage as shown in Fig. 1 occurs. Its amount varies with the setting of the gap, the applied voltage, and the shape of the electrode. The effect of the latter with spheres of different sizes is shown in Table 1. In Fig. 1, where the electrodes consist of spheres of 12.5 cm. diameter, the earthing had

practically no effect up to 100 kilovolts; if, however, a needle gap be used, the curves have been found to diverge at about 30 kilovolts.

The electrodes in these tests were separated by at least three times the gap distance from all surrounding objects; although no figures are available for tests at other distances, it is probable that the electrostatic field is considerably changed at shorter distances and the breakdown voltages further reduced.

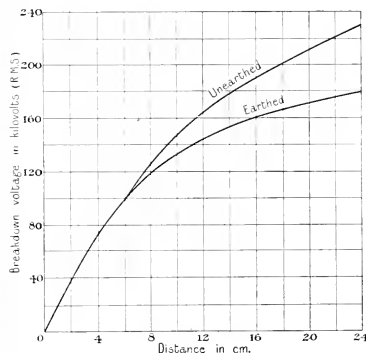

FIG. 1.

(3) *Shape of electrodes.*—The shape of the electrodes employed has a considerable influence. In Table 1 the breakdown voltage of the constant gap of 25 cm. and with both terminals unearthed varies from 230 kilovolts for spheres of 12.5 cm. diameter to 400 kilovolts for 50 cm. spheres.

TABLE 1.

Decrease in Breakdown Voltage for a Constant Gap
Setting of 25 cm.

Diameter of Spheres	Breakdown Voltage, Unearthed	Breakdown Voltage, Earthed	Percentage Decrease in Breakdown Voltage
Cm. 12.5	Kilovolts (R.M.S.) 230	Kilovolts (R.M.S.) 180	21
25	310	280	9.7
50	400	375	6.2

Fig. 2 shows the results of another series of tests made between electrodes of the shape shown. Here it will be

observed that the curve between point and plane is much lower than the point-to-point curve, whilst the curves for circular plates to points are lower still.

For gases and liquids the order of electrodes placed in a descending scale is roughly as follows:—

- Parallel plates of infinite area.
- Spheres of large diameter.
- Spheres of smaller and smaller diameter.
- Point to point.
- Point to plain.

The cause of the vast difference observed in the breakdown voltage with differently shaped electrodes is to be

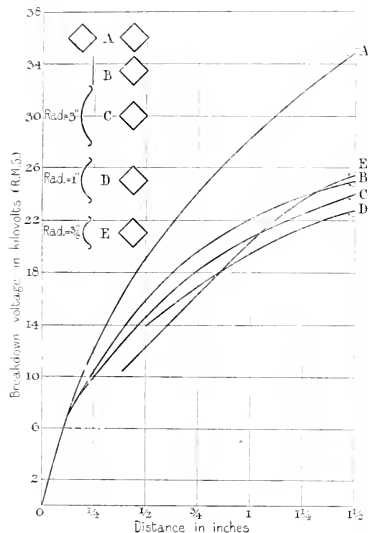

FIG. 2.

found in a study of the flux distribution on the electrodes. Some interesting diagrams which the author obtained by sticking flat tin-foil electrodes to an unexposed photographic plate and causing a brush discharge to pass between them in a dark room, have shown that the electrons and atoms are shot off approximately at right angles to the surface of the electrodes, and that the amount of concentration possible in these electric fields is far greater than in magnetic fields, so that the latter cannot always be taken as a true indication of the conditions existing under an electric stress. This non-uniformity of the electric field increases as the voltage between the electrodes increases. Thus at fairly low

voltages the effect of the shape of the electrode is not very marked; its influence, however, becomes of far greater importance at higher voltages.

(4) *Character of the circuit.*—(a) *Frequency.* Over the range of commercial frequencies (25–100 \sim) there has been found to be practically no variation in the breakdown voltage. At telephonic frequencies a slight decrease has been observed with increase in frequency.

(b) *Wave-form.* Since the strength of a dielectric is dependent on the maximum voltage and not on the R.M.S. voltage, peaked waves produce breakdown at a lower voltage than a sine wave.

In comparing tests on air with both alternating and continuous currents it is found that the continuous-current breakdowns are approximately $\sqrt{2}$ times the alternating-current values.

(5) *External ionization.*—Since electrical conduction consists of definite motion of free electrons, and dielectrics are materials which naturally contain very few free electrons, it follows that a breakdown does not take place until electrons are liberated. This liberation of electrons may take place in two ways:—

(a) By placing the dielectric between two plates maintained at different potentials. The atoms will then tend to fly towards the negative plate and the electrons to the positive, so that as soon as the electrical field is strong enough to overcome the atomic attraction electrons will be liberated and a current will pass. (b) When a radioactive particle passes through the atoms of a dielectric it liberates a number of the electrons by displacing them in their orbit round the atom—a phenomenon known as ionization by impact. Ultra-violet rays and sunlight possess in a less degree this power of causing ionization by impact. During some experiments conducted by Dr. W. Weicker in Germany it was found that the ultra-violet rays produced by two arc lamps lowered the voltage of a glow discharge by 4 per cent. No effect was in this case found on the breakdown voltage, probably because the experiments were conducted with needle points or spheres of small diameter, in which case ionization would be already present as the result of the brush discharge.

(6) *Thickness of test piece.*—The breakdown voltage of a dielectric per mil always decreases with increase in thickness but not proportionally therewith. The various formulæ put forward from time to time show so much disagreement that the subject requires further investigation. The reason for this decrease is not perfectly clear, but since it is a common property of all dielectrics it seems probable that it is due rather to a change in the electric field produced by increasing the distance between the electrodes than to any property of the dielectric, such as the heating of certain layers or the heterogeneity of the material. On account of this decrease in voltage with thickness, the practice of comparing various insulating materials by comparing the breakdown voltages per mil is not to be recommended unless the thickness of all the test pieces is approximately the same and the tests have been carried out between electrodes of the same size and shape.

(7) *Mechanical pressure.*—This is another special study in dielectrics which has not as yet been very fully investigated. In the case of air, however, it is known that the breakdown voltage is very susceptible to mechanical

of water for oil being much less than that of water for water, it is found possible by this means to carry the drying to a very high point on the curve, not only in a laboratory test but also in practice.

(10) *Time of application of voltage.*—Fig. 4 is a typical time-voltage curve for oils. It will be noticed that after about 200 seconds the curve becomes parallel to the time axis. This time (200 seconds) is known as the "time factor" of the dielectric. It varies from about 1 minute to 15 minutes for most insulating materials, and it also depends to some extent upon the amount of moisture present in the sample under test.

(11) *Presence of foreign matter in the oil.*—(a) In switch work due to the breaking of the arc under oil a large number of carbon particles are formed. Due to the electrostatic field these particles will, under certain conditions, line themselves up so as to produce a breakdown at a very much lower value than is required to break down the oil when clear, as shown in Table 2.

TABLE 2.

Name of Oil	Breakdown Voltage of Clear Oil	Breakdown Voltage of Oil Containing Carbon Deposit	Per Cent Decrease in Breakdown Voltage
A	22,000	16,000	27
B	14,200	9,000	36

One of the most interesting points about this "lining up" is the time element involved. The action is by no means instantaneous and the time of duration varies with the quantity of carbon, the shape of the electrodes, the voltage between them, and the viscosity of the oil.

(b) In transformer work another form of deposit is met with, which is precipitated as the result of certain chemical changes that take place in the oil due to oxidation. The presence of this sludge in oils, however, was found to reduce the breakdown voltage by only 5 per cent, and it is not as detrimental as the carbon deposit.

III. SOLID DIELECTRICS.

Solid dielectrics used in practice are as numerous as the liquids and gases are few. Roughly they may be divided into two main groups:—(a) organic, (b) inorganic; and in considering the dielectric properties of solids both of these groups may in many cases be treated together. Roughly speaking, sections (1) to (6), with the exception of section (3), in the first part of this paper apply equally to solids.

(3) *Shape of electrodes.*—It was pointed out in the first part of this paper that in the case of gases and liquids the breakdown voltage decreased as the radius of the electrodes was decreased. In the case of solid dielectrics the reverse is, however, found to be true. Thus we have a rather remarkable state of affairs, for in order to determine the minimum value of the dielectric strength of gases and liquids, points, or better still a point and a plane, should be used; whilst for solids, on the other hand, flat plates are the correct electrodes to use in order to de-

termine this minimum value. The cause of this difference seems to lie in the fact that gases and liquids being physically homogeneous bodies the breakdown voltage is independent of the area under stress, whilst solids being far less homogeneous will be influenced by the area under stress.

(7) *Mechanical pressure.*—Here again the subject does not appear to have been scientifically studied, and the results of what few experiments the author has been able to make tend to show that with most fibrous materials the breakdown voltage decreases with increase in the mechanical pressure. The decrease was small within the range of pressures applied, viz. up to about 80 lb. per square inch.

(8) *Temperature.*—The breakdown voltage of all solid dielectrics decreases with temperature, although moderate rises of temperature have little effect as a rule upon inorganic materials. Fig. 5 shows the decrease in the

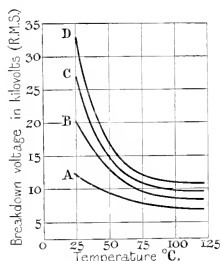

FIG. 5.—Empire Cloth.

A = 1 layer. C = 3 layers
B = 2 " D = 4 "

case of empire cloth. These tests were done by immersing the material in oil, which had previously been heated to the required temperature, and obtaining the breakdown before any drying of the material could take place. When fibrous materials containing a large percentage of water are slowly heated at moderate temperatures some of the water is driven off and the dielectric strength is in consequence increased. This effect, however, is really due to moisture, and when tests are carried out on dried samples of the same material at the same temperature there is always found to be a decrease in breakdown voltage with increase in temperature.

(9) *Moisture.*—All organic materials contain a certain percentage of moisture, and unfortunately they are all capable of absorbing an excess of moisture from the air in such a way as to cause a serious decrease in their dielectric strength. Papers, for example, usually contain from 5 to 15 per cent of moisture, and in order to preserve the mechanical properties of the paper it is essential that the majority of this natural moisture should remain. The problem thus consists in drying off all excess moisture and in treating the material by means of varnishes, oils, or compounds, so as to prevent a re-absorption of any excess moisture.

(10) *Time of application of voltage.*—All solid dielectrics possess a considerable time factor, and there appears to be a marked similarity between the time-voltage curves of different solids. Fig. 6 is a typical curve for a stator coil insulated with empire cloth and mica. When a number of thicknesses of the same material are tested together it is found that the time factor increases as the number of layers is increased.

(11) *Testing solid materials in air or oil.*—Very often in commercial insulation testing it is found impossible to

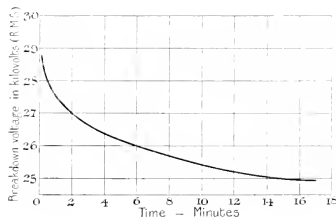

FIG. 6.—Stator Coils Insulated with Empire Cloth and Mica.

obtain an ordinary breakdown test on a particular sample owing to the flash-over voltage being less than the puncture voltage. The usual practice is then to immerse the sample and electrodes under oil, thereby increasing the flash-over voltage four or five times and rendering a puncture test possible. Placing the material in a medium having a specific inductive capacity more nearly equal to its own, however, is bound to alter the distribution of the electrostatic field, and in consequence a different breakdown voltage may thus be obtained. This is impossible to calculate, but when using electrodes of flat discs with rounded edges it has seldom been found in practice to vary more than 5 per cent from the breakdown voltage obtained in air.

Tests under oil have a peculiar effect upon certain

dielectrics. Former experimenters have remarked on the decrease in the breakdown voltage obtained when testing mica under oil, compared with that obtained in air. The author has noticed this in the case of built-up mica and also in the case of celluloid. It is never experienced in fibrous materials and appears to be due to the imprisonment of a thin film of oil between the electrodes and the dielectric.

(12) *Flash-over voltage.*—In all solid dielectrics there is a path across the surface of the material alternative to the

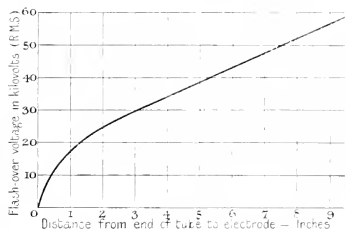

FIG. 7.—Mica Tube.

path through the material. In certain insulation designs this flash-over voltage becomes a more serious factor than the actual puncture voltage, and the question has been studied to some extent, but no very definite laws have been deduced. Fig. 7 shows the flash-over voltage across a mica tube, and it is interesting to note that after a certain point the curve is a linear one, which property seems common to most flash-over curves across a clean surface. When the surface is dirty or dusty the flash-over voltage is enormously reduced. It varies considerably with the material of which the surface is composed, and is very susceptible to a rough or smooth surface, the presence of irregularities on the surface of fibrous materials causing a decrease in the flash-over voltage.

THE CONTROL OF ELECTRICAL GENERATORS BY AUTOMATIC PRESSURE REGULATORS.

By E. L. M. EMTAGE and A. ARNOLD, Students.

(Abstract of Paper read before the STUDENTS' SECTION 1st April, 1914)

Automatic pressure regulators for the control of electrical generators may be roughly classified as:—

- (a) Rheostat type,
- (b) Vibrating-contact type.

These names have been chosen as covering the various types of regulators discussed in this paper, although regulators which fall under either of these headings may differ widely in their constructional details.

By the "rheostat type" is meant all those regulators which act by adding or cutting out more or less of a variable resistance in the field circuit of the machine which is automatically controlled. This operation may be performed in one step or gradually, and class (a) may therefore be subdivided into:—

- (1) Regulators in which the rheostat is directly controlled by a motor operated by the fluctuation of the line pressure.
- (2) Regulators in which the rheostat is adjusted by means of a relay (electrical or mechanical) controlled by apparatus actuated by the fluctuation of the line pressure.

By the "vibrating-contact type" is meant all those regulators in which a vibrating or oscillating member short-circuits and puts into circuit a device for altering the excitation of the generator or exciter. This type includes:—

- (1) Regulators in which there is intermittent short-circuiting of the whole or part of a field resistance by means of vibrating contacts which are controlled by suitable apparatus actuated by the line pressure.
- (2) Regulators in which an oscillating member alternately short-circuits the two opposing components of a booster field, thereby causing an electromotive force to be introduced into the generator or exciter field-circuit.

Under these headings the paper deals with the following regulators:—

Rheostat type.—Thury, Routin, and Brown Boveri automatic pressure regulators.

Vibrating-contact type.—Tirrill, British Westinghouse (Olmsted), Oerlikon (Fuss), Siemens Schuckert, and Taylor Scotson automatic pressure regulators.

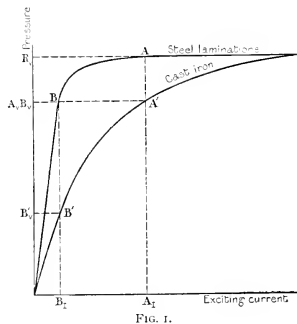

At first sight it would appear that the advantages are all on the side of the vibrating-contact systems, but troubles originating from sparking at contacts—when they do occur—cause greater inconvenience than is possible with the rheostat type, owing to the regulator raising or lowering the excitation to a greater extent than it is possible for the rheostat type of regulator to do. Sparking with the rheostat type is less frequently met with, and in

the event of failure this type of regulator merely cuts itself out of circuit, leaving the pressure nearer to the normal than the vibrating-contact type would do. Contact troubles with the vibrating-contact type are easily avoided by cleaning the contact points from time to time.

STABILITY.

The regulation of a given generator depends upon its magnetization characteristic, which is usually of the shape shown in Fig. 1.

The best results in automatic pressure regulation are obtained when working on the middle portion of the characteristic, just on or above the "knee" (from A to B in Fig. 1). This portion of the curve gives a proportionate

increase in pressure for a given change of the excitation, whereas in the flatter portions of the curve, beyond the saturation point, a large variation of the exciting current gives but a small increase in the generator pressure, with the result that regulation would be slow and the currents with which the regulator has to deal would be unnecessarily large.

Below the knee of the magnetization characteristic the regulation is much more rapid, but if the curve is at all steep, as with a laminated steel field (see Fig. 1), there is a tendency to instability with self-excited machines, which is more particularly noticeable with the rheostat type of regulator.

For a given generator or exciter pressure V the exciting current is I and the resistance in the field circuit is R , this giving stable working. Supposing now that, due to a change in load, V becomes increased to V' then the equation $V = I R$ becomes $V' = I'(R + r)$, where r is the resistance inserted by the automatic pressure regulator. This

equation may not give stability, for the current I' may not give sufficient excitation to maintain the pressure at V , and V may not be a sufficient terminal pressure to maintain the excitation, so that the effect becomes accumulative and the pressure falls away. The automatic regulator will cut its resistance out of circuit with this fall in pressure, the field resistance again becoming R , but the values V and I are not obtained at once as the field must be built up; due to the inertia of the field there will be an overshooting effect so that V will be momentarily exceeded, when the automatic regulator will again insert resistance reducing both the exciting current and the terminal pressure. The cycle of operations will thus be repeated, with the result that there will be continuous surging, the extent of which will depend upon the rapidity of action of the regulator. The vibrating-contact type of regulator, however, operates so rapidly that surging is not usually obtained.

For the rheostat type of regulator a curve with a gradual slope and a "knee" spread over a considerable portion of the curve—such as is obtained with a cast-iron field system—gives the better regulation, since a given change in excitation will give a proportionate change in terminal pressure, and not too large a change such as would be obtained with a steeper characteristic curve.

In installing a regulator of the rheostat type to operate in conjunction with an exciter which has a steep magnetization characteristic, or which is working on the steeper portion of its magnetization characteristic, it is often an advantage to introduce a fixed rheostat into the generator field circuit, so as to cause the exciter to work on a higher and less steep part of its characteristic. A further advantage obtained by the insertion of the main field rheostat is discussed under "Speed of Regulation."

In the case of vibrating-contact regulators the shape of the magnetization characteristic is of less importance, as the regulators can compensate for the steepness or shape of the curve by dwelling rather longer in one position of each oscillation.

AUTOMATIC REGULATOR CHARACTERISTICS.

There are two main regulator characteristics, the "static," in which each position of the regulator corre-

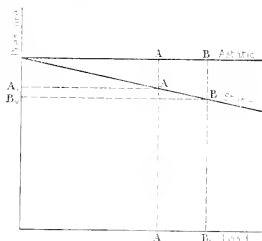

FIG. 2.

The static characteristic is a falling characteristic owing to an increase in the action of the controlling force of the regulator as the load increases not being accompanied by a corresponding increase in the operating force (the pressure coil). This characteristic is admirably adapted for use with generators operating in parallel, since no generator can take more than its fair share of the load without a corresponding decrease in pressure due to the falling characteristic (see Fig. 2).

The astatic characteristic is a level characteristic giving a steady pressure from no-load to full load, and it is obtained either by adjusting the controlling force so that it is constant at all loads, or by introducing a current element into the operating force, thereby causing an increase in the effect of the regulator with an increase in the load. This type of characteristic is unsuited for parallel operation (except in one instance), since one generator may take all the load without any action of the regulator, unless the latter is provided with a current element.

TRAILING.

By the term "trailing" is understood the regulation of a generator by means of circulating currents from an automatically regulated generator with which it is operating in parallel; that is to say, for changes in load and pressure the excitation of the automatically regulated generators is altered but that of the trailing generators remains fixed, and they are regulated by armature reaction by means of circulating currents from the regulated generators. If there is any difference in size it is usual to arrange for automatic regulation on the generators having the largest outputs. This system gives excellent results but is not so convenient, quick, or accurate, as the separate regulation of each generator.

SPEED OF REGULATION.

The accuracy of a given automatic pressure regulator depends almost entirely upon the speed of regulation. The latter depends not only upon the regulator itself but also very largely upon the design of the generator and of the exciter. A fall in pressure calls for an increase in excitation, and the time taken to effect this depends upon the "time constant" of the magnetic circuit. In the case of generators with exciters the excitation of both the generator and the exciter having to change takes a correspondingly longer time. In the case of the generator there is no final change in flux, the extra excitation being required to overcome armature reaction. The flux of the exciter, however, has also to change; this takes a longer time, and so the chances of pressure variation are greater than with a self-excited generator.

The "time constant" of a field circuit being proportional to the self-induction divided by the ohmic resistance of the circuit, it can evidently be reduced by increasing the ohmic resistance, and this is often done in the case of old-pattern machines by means of inserting ohmic resistance in the field circuits so as to increase the speed of regulation.

The speed of the vibrating-contact type of regulators is usually somewhat greater than that of the rheostat type of regulator, but in practice an accuracy of ± 1 per cent to ± 0.25 per cent is obtained with either type, this accuracy being sufficient for all practical purposes.

sponds to a definite pressure, and the "astatic," in which any position of the regulator corresponds to a constant pressure.

The principle of "overshooting," or allowing the regulator to add or cut out more resistance than is necessary to obtain correct pressure, so as to overcome the inertia of the field circuits, is one of the essential principles of the Tirrill type of regulator, but it has been employed in various other types of regulator and is successfully used with the rheostat type.

AUTOMATIC REGULATION OF CONTINUOUS-CURRENT GENERATORS.

Continuous-current generators may be classified as separately excited generators, and self-excited generators. The former type may be excited, either by an entirely separate source—in which case the regulator would act directly on the field circuit—or by means of an exciter, when it is usual for the regulator to operate on the exciter field circuit, the energy to be dealt with in that case being considerably less.

In the case of self-excited generators, whether of the shunt or compound type, the regulator must necessarily act directly on the generator field circuit. In each case, whether separately or self-excited, shunt or compound wound, it will be noticed that the generator characteristics tend to droop over on the higher loads owing to the saturation of the iron and the predominance of armature reaction. This is also true of over-compounded generators, and although certain machines are said to be "level compounded" this merely signifies that the terminal pressure at full load is the same as that at no-load.

The effect of a purely pressure regulator with a static characteristic is to straighten out the characteristic curves of the generators, raising the drooping portions and levelling the upward curves of the compounded machines.

By using an astatic or compounded regulator the generator characteristics can be so altered as to obtain level compounding with a shunt-wound generator, or overcompounding if required, which is a great advantage inasmuch as it abolishes the necessity for a compound winding on the generator.

AUTOMATIC REGULATION OF CONTINUOUS-CURRENT GENERATORS IN PARALLEL.

The automatic regulation of two or more continuous-current generators can be effected in either of two ways: each generator may have a separate regulator which is arranged with a "static" characteristic, or else one astatic regulator may control all the generators. The latter arrangement will only be possible with generators having exactly similar characteristics to avoid the circulation of currents between the generators and the demagnetization of one of them.

Trailing as a means of automatic regulation may be satisfactorily adopted with continuous-current generators operating in parallel, but in this case also the generators have to be similar in order to prevent demagnetization.

The advantage of controlling each generator separately is that the characteristics of the generators can be so altered by adjustment of their individual regulators that they will share the load equally at all loads and at constant pressure. In this case if there is no compounding arrangement the regulators should have static characteristics, so that the falling characteristics will tend to keep the load evenly distributed among the generators by

alteration of the excitation with change of load. In the case of separately excited generators operating in parallel and controlled by the same regulator, the exciters must be connected in parallel in order to ensure uniform excitation of the generators. If the excitation is not uniform then one generator may take the bulk of the load, possibly also demagnetizing the other generators.

An interesting application of the continuous-current compounding regulator is seen in the case of the automatic regulation of traction generators in parallel. In place of the usual compound-wound generators with equalizing connections, shunt-wound generators compounded by means of compounding regulators can be used, a separate regulator being provided for each generator and a current shunt being substituted for the compound winding of each generator. It will be seen from this that a single current shunt placed in the busbars and connected to each of the regulator compounding coils will give the same effect—an arrangement which is cheaper and more simple than that of using compound-wound generators and equalizing connections.

AUTOMATIC REGULATION OF ALTERNATORS.

The automatic regulation of alternating-current generators is essentially the same in practice as that of

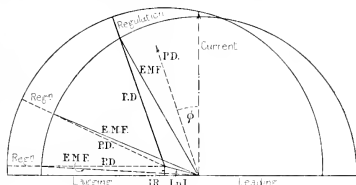

FIG. 3.

continuous-current generators, the pressure of the alternator depending upon the balance between the magnetic effect of the field and that of the armature reaction. When this balance is upset in either direction, the excitation is altered accordingly until balance is restored.

There is, however, a question of power factor to be taken into account. From a consideration of the vector diagram shown in Fig. 3 it will be seen that the amount of the regulation of an alternator depends upon the power factor at which it is working. The current is set off vectorially, and against it is plotted a vector at an angle ϕ , the cosine of which represents the power factor at which the alternator is working; this will represent the direction of the terminal potential difference of the alternator. The $I_a R$, $I_a X$, and E.M.F. vectors are set off in the usual manner and the P.D. vector will be drawn at an angle ϕ to the vertical. The difference between the P.D. and E.M.F. vectors will give the regulation pressure-drop of the alternators, and by drawing circles having their radii equal to the E.M.F. from the lower ends of the E.M.F. and P.D. vectors respectively, the regulation pressure-drop of the alternator at any power factor will be represented by the distance between the circumferences of these circles.

From the diagram (Fig. 3) it can be seen that the

potential difference is least when $\phi = 90^\circ$, and that the regulation will then be greatest; also that with a leading power factor the potential difference may exceed the E.M.F. and the regulation will be a negative quantity. This is due to the magnetizing effect of the armature reaction.

With single alternators separately controlled and working alone it is possible to regulate the pressure, but the power factor must vary with the load. With this arrangement the automatic variation of the excitation alone brings about variations of a power factor, for an increase in the excitation cannot increase the output of the alternator, this being dependent upon the mechanical power supplied to the generator.

When alternators are operating in parallel the question of the variation of power factor with automatic variations of the excitation becomes more serious and the distribution of the synchronizing and circulating currents between the generators has to be taken into account.

The following case will serve to illustrate the variation of the power factor with a variation of the excitation:—

An alternator operating in parallel with several others is automatically regulated. The potential difference at the

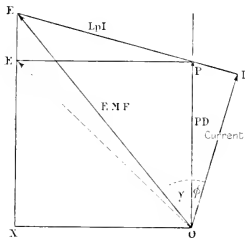

Fig. 4.

terminals will be practically constant, as will also be the mechanical power supplied by the prime-mover. The armature resistance being so small can be neglected, so that the power taken from the prime-movers and converted into electrical power

$$= \frac{\text{E.M.F.} \times \text{terminal P.D.}}{\text{Self-induction of the armature}} \times \text{Sine of the angle between E.M.F. and P.D. vectors.}$$

In Fig. 4 the terminal P.D. is shown lagging by an angle γ behind the vector of the E.M.F. generated and in advance of the current by an angle ϕ .

Let OP = terminal P.D. vector,

OE = vector of E.M.F. generated,

P = power taken from the prime mover and converted into electrical power,

$L\phi I$ = armature self-induction,

$L\phi I$ = E.M.F. of armature self-induction.

$$\text{Now } P = \frac{\text{E.M.F.} \times \text{P.D.}}{L\phi} \times \sin \gamma,$$

$$\therefore P \times L\phi = \text{E.M.F.} \times \text{P.D.} \times \sin \gamma.$$

Since P and the P.D. are constant, and the triangle $OPE = P.D. \times \text{E.M.F.} \times \sin \gamma = P \times L\phi$, \therefore the triangle OPE must have a constant area.

The result of this is that as the E.M.F. is varied by automatic adjustment of the excitation, the point E (Fig. 4) will move up and down a line EX parallel to the P.D. vector OP , which is the base of the triangle OPE .

Now $PE = L\phi I$ = the inductive drop in the armature 90° out of phase with the current. If the excitation be decreased till $OE = OE_n$, the inductive drop $L\phi I$ will have a minimum value PE_n .

And since $\sin \gamma$ now = $\frac{PE_n}{\text{E.M.F.}}$, by substituting in the equation—

$$P = \frac{P.D. \times \text{E.M.F.}}{L\phi} \times \sin \gamma,$$

$$\text{one obtains } P = \frac{P.D. \times \text{E.M.F.}}{L\phi} \times \frac{PE_n}{OE_n}$$

$$= \frac{P.D. \times \text{E.M.F.} \times L\phi I}{L\phi \times \text{E.M.F.}}$$

$$= I \times P.D.$$

That is to say the power taken from the prime-mover and converted into electrical power is equal to the product of the terminal pressure and the current; hence the generator is working at unity power factor.

From this it can be seen that if a generator operating in parallel with other alternating-current generators at a certain load has its excitation reduced until the armature current is a minimum, the machine becomes loaded non-inductively. Increasing the excitation increases the E.M.F., causing E to travel further along EX and causing the current to lag; and similarly decreasing the excitation will cause the current to lead. It can also be seen that the excitation cannot be reduced so that PE becomes less than OX , for the generator will then fall out of step. By increasing PE greater changes of OE and hence of the excitation can be brought about without such a great effect on the current, and generators with large internal inductive pressure-drops will be comparatively insensitive to changes of excitation; hence they are not good for purposes of rapid automatic pressure regulation and call for considerable over-shooting on the part of the regulator.

There is no advantage to be gained by trying to lower the excitation of one generator so as to obtain unity power factor, since the generator would then have no wattless component to its load, so that if the external load were at all inductive, as is more than probable, the wattless component would have to be entirely taken up by the other generators. It is therefore better to arrange the excitation so that the wattless component of the load is shared equally among the generators, and one of the objects of automatic pressure regulation is to share out the wattless component of the load equally among the various generators.

AUTOMATIC REGULATION OF ALTERNATORS IN PARALLEL.

The automatic regulation of alternators in parallel consists in the maintenance of constant busbar pressure

and the even distribution of wattless currents as indicated above. The busbar pressure is maintained by the regulators operated by the pressure of the busbars to which their pressure coils are attached directly or through pressure transformers.

If all the generators be similar and have similar exciter characteristic curves they may be controlled by a single regulator provided that the exciters are paralleled to ensure uniform excitation, without which regulation would be carried out by the circulation of currents between the generators, resulting possibly in demagnetization.

Better regulation is obtained by using a separate regulator for each alternator; it is then unnecessary to parallel the exciters and the individual regulators can be adjusted to compensate for peculiarities of their respective generators. In this case the regulators should have static characteristics. If the generators are unlike or are excited by dissimilar exciters it is quite feasible to regulate one or two generators and allow the others to trail.

For the proper distribution of wattless currents between the generators at the same time that constant busbar pressure is maintained, it is necessary that the regulators should be operated both by the pressure and the current of each generator; also each generator should have a separate regulator, with a pressure transformer, and a current transformer should be placed between the generator and the busbars in one of the phases to which the pressure transformer is connected. The regulators should be arranged so as to have static characteristics when operating without the current transformers.

If there is a phase displacement between the current and pressure of an alternator controlled as described above, the action of the current coil on the regulator will be modified proportionately to the phase displacement. The regulation by this arrangement will therefore not be uniform unless the power factor of the station is practically constant. In spite of this disadvantage there are many power stations supplying traction and colliery loads where this arrangement is operating very satisfactorily, although there are necessarily circulating currents between the generators.

A method of automatically controlling both the pressure and power factor of alternators operating in parallel and supplying rapidly fluctuating loads is due to Messrs. Brown, Boveri & Co. Regulators with astatic characteristics are employed, and the secondary coils of the several current transformers are connected in opposition, so that as long as there is an even distribution of load and of the wattless component no current flows from them to any of the regulators, which latter will be acting merely as pressure regulators. Any phase displacement, however, will be accompanied by a circulation of currents between the generators, so that the current transformers of the various generators will supply current to the current coils of their respective regulators, increasing and decreasing the excitation of the generators as required. This system gives an even distribution of the wattless component of the load between the generators independently of their types and sizes, and it is very satisfactory in the case of heavy and rapidly varying loads.

CASCADE CONNECTIONS.

By H. V. HENNIKER, Student.

(Abstract of Paper read before the NEWCASTLE STUDENTS' SECTION 28th April, 1913.)

One of the foremost problems in connection with the use of polyphase current for power purposes is the provision of suitable variable-speed motors. The disadvantages attending the usual arrangement of an induction motor with a variable resistance for adjusting the amount of slip are well known, and it is unnecessary to enter into a discussion of them here. In view of the incomplete state of development of the 3-phase commutator motor, however, the induction motor has been extensively used as a variable-speed machine; in fact, there has been no alternative in the case of large installations.

There have been many suggestions for varying the speed of an induction motor without the waste of energy entailed in the rotor resistance method, and probably the most important of these, at any rate for large powers, are the various applications of the cascade or series principle.

CASCADE CONNECTION OF INDUCTION MOTORS.

We may define the cascade system as an arrangement of an induction motor having in its rotor circuit a machine or machines which, in addition to providing the back electromotive force necessary to effect speed variation of the

induction motor, can at the same time usefully employ the slip energy which would otherwise be wasted in resistance. The original arrangement, as suggested independently by Steinmetz in America and Gorges in Germany so long ago as 1807, is shown in Fig. 1. Connected in series with the rotor of the induction motor of which the speed is required to be varied is another induction motor, known as the auxiliary or regulating motor. The function of this auxiliary motor is to provide a back electromotive force and to employ the slip energy of the main motor usefully. The rotors of the two machines are mechanically coupled, and by this means the energy of the auxiliary motor is added to that of the main motor. Such a combination has a definite synchronous speed, which is quite different from the synchronous speed of the main motor or auxiliary motor when running alone. The synchronous speed of a cascade set depends upon the number of poles of both motors, and the following considerations should make this clear.

At the moment of switching on, the frequency of the supply to the stator of each machine is the same, since the rotor of the main motor is stationary. As the set gains

speed, however, the frequency of the rotor currents in the first motor decreases, i.e. the frequency of supply to the second stator decreases. Thus in the second machine the speeds of the rotating field and of the rotor become more nearly equal, and clearly there is some point at which they would be the same. The speed at which the second motor is rotating in synchronism with its field is the limiting speed of the set and may be termed the "synchronous speed of the combination." This speed could be actually attained if the second motor were a true synchronous machine, or in the hypothetical case of a second induction motor having no rotor resistance; but in the present case a state of stability is reached when a speed only slightly less than that of the rotating field of the second motor is attained, and at this point the combined torque is a minimum. The fundamental theory of the cascade connection of induction motors states that the speed of the common shaft must be such that the last motor is rotating almost synchronously with its field, and this holds true whatever the number of motors connected in cascade.

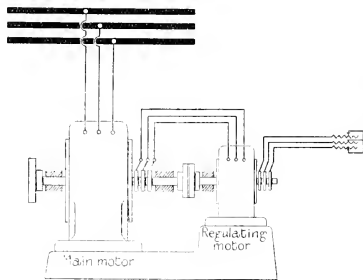

FIG. 1.

Consider, first, the case of the direct coupling, or a gear ratio of 1:1.

Let f = frequency of supply to first motor,
 f_1 and f_2 = number of pairs of poles on first and second motors respectively,
 n_1 and n_2 = speeds of rotating field in first and second motors respectively,
 f_s = frequency of rotor currents of first motor,
 s_2 = fractional slip of second motor,
 n = speed of common shaft.

When the combination is running we have from first principles—

$$f_s = f_1 (n_1 - n) \quad \dots \dots \dots (1)$$

Now f_s is the frequency of the currents supplied to the stator of the second motor. Therefore $f_s = f_2 n_2$. Transposing, we have—

$$f_1 n_2 = f_2 (n_1 - n) \quad \dots \dots \dots (2)$$

Further, the slip of the second motor is given by

$s_2 = (n_2 - n)/n_2$, or $n_2 = n/(1 - s_2)$. Substituting in equation (2) we obtain—

$$n = n_1 \frac{f_2 (1 - s_2)}{f_1 (1 - s_2) + f_2} \quad \dots \dots \dots (3)$$

and this is the actual speed of the shaft.

Now we have seen that s_2 is small; therefore neglecting this quantity we may write $n = n_1 f_2 / (f_1 + f_2)$, or—

$$n = \frac{f}{f_1 + f_2} \quad \dots \dots \dots (4)$$

which is the synchronous speed of the combination. Thus the effect of connecting up the motors in cascade is to combine their respective numbers of poles, so that the synchronous speed of the cascade couple is the same as that of a single motor having $(f_1 + f_2)$ pole pairs. In general, with two motors connected up in this manner three speeds are available—

- (1) The speed of the first motor (the second motor running idle).
- (2) The speed of the second motor (the first motor running idle).
- (3) The cascade speed.

Intermediate speeds under load can be obtained by the use of rotor resistance in the second motor. Pole-changing windings may also be provided, and other speeds made possible. If $f_1 = f_2$, then $n = \frac{1}{2} n_1$, and the cascade speed is half the speed of either motor when connected alone to the mains. In this case the arrangement is similar to the series-parallel control of continuous-current motors, since the machines may be used separately, in cascade, or in parallel.

Torque and horse-power.—In an induction motor the total number of watts W supplied to the rotor may be considered as consisting of (a) the useful watts, and (b) the losses.

The rotor efficiency is given by—

$$\eta_r = \frac{\text{useful watts}}{\text{useful watts} + \text{losses}}$$

The torque is proportional to $\frac{\text{useful watts}}{\text{actual speed of shaft}}$.

Applying these principles to the first motor of a cascade set, let—

W = total watts supplied to rotor of first motor,
 and w = watts usefully employed.

Then, from the well-known equation for rotor efficiency—

$$\eta_r = \frac{w}{W} = \frac{n}{n_1} \quad \text{or} \quad w = \frac{W n}{n_1} \quad \dots \dots \dots (5)$$

Now if the speed of the main motor had been reduced to n by means of external resistance, we should be continually wasting the other component of W in resistance, this loss being almost entirely external in the case of anything more than a slight speed reduction. What the auxiliary motor really does is to provide a back electromotive force equal to the drop of voltage which would take

place across an external resistance necessary to effect this speed reduction. Moreover, this back electromotive force, instead of representing additional loss, is a measure of the mechanical energy exerted by the auxiliary motor. Thus, neglecting the small losses in rotors 1 and 2 and in stator 2, the power exerted by the second motor may be denoted as—

$$W(1 - n/n_1) \quad (6)$$

Since the actual speeds of the motors are the same, namely n , expressions (5) and (6) will be proportional to the torques exerted. Substituting for n/n_1 from equation (4) we find that the relative torques are such that $T_1/T_2 = f_1/f_2$, i.e. the motors share the torque in the proportion of the number of their poles to the total number of poles. The total torque is of course the sum of the individual torques, and neglecting losses is given by—

$$T = \text{constant} \times \frac{W}{n} \quad (7)$$

It is of course to be understood that motor 2 cannot strictly be looked upon as a non-inductive resistance.

As regards horse-power, it is clear that this is limited by the rating of the first motor, since the second motor only takes up energy proportional to the regulation of the first motor, whatever the actual rating of the second machine may be. The latter would of course be designed according to the maximum regulation required for the former.

Efficiency.—The efficiency of a cascade set may be determined as follows:—

Let P = power drawn from mains,
 P_1 = power exerted at shaft.

Then P_1 = mechanical energy of main motor + mechanical energy of auxiliary motor.

$$= P e_1(1 - a) + P e_1 e_2 a \quad (8)$$

where e_1 = efficiency of main motor,
 e_2 = efficiency of auxiliary motor,
 a = speed regulation of main motor.

Then overall efficiency = $P_1/P = e_1 - e_1 a + e_1 e_2 a \quad (9)$

As regards losses, the losses in the first machine are relatively the higher, and Hobart* has suggested that each motor should be alternately connected to the mains. This would be satisfactory in the case of two similar motors so long as both are wound for the supply voltage. In the case of a smaller second machine, however, the rating of the set will become less if the change of connections takes place; moreover, the frequency in the circuit connecting the machines will be higher and the total iron loss greater, causing a decrease in efficiency and a greater temperature rise. The cascade speed will of course remain practically the same in either case.

Gear ratio.—The case where gearing is used between the machines requires special treatment. As before, the second machine must rotate almost synchronously with its field; thus the effect of the gear will be to alter the slip of the main motor.

Let the gear ratio be such that $N_1/N_2 = K$,

where N_1 = actual speed of first motor,
 N_2 = actual speed of second motor.

From the equation for rotor frequency—

$$\begin{aligned} f_1 &= f - f_1 N_1 \quad (10) \\ &= f_2 N_2 \\ &= f_2 N_2, \text{ neglecting slip of second motor,} \\ &= f_2 N_1/K \quad (11) \end{aligned}$$

$$\text{Equating (10) and (11) we have } N_1 = \frac{f}{f_1 + f_2/K} \quad (12)$$

The speed of the second motor is obviously $1/K$ of this.

DIFFERENTIAL CONCATENATION.

The foregoing calculations have been based on the assumption that the field in each motor revolves in the same direction. If the leads to the second machine are crossed so that the field in this machine rotates in the opposite direction to that in the first, the synchronous speed of the set will be that of a motor having poles equal to the difference of the individual poles, and is such that—

$$n = \frac{f}{f_1 - f_2} \quad (13)$$

The torque of the set will be given by the difference of the individual torques, but the aggregate horse-power remains the same as for direct concatenation. The above equation may be deduced in a similar manner to that already given for direct concatenation, provided a proper convention is preserved with regard to which is positive and which negative rotation, but the theoretical considerations involved are outside the scope of this paper. Also the equations require careful interpretation according to whether the first motor is that having the greater or lesser number of poles. It may be mentioned that if the motor with the greater number of poles is connected to the line, the set will not of its own accord reach cascade speed, since the speed of synchronism of the first motor is lower than the cascade speed. It will therefore be necessary to run up by connecting the machine having the smaller number of poles to the line and to change over to the normal connections when the cascade speed is nearly attained.

It is not necessary to limit the set to two motors. For instance, the synchronous speed of an arrangement consisting of three motors, the first two being in direct and the second and third in differential connection, may be shown to be:—

$$n = \frac{f}{f_1 + f_2 - f_3} \quad (14)$$

With an arrangement of three motors 10 different speeds could be obtained; but such arrangements seem to be of purely theoretical interest.

It is well known that the behaviour of an induction motor is only altered as regards rotation if instead of the stator the rotor is wound for connection to the mains. In such a case the stator forms the secondary, and this being fixed and not able to follow the field, the rotor must

* H. M. HOBART. "Electric Motors."

* Electric Journal, vol. 6, p. 422, 1909.

rotate in the opposite direction to the field. The limiting speed will be attained when the rotor runs at a speed equal to that of the field but in the opposite direction to it, since at this point the field will be stationary in space and there will be no electromotive force induced in the stator. In the cascade set we may connect the rotors electrically instead of connecting the first rotor to the second stator. To obtain, however, an additive effect of the poles, and in order that the torques of the machine may be in the same direction, it will be necessary to arrange the connections so that the field in the second machine revolves in the opposite direction to that in the first, otherwise the effect will be that of the differential method. Slip-rings may now be dispensed with, and the starting resistance may be inserted in the second stator. These are the underlying principles of the Hunt cascade motor, in which the two rotor and two stator windings are merged into two single windings.

APPLICATIONS.

It has been stated that the method shows a higher efficiency than where the control is by resistance in the rotor circuit, since the only losses are those in the machines themselves. Against this, however, must be balanced the low power factor obtained with the ordinary cascade set. Two magnetizing currents have to be supplied; for, in addition to the magnetizing current necessary to produce the rotating field in the first motor, the first motor has to supply the wattless current of the second motor. Thus, although it is theoretically possible to run a large number of motors in cascade and so obtain many different speeds, power factor imposes a limit. In fact with large low-speed sets the advisability of connecting up even two motors in this manner is extremely doubtful. Whether the cascade system is desirable in any particular instance will depend upon circumstances. The following comparative figures are interesting in connection with the question of power factor *versus* efficiency. They refer to a fan installation in a German colliery.

System	Main Motor		Speed Regulation, 8%		Speed Regulation, 20%	
	h.p.	i.p.m.	Eff.	Power Factor	Eff.	Power Factor
Slip resistance ...	1,200	250	0.89	0.89	0.72	0.80
Cascade	1,200	250	0.94	0.75	0.92

Reference has just been made to the use of this method of control in connection with fan driving. As the workings of a mine extend the fans are required to run at higher speeds in order to deal with the increased volume of air. At week-ends also it is often not necessary for them to run at full speed. Two or three fixed speeds generally meet the case, and continuous speed control is unnecessary. Consequently the cascade system has achieved some popularity in this direction. A number of rolling mills in Sweden have been equipped with cascade control. An important requirement in connection with rolling-mill work is the adjustment of the no-load speed so as to ensure proper handling of the material at

the beginning of a pass. Although the cascade system suffers from the defect of running back to synchronous (cascade) speed directly the load is removed (as is the case with a single motor), it is possible to obtain several no-load speeds by suitably choosing the numbers of poles. Also the characteristic of a cascade set is suitable for rolling-mill work, for the available energy on the shaft being constant for a given input, the torque varies inversely as the speed. It is not possible, either with the rotor resistance method or the cascade method, to compound for flywheel effect, except by the use of an automatic slip regulator.

The cascade system lends itself to fraction owing to the possibility of regenerative braking when the set is artificially raised above cascade speed. The extent of this generator period depends upon the sizes of the machines, but can be extended by the use of rotor resistance in the second motor.² The best-known examples of cascade control for traction work are afforded by the locomotives running on the section of the Italian State Railways known as the Valtellina Railway. These locomotives, supplied by Messrs. Ganz & Co. of Buda-Pesth, have been fully described elsewhere.

MOTOR CONVERTER.

A familiar example of a cascade connection for a purpose other than variable-speed work is afforded by the well-known La Cour motor converter. This consists of an induction motor connected in cascade with a rotary converter. The machines are rigidly coupled, and the rotor of the induction motor and the armature of the converter are connected in series. From the formula for the cascade speed the synchronous speed of a motor converter is given by $n = f/(p_m + p_c)$, where p_m = number of pairs of poles on motor, and p_c = number of pairs of poles on converter. This speed, moreover, will actually be attained, since the second machine is a synchronous one. At the cascade speed the rotor currents of the induction motor will drive the converter in an exactly similar manner to the armature currents of a synchronous motor, since the rotating field in the armature of the converter will be stationary in space relative to the poles of the machine. As in the case of two induction motors, a portion of the input is given out as torque at the induction-motor shaft, and the remainder is transmitted electrically to the second machine, in this case the converter. The generator portion of the machine therefore acts partly as a generator driven by the induction motor and partly as a converter driven by the rotor currents of the induction motor. On reference to the previous calculations it will be clear that—

$$\frac{\text{Mechanical power exerted by induction motor}}{\text{Power transmitted electrically to converter}} = \frac{p_m}{p_c}$$

MODIFICATIONS OF THE CASCADE PRINCIPLE.

It is obvious that it is by no means necessary to employ an induction motor as the auxiliary motor of a cascade set, and also that the slip energy need not necessarily be given up to the main shaft (though this is the only solution in the case of the induction-motor auxiliary). Consequently we find that there are many variations of the cascade

* STEINMETZ. "Theory and Calculation of Alternating-current Phenomena."

principle, and that the whole field is covered by patents in all directions. It will only be possible to consider a few of the more important systems here.

It has been suggested that a synchronous motor be used as the auxiliary machine. Such an arrangement would allow of phase compensation. There are several obvious disadvantages, however, and the author can find no indication that the method has been employed. A more satisfactory solution is the adoption of a commutator-motor auxiliary, and such a motor can be designed to lend itself admirably to the purpose. The well-known Krämer and Scherbius systems both employ a 3-phase commutator motor to give the necessary back electromotive force, but they differ in the method of making use of the energy developed by the commutator motor. In both cases speed regulation of the main motor is obtained by varying the excitation of the commutator motor, and thus varying its back electromotive force. In the case of the induction-motor auxiliary there is only a small range of variable back electromotive force available, and, in general, if a speed higher than the cascade speed is desired the auxiliary

According to the characteristic required for either of these sets, the commutator motor is series wound and has a brush-rocking device, or is shunt or compound wound and has pressure regulation. In the case of the shunt winding any no-load speed may be obtained, and the speed will vary only slightly with the load. With a compound winding on the regulating motor the speed of the main motor may be made to decrease by any desired amount as the load increases. The figures show the shunt arrangement, which is more commonly employed. The Scherbius system is particularly applicable to the driving of large centrifugal machines in which the horse-power required greatly diminishes with the speed. The Krämer system is recommended for rolling mills, but for cases in which wide regulation is required it is generally preferable to adopt the former system. The commutator motor is of special design to meet the requirements of the case, and has the characteristics of a continuous-current machine. Moreover, by means of a special form of field winding it is possible to compensate for lag in the main motor.* This machine must not be confused with the Scherbius phase advancer.

- D Belt drive.

motor must be disconnected. With the commutator motor, however, a far wider range of back electromotive force can be obtained, and the speed of the main motor can be controlled through a wide range without loss. The commutator motor can, moreover, be rendered entirely independent of the frequency of the current supplied to it, so that it is not necessary to couple it mechanically to the main motor. In the Krämer system, however, the machines are mechanically and electrically coupled as shown in Fig. 2. The slip energy is thus given out as energy at the main shaft, and at any load the torque will vary inversely as the speed.

In the method of Dr. Scherbius (see Fig. 3) the commutator motor is independent of the main motor, but is coupled to an induction generator which returns the greater portion of the slip energy of the main motor to the line in the form of electrical energy. In this case the horse-power of the main motor decreases with the speed, since the regulating set is not mechanically coupled. The torque of the main motor will therefore remain constant.

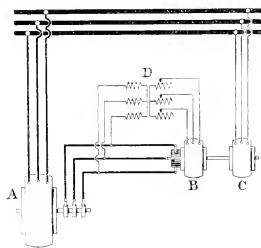

FIG. 3.—Scherbius System.

- A Main motor.
- B Auxiliary commutator motor.
- C Induction generator.
- D Variable-ratio transformer.

For purposes of comparison the following table may be given. The figures refer to a mine fan installation in Westphalia. The main motor is a 5,000-volt, 3-phase, 50-cycle machine, the commutator motor is built for 200 k.v.a., and the induction generator for 85 kw.

System		Main Motor		Speed Regulation, 8 %		Speed Regulation, 26 %	
		h.p.	r p m.	Eff.	Power Factor	Eff.	Power Factor
Scherbius	...	1,000	363	0.90	1.0	0.83	0.98

There is seen to be a great improvement in power factor but a slight reduction in efficiency when compared with

simple cascade control. Besides the driving of rolling mills and fans the Scherbius system has been used in connection with flywheel buffer sets to relieve a central station of heavy overloads, and it is interesting to note that a set is

motor set is here useful owing to the possibility of raising the speed above synchronism.

KRÄMER CONVERTER SYSTEM.

Another well-known system, also due to Mr. Krämer, is that employing a rotary converter. The slip energy is led to a rotary converter which converts it into continuous current. This current is led to a continuous-current motor which is mechanically coupled to the main motor, and the slip energy is thus given up to the common shaft. Speed variation is obtained by altering the excitation of the continuous-current motor. For instance, if resistance is removed from this excitation circuit the back electromotive force of the motor increases. This causes the continuous-current pressure of the rotary converter to rise, and with it the pressure at the slip-rings. To enable this to take place the slip of the main motor must increase and there will be a decrease in speed. When working with a flywheel, a compound winding may be provided on the continuous-current motor. The power factor may be adjusted by means of the converter field. It is possible to extend the speed above synchronism by reversing the excitation of the continuous-current motor when the set is running at full speed. This motor will then run as a generator and reverse the direction of rotation of the converter. A field will consequently be set up in the rotor of the induction motor revolving in the opposite direction, and the speed will rise above synchronism. Normally, however, the highest speed possible is limited by the lowest frequency necessary for stable running of the converter, say 3 cycles per second. This set is particularly useful in cases of wide regulation, and is at work in a number of large rolling mills.

to be employed for this purpose on the Valtellina Railway. Both systems have been applied to the driving of turbo-pumps, compressors, and blowers. Owing to the very high speeds often required in such cases, a commutator-

HEATING OF BURIED CABLES.

INTRODUCTORY.

Last year the Council announced that it had appointed a Research Committee to promote and organize research on electrotechnical matters. The lack of sufficient data on the temperature rise of mains and cables buried in the earth was brought to the notice of the Committee and a Sub-committee was appointed to consider this matter. The Sub-committee was of the opinion that additional data were required, especially in those cases where the cables are buried and protected in the manner usually employed in this country; and the Sub-committee considered that experimental tests should be made in order to obtain these data.

On the recommendation of the Research Committee the Council decided to make a grant in aid of a research on the Heating of Buried Cables.

The Sub-committee has had a careful investigation made of the previous work which has been done and of the matters which require further investigation. A summary of the present knowledge on the subject has been prepared for the Sub-committee by Messrs. S. W. Melsom and H. C. Booth and is reproduced below, so that the members of the Institution may be able to judge of the present position and may make suggestions for consideration by the Committee.

The research will be divided into two parts. The first part will consist of a series of tests which will be carried out at the National Physical Laboratory. Lengths of cables of various sizes will be laid on different systems in the Laboratory grounds, and a number of tests will be made on the temperature rise of these cables under various conditions, and the soil constants, etc., will be determined. The second part of the research will consist of tests on actual mains under as nearly as possible practical conditions.

The facilities for these tests will be available owing to the courtesy of many of the supply authorities and others who have offered, on the invitation of the Sub-committee, to co-operate by allowing tests to be carried out on their networks.

The following provisional programme, prepared by the National Physical Laboratory, indicates the points which it is hoped to elucidate by the present research.

The Sub-committee will welcome any suggestions which may be of assistance in bringing the work to a successful conclusion.

W. D.

REPORT OF THE NATIONAL PHYSICAL
LABORATORY.

From the summary (see below) of the experimental work already done it will be seen that while the constants for armoured cables laid direct in the ground have been fairly well determined, there is practically no information available regarding cables drawn into conduits or laid solid in bitumen.

In considering the German tables for armoured cables laid direct in the ground in relation to the conditions obtaining in this country, it is probable that such important factors as the depth of laying, the amount of moisture in the soil, the temperature of the soil, etc., will be rather different.

In the absence of any knowledge as to the requisite thermal constants it is obviously impossible to produce from the information already published a table of permissible currents for cables laid solid in bitumen or drawn into ducts. Even for armoured cables laid direct in the ground, owing to the possible difference of the important factors mentioned, it would be necessary to re-determine the constants before the formulae could be applied. It must also be pointed out that in arriving at these formulae it has been necessary to make certain assumptions which render it doubtful whether they can be regarded as of greater validity than empirical formulae. Thus, there is considerable doubt involved in assuming the surface of the ground to be an isothermal surface. This certainly cannot be the case where the size of the cable or of the surrounding duct is more nearly comparable with the depth of laying than is assumed in the mathematical treatment.

Further, even where the mathematical conditions are better realized as in the case of armoured cables laid direct in the ground, on account of the different conditions as regards the amount of moisture at various depths and other causes it cannot be definitely assumed that the surrounding soil is even approximately homogeneous in its thermal properties.

Some preliminary experiments made at the Laboratory, the results of which were given in a previous paper,^{*} show that the heating may differ under various conditions of laying by as much as 100 per cent, and in the discussion of the paper Mr. Beaver gave some curves showing the same order of difference.

Another important factor to be borne in mind is the rate of heating and cooling of a cable and its relation to the load factor.

The more important points to which the research should be directed are as follows:—

- (1) To obtain definite information as to the temperature of, and the moisture in the soil.
- (2) Determination of the thermal constants of the soil, of the cable coverings, and of the various ducts.
- (3) The heating of cables when laid (a) direct in the ground, (b) solid in bitumen, and (c) drawn into ducts, the external thermal conditions being the same.
- (4) The temperature attained by mains in actual service and the load factor of the cables. (This would, it is expected, give also valuable information as to the rate of heating and cooling of cables laid in various ways.)
- (5) To determine the watt losses in different types of cable with alternating current.

SUMMARY OF THE THEORETICAL AND EXPERIMENTAL WORK ALREADY PUBLISHED ON THE HEATING OF BURIED CABLES.

By S. W. MELSOM, Associate Member, and H. C. BOOTH.

INTRODUCTION.

The theory of the rise of temperature of a buried cable appears to have first been given by Kennelly.¹ The surface of the conductor itself is an isothermal surface, and if θ be the excess of temperature of this surface above that of some other surrounding it, H the heat generated per unit time in unit length of the cable, R the resistance to heat transference of the space bounded by these two isothermal surfaces and two planes perpendicular to the cable at unit distance apart, then we have $H = \theta/R$. Now we may divide R into two parts, S and G , where S is the resistance of the insulating and other coverings surrounding the wire, G that of the material—earth, sand, etc.—between the outer covering of the wire and the external isothermal. We have then $H = \theta/(S + G)$.

As to S , in the case at least of a single core of diameter d with a single outer covering of diameter d_1 and heat resistivity σ_1 , its value is $\frac{\sigma_1}{2\pi} \log_e \frac{d_1}{d}$, while if there be a number of concentric coverings of diameters d_2, d_3, \dots, d_n of heat resistivities $\sigma_2, \sigma_3, \dots, \sigma_n$, we have—

$$S = \frac{1}{2\pi} \left\{ \sigma_1 \log_e \frac{d_1}{d} + \sigma_2 \log_e \frac{d_2}{d_1} + \dots + \sigma_n \log_e \frac{d_n}{d_{n-1}} \right\}$$

a formula employed by Teichmüller. This formula can be simplified if any of the layers are good conductors, for then for such a layer σ vanishes; while if the insulating materials between these conducting layers, e.g. in a concentric cable, be the same, σ is for these the same; thus in a concentric cable we might have $\sigma_2 = \sigma_3 = \sigma_4 = \dots = \sigma_n$, say; thus—

$$S = \frac{\sigma_s}{2\pi} \left\{ \log_e \frac{d_1}{d} + \log_e \frac{d_2}{d_1} + \dots \right\} \\ = \frac{\sigma_s}{2\pi} \log_e \frac{d_1}{d} \cdot \frac{d_2}{d_1} \cdot \frac{d_3}{d_2} \cdot \dots$$

For a multicore cable non-concentric, Mie has shown how to deduce a corresponding expression.

As to G , various suppositions have been made. Kennelly supposes that we may consider the earth as a plane isothermal surface; and treating the problem by the method of images, as in Foster and Lodge's paper,² arrives at the result that—

$$G = \frac{\sigma_e}{2\pi} \log_e \left\{ \frac{2l}{d_n} + \sqrt{\left(\frac{4l^2}{d_n^2} - 1 \right)} \right\}$$

where σ_e is the thermal resistivity of the soil, d_n the diameter of the external covering of the cable, and l the depth below the surface of the ground of a point in the cable, not far removed from its centre and coinciding with the focus of the system of isothermals of which the cable forms one. In the practical application of theory the point may be taken as on the axis of the cable. More—

* A. E. KENNELLY. On the carrying capacity of electric cables submerged, buried, or suspended in air. *Electrical World*, vol. 22, p. 183, 1893.

† *Philosophical Magazine*, 1875.

over, the ratio l/d_n is large in practice— l may be about a metre and d_n some 2 or 3 cm.—thus $4l^2/d_n^2$ is large compared with unity, and we may write—

$$G = \frac{\sigma_e}{2\pi} \log_e \left(\frac{4l}{d_n} \right).$$

In this form the formula is used by Teichmüller and others.

A different assumption is that the isothermals form a system of cylinders round the wire, and that we may assume that a cylinder with the axis of the cable as centre and of radius l which just touches the earth's surface, therefore above the cable, has the temperature of the surface. On this assumption

$$G = \frac{\sigma_e}{2\pi} \log_e \frac{2l}{d_n}.$$

This is used by Apt, Humann, and, with a slight modification, by Wilkens. These writers also neglect the term S in comparison with G , thus assuming that the thermal resistance of the insulating coverings is small compared with that of the earth. If, however, the two terms are evaluated for some actual cases, it appears (p. 783) that S and G are of the same order of magnitude. Again, the assumption of cylindrical isothermals round the cable is not justifiable: the cable is not under symmetrical conditions all round, and while experiments show that the surface temperature above a cable may be affected by its presence to some extent, Kennelly's assumption that the earth's surface is isothermal probably expresses the facts fairly closely.

This theory, then, of cylindrical isothermals will give too low a value for the resistance, and will lead to the inference that a given current will produce a smaller rise of temperature than is actually found to be the case, and in the Report of the Commission of the Verband deutscher Elektrotechniker in 1907 its authors accepted Kennelly's theory, as extended by Teichmüller, as giving a better representation of the facts.

Thus, so far as an isolated single-core or concentric cable laid direct in the ground is concerned, if we know the diameters of the conductor and its coverings and the thermal resistivities of these and of the ground, we have the material for calculating the rise of temperature due to any current. If we can neglect the term S , both formulae can be simplified, since the values of the ratio d_n to l occurring in practice are such that for considerable variations in the value of either of these quantities the terms $\log_e 4l/d_n$ and $\log_e 2l/d_n$ are practically constant, as is illustrated on p. 782. Thus Apt's formula becomes

$$H = \frac{2\pi\theta}{\sigma_e \log_e 2l} = k\theta, \text{ say.}$$

Now $H = 4\rho I^2/\pi d^2 = \rho I^2/\Lambda$, where ρ is the resistivity of the conductor. Thus $I = \sqrt{k\theta\Lambda/\rho} = \gamma\sqrt{\Lambda}$ if $\gamma = \sqrt{k\theta/\rho}$, a constant for a given rise of temperature θ . On Kennelly's theory, omitting S we get the same form, but the value of γ would be decreased in the ratio $\log_e(2l)/\log_e(4l)$.

If the term S be included no such simplification is possible. The problem of a number of cables close together of various sizes and each carrying its own current is much more complex, and for this data are wanting.

Reference should be made to Mie's paper which deals with the case when the current is the same in each branch of a multicore cable.

A more detailed account of the various experimental investigations follows.

SYMBOLS EMPLOYED.

The various authors have naturally used different symbols in their mathematical treatment of the problem. In order to facilitate a comparison of the various formulæ, the following common list of symbols has been prepared and used as far as is possible throughout the abstracts.

I = Current, in amperes, for a single cable.

I_1, I_3 , etc. = Current which each conductor in a concentric or multicore cable can carry.

ρ = Resistivity of the metal of the conductor in ohms per square millimetre at the temperature of working.

A = Cross-section of conductor in square millimetres.

θ = Temperature rise in the conductor in degrees Centigrade.

σ_e = Thermal resistivity of the material of the soil in electrical measure at a temperature corresponding to the mean temperature elevation.

σ_k = Thermal resistivity of the insulating material and covering of the cable in electrical measure.

$m = \sigma_k / \sigma_e$.

d = Diameter of the conductor in millimetres.

d_1, d_2, d_3 , ... = Diameters of the successive layers of the insulating material, sheathing, armouring and protective wrappings in millimetres.

d_4 = Outer diameter of finished cable in millimetres.

Z = Number of conductors in a concentric or multicore cable.

l = Depth of the cable axis below the surface of the ground in millimetres.

Dr. Kennelly discusses* the theory of the subject and describes the practical experiments which he had made at the Schenectady Works of the General Electric Company. Kennelly's theoretical treatment of the subject, which has been followed by several subsequent investigators, has been fully dealt with in the introduction. It is an essential part of his theory that the surface of the ground should be supposed to be an isothermal. From experiments with a 750-ampere cable buried at a depth of 1 metre, he found that the temperature elevation at the surface of the ground immediately over the cable would differ from the normal by less than 2° C., even ignoring the greater reducing influence of the wind, etc.

Experimenting under working conditions on a particular type of cable (insulated with Siemens' compound and lead covered), Kennelly found values for the two thermal resistivities involved, viz. $\sigma_k = 750$; $\sigma_e = 50$. These values are most conveniently expressed in electrical units, i.e. a centimetre cube has unit resistivity when 1° C. difference

of temperature between two opposite faces produces a steady flow of one Joule of heat per second.

In order to deal with cases where two or more cables are laid in the same trench, Kennelly gives curves and tables which enable the position of the isothermal surfaces in the region surrounding the cable to be determined. In addition to the heat developed by the current which it carries, each cable will assume the temperature corresponding to the isothermal at that place, due to the presence of a neighbouring active cable. If there is more than one such cable the separate effects of each must be superposed. This involves as a further assumption that the introduction of the neighbouring cables does not materially affect the homogeneity of the thermal field, an assumption which is only valid if each cable is small and at a distance of at least 10 to 20 diameters from its fellows. Kennelly's experiments prove that with this restriction the assumption was very fairly justified. Observations made on cables horizontally separated by a distance of 11·4 diameters in the same trench showed that the temperature of one cable which was kept inactive acquired in 3 hours 38 per cent of the temperature elevation present in the sheath of its active neighbour, while the isothermal passing through the region occupied by the inactive cable indicated a 42 per cent elevation. The difference was probably due to the fact that 3 hours is not long enough for the isothermal to become permanently established. In this connection the influence of duration upon the temperature elevation becomes a very important factor. Strictly the maximum elevation is only attained after an indefinitely long period of activity. In the light of more recent experience it is doubtful whether in any working cable system this condition will be even approximately attained during the period of maximum load, which in practice is rarely longer than 3 to 4 hours daily.

Wilkins* proposed the following formula for the current which produces a given temperature rise :—

$$I = \sqrt{\frac{\theta 57 \pi (d_n + l_0) A}{l_0}}$$

l_0 in this case is the distance from the cable of a point in the surrounding medium at which the heating effect may be regarded as zero. If a definite value is assigned to θ , then since $(d_n + l_0)/l_0$ is in practice approximately equal to unity, the formula may be simplified to $I = C \sqrt{A}$, where C is a constant having for one of its factors the thermal resistivity of the soil.

Wilkins remarks on the length of time required before a stationary condition is attained. In his practical determinations of the value of the thermal resistivity constant he used a horizontal iron tube filled with oil and electrically heated. This tube was surrounded by the material under investigation. Wilkins considers 45° C. as the permissible upper limit of temperature, and taking the mean temperature of the earth as 15° C. he therefore obtains 30° C. as the maximum permissible temperature rise. Wilkins tested his results on a normal heavy-current system with cables laid direct in the ground. A 24-hours' run was taken and three types of cables were investigated :—

* K. WILKENS. Ueber die Erwärmung unterirdische elektrischer Leitungen. *Elektrotechnische Zeitschrift*, vol. 21, p. 413, 1900.

* *Loc. cit.*

- (1) An iron-armoured lead-sheathed single cable of 3,300 m. length and 120 sq. mm. cross-section, carrying 252 amperes.
- (2) A cable of 2,400 m. length, 400 sq. mm. cross-section, carrying 560 amperes.
- (3) A cable of 3,212 m. length, 725 sq. mm. cross-section, carrying 1,000 amperes.

The values obtained for l_e varied from 11 mm. to 46 mm. In order to allow for cases in which several cables are laid in one trench, Wilkens in drawing up his tables took $l_e = 50$.

A table of permissible currents is given, based on his theoretical formula. Values reduced from his experimental results agree with those given in the table to within about 1 per cent.

The temperature rise was measured by means of the resistance change of the conductor. In one case Wilkens found the temperature difference between the conductor and the outside of the insulation of the cable to be 3.2°C .

Apt was investigating the subject at about the same time.⁵ His experiments were carried out in the laboratory of the cable works of the Allgemeine Elektrizitäts-gesellschaft. Apt assumes, to simplify the mathematical treatment, that a cable buried in the earth is to be regarded as a cylindrical conductor surrounded by a concentric layer of earth having a radius approximately equal to the depth of the cable below the surface, and that the temperature of this layer is that of the surface. Also it is assumed that in consequence of the thermal conductivity of the surrounding medium the heat dissipation is only dependent on the temperature difference between the cable and the surface of the earth, and is nearly independent of the diameter of the cable. The term S of Kennelly's formula is omitted as being small.

For a temperature difference θ between the cable and the surface of the earth we have in this case the heat

$$\text{transference } H = \frac{\text{const} \times \theta}{\log \frac{2l}{d_n}}$$

The thermal resistivity of the soil is included in the constant.

Since $2l$ is in all cases much greater than d_n , the expression for H for a constant value of l , that is, for a fixed depth at which the cable is buried, only alters very slightly for quite considerable changes in the value of d_n , as is shown in the following table where $2l$ is taken equal to 1,000 mm., corresponding to a cable buried at a depth of 500 mm.

d_n in mm.	A in sq. mm.	$\frac{2l}{d_n}$	$\frac{1}{\log \frac{2l}{d_n}}$
6.9	25	145	0.47
9.4	50	106	0.49
14.5	120	69	0.54
16.3	150	61	0.56
41.4	1,000	24	0.72

* R. APT. Ueber die Erwärmung unterirdisch verlegter Kabel. *Elektrotechnische Zeitschrift*, vol. 21, p. 613, 1900.

Thus a 40-fold change in the cross-section of the cable only causes a 14-fold change in the last term. With sufficient accuracy H may therefore be regarded as independent of d_n ; and hence, as shown in the introduction,

$$I = \gamma \sqrt{A}$$

In his experimental determinations, Apt used continuous-current cables with jute insulation and lead sheathing. Each cable was placed in moderately moist sand contained in a tank of dimensions 6.8 m. \times 1.5 m. \times 1.5 m., and was wound backwards and forwards upon itself in order to conform more nearly to practical conditions, in which many cables are placed in one trench. There was everywhere a thickness of at least 0.5 metre of sand. Thus the condition of symmetry demanded by Apt's formula was approximately satisfied. The tests were continued for 24 hours, although a stationary condition was reached after a much shorter interval. The temperature rise was determined by the Kelvin double-bridge method. Five cables were investigated in this way, their cross-section ranging from 25 to 1,000 sq. mm. The values of the constants obtained by Apt varied by approximately 25 per cent with the same cable tested with different currents, and by about 16 per cent between the mean values of the various cables in the series.

Herzog and Feldmann⁶ gave the result of investigations, including the case of concentric and eccentric cables, which appear to have been largely theoretical in character.

In 1903, Humann⁷ described the results of a very extensive series of tests made at the laboratory of the Felten & Guillaume Company, on heavy-current cables buried direct in the soil. In each case a piece of cable at least 30 m. long and buried at a depth of 80 cm. was used. The soil was sand with a little loam. The time of test was usually six to ten hours, and in all 29 different cables were brought under investigation. Humann followed the general lines of Apt's theory, and, taking the equation $I = \sqrt{\theta A} / \text{constant}$ to which either Apt's or Kennelly's equation reduces if we neglect S , he set out to determine the values of the constant.

In the case of the concentric and multicore cables Humann makes the statement that a "multiconductor cable corresponds exactly to a single cable if as the cross-section we take the total cross-section of all the conductors and as the current the sum of the currents in the separate conductors."

The values of the "constants" obtained by Humann vary over a somewhat wide range. In each series of cables tested there also appears to be a systematic variation depending on the size of the cross-section, which indicates the failure of the formula. Thus for cables of 25 sq. mm. cross-section a mean value for the "constant" is given as 0.02455, whereas in the case of a 300 sq. mm. cable it is given as 0.01356.

For the purpose of comparing the behaviour of buried cables with those suspended in air, Humann made comparative tests on two of the cables. He found that when suspended in an enclosure under similar conditions of

* J. HERZOG and C. FELDMANN. Ueber die Erwärmung elektrischer Leitungskabel. *Elektrotechnische Zeitschrift*, vol. 21, p. 783, 1900.

† P. HUMANN. Ueber die Erwärmung in Erdboden verlegter Starkstromkabel. *Ibid.*, vol. 24, p. 599, 1903.

laying, the temperature rise was about twice as great as when buried direct in the ground.

Humann also investigated high-tension cables. Eight different types were tested, but this number was not thought sufficient to warrant any general conclusions being drawn.

The tables and rules proposed by Humann were the subject of considerable criticism, which, however, turned principally on the limits of temperature rise adopted or recommended by Wilkens, Apt, and Humann respectively.

In 1904 appeared the load tables of the Wire and Cable Commission,* which applied to the case of one cable or two cables lying close together at the usual depth (70 cm.). The temperature rise allowed is 25°C. The tables are derived from the formula—

$$I = 11.55 \sqrt{\frac{\Delta \theta}{\log 4/d_n'}}$$

which can readily be deduced from Kennelly's work by neglecting the term S and adopting certain values for the thermal resistivity.

Kath† explains the reasons which led the Wire and Cable Commission to adopt the formula and the constant 11.55. He discusses the results of some experiments on nine samples of 50 sq. mm. cables supplied by a union of the leading German cable firms. Among the objects of the investigation were the influence of the weather, the humidity of the soil, etc. The common experience of the Commission appointed by the Union was that the moisture of the soil was a principal factor in determining its thermal resistivity. In two experiments with soil of which the humidity was in one case 15.9 per cent and in the other 22.5 per cent, the temperature rise of cables buried in it was 11.5 per cent lower than with similar tests in dry soil. In these experiments some attempt was made to study the special case presented where several cables were grouped together. The nine

cables were placed thus $\begin{smallmatrix} \text{ooo} \\ \text{ooo} \end{smallmatrix}$ and the nature of the curve showing the temperature rise with time when a current of 200 amperes was flowing was compared with its appearance when only one cable was carrying this load. The two curves show a striking difference. In the case of the single active cable the curve has become almost horizontal, showing that the stationary condition had been practically attained. Where all the nine cables were active, the curve, besides showing a 25 per cent greater temperature elevation, is still rising after a seven hours' run. For this reason it was considered that a run of at least 15 or 20 hours would be necessary in the investigation of cables laid in groups.

The temperature of the ground varies between 0°C. and 20°C. due to natural causes. This, and the fact that the placing of several cables in one trench may easily result in the temperature rise for a single cable being exceeded by 10°C., constituted a difficulty in deciding whether the maximum permissible temperature should be taken as 40°C. or 50°C. As a compromise it was suggested that the permissible current where several cables are placed

together should be three-quarters of that allowed for a single cable, and this was adopted by the Commission.

In 1904 Teichmüller called attention in the *Elektrotechnische Zeitschrift*‡ to the deficiencies of the previous formula, and brought forward a more complete theory of the heating of cables, based on Kennelly's work, leading to the formula—

$$I = \frac{C}{\sqrt{\rho \sigma_1}} \sqrt{\frac{\Delta \theta}{m \log \frac{d_n'}{d} + \log \frac{4}{d_n}}}$$

where m is the ratio of the thermal resistivity of the cable insulation and covering to that of the earth; and where

$$C = \sqrt{\frac{2 \pi 10^{-2}}{2.303 \times 10^{-4}}} = 16.52.$$

In this case d_n' is the "reduced" outer diameter of the cable, i.e. the outer diameter of the cable d_n multiplied by a factor h which is equal to $d_1 d_2 \dots [d_n d_n']$.

Thus these formulae, as is shown in the introduction, take into account the interposition in the cable of layers of materials, such as lead covering and steel armouring, which in comparison with the insulation and the protective wrappings are held to have a negligible thermal resistance. The term h varies with different sizes of cables from about 0.67 to about 0.83.

The relative importance of the two logarithmic terms may be seen by taking the dimensions of a typical cable. Thus taking a particular 70 sq. mm. cable we have $d_n'/d = 21/10$, $d_n = 30$, $l = 1,000$ mm., and $m = 500/50$, then

$$m \log d_n'/d = 10 \log 2.1 = 3.22 \\ \log 4/l d_n = \log 4000/30 = 2.12.$$

Thus the inclusion of the term $m \log d_n'/d$ increases the denominator from approximately 2 to 5.

The difference between the load tables calculated by this formula and the old tables is about 10 per cent, except for cables exceeding 500 sq. mm. (0.75 sq. in.) section, where it rises to 15 per cent.

Teichmüller shows how this formula can be adapted to the case of concentric cables. For concentric cables—

$$I = 1/\sqrt{\lambda Z} \times I_{\text{single}}$$

where I = current which one conductor will carry;

Z = number of conductors, all naturally of the same cross-section;

I_{single} = current which an ordinary single cable can carry at the same temperature elevation and under the same conditions;

λ = factor depending on the dimensions of the cable. (For cables of ordinary construction the following are good mean values: for twin concentric cables: $\lambda = 0.92$; for triple concentric cables: $\lambda = 0.77$.)

The validity of these formulae Teichmüller considers to have been sufficiently established by such observations as were available, and especially those made by Humann as previously described. In the development of his formula

* *Elektrotechnische Zeitschrift*, vol. 24, p. 404, 1903.

* J. TEICHMÜLLER, Zur Theorie der Kabelerwärmung, *Elektrotechnische Zeitschrift*, vol. 25, p. 933, 1904.

Teichmüller assumes that the surface of the ground over the cable is an isothermal surface.

He also considered that there was then (1904) need for further experiments in the following directions:—

- (1) The thermal resistivity of the insulation and covering and its dependence on temperature.
- (2) The thermal resistivity of the soil in various conditions.
- (3) The temperature rise of the surface of the earth in various conditions in comparison with the temperature of surrounding points.
- (4) Whether the circumstance that the surface of the ground cannot be an exact isothermal has any considerable influence on the nature of the function $I=f(A)$.

A further contribution to the subject was that of Apt and Mauritius.* Three-core stranded 1,000-volt cables with iron armouring and fibrous insulating material were selected for these tests. They were placed in an iron tank and surrounded by sand so that there was everywhere a thickness of at least 0.8 metre of sand between the cables and the side of the tank. The temperature of the conductor was measured by its resistance change, determined by the Kelvin double-bridge method, and the temperature of the lead sheathing was ascertained in the same way. The formula $I = \text{constant} \sqrt{A \theta \log(2l/d_n)}$, in which a symmetrical distribution about the cable is assumed, was adopted and a series of tables was drawn up for three-core stranded cables. The temperature rise allowed was apparently 25°C., the value adopted by the Verband deutscher Electrotechniker. It was shown that the rule given by Humann for multicore cables (p. 782) is not justified except in the case of very small cables. The values obtained by experiment are much greater than what would be indicated by the rule given by Humann.

High-tension cables were also tested. The maximum permissible current was found to be smaller than for low-tension cables—in the case of the larger sized cables in an almost constant ratio of 0.76 or 0.77. Here again results were obtained which were not in accordance with the conclusions of Humann, and Messrs. Apt and Mauritius state it as their opinion that it is not practicable to draw up general rules or tables for high-tension cables since the practice of the various firms as regards material and thickness of insulation varies so widely.

Humann† discussed the case of three-core cables and gives the results of some experiments. His work appears to have been based on the mathematical theory of Teichmüller taken in conjunction with that of Mie,‡ who gave formulae by which multicore cables could be reduced to the case of a single-core cable.

Humann's experimental investigations were in connection with some three-core cables of 30 m. length which were buried at a depth of 70 cm. and run for 10 hours with continuous current. A series of values for heating effect was obtained for six different cables ranging in size from 3 × 25 sq. mm. up to 3 × 240 sq. mm.

‡ G. MIE. Über die Wärmeleitung in einem verselten Kabel. *Ibid.*, vol. 26, p. 137, 1905.

Humann's values obtained experimentally point to great variations in the value of the constant m , the ratio of the thermal resistivity of the cable covering to that of the earth. Thus for a cable of 25 sq. mm., m is 256; for a cable of 50 sq. mm., $m=61$; and for a cable of 240 sq. mm., $m=21$, as against values for m ranging from 11 to 15 determined or assumed by the previous investigators, Kennelly, Teichmüller, and Apt.

Humann in a later investigation also studied the effects produced by temperature fluctuations at the surface of the earth due to climatic causes. He found, as is well known, that even in strata only a few centimetres below the surface the range of such fluctuations was greatly reduced. Thus a fluctuation of 4°C. at the surface was reduced to a fluctuation of about 1°C. at a depth of 5 cm.

In a paper entitled "Die Materialkonstanten zur Berechnung der Kabel und Erwärmung,"* Teichmüller in conjunction with Humann returns to the formula quoted on page 783. It had been proposed to simplify this formula by reducing the logarithmic numerator to one term, but this can only be done if the values of σ_2 and σ_3 , the thermal resistivity of the insulation and packing and that of the soil respectively, can be regarded as the same to a reasonable degree of approximation. The two authors therefore undertook an exact determination of these constants, the values of which were not known with any certainty.

The determination of the value of the constant σ_2 , the thermal resistivity of the insulation and filling material, was based partly on specially devised experiments, and partly deduced from an examination of earlier results. It was considered to be of the first importance that practical conditions should be realized as closely as possible, as it was not improbable that pressure and position and mechanical treatment might affect the value of the constant. Bare lead-sheathed single cables of normal construction with impregnated jute or paper filling were therefore chosen. They were laid out on porcelain carriers so that the air had unimpeded access on all sides. A current was passed through the conductor and its temperature determined from the resistance by the usual double-bridge method. The temperature of the lead sheath was also measured in the same way by means of a small momentary testing current, the temperature coefficient of the lead having been specially determined. As a check method the temperature of the lead sheath was also determined by keeping a constant stream of water running over it. Practically identical results were obtained by both methods. It follows that under these conditions—

$$\sigma_2 = C \times \frac{A \theta}{\rho l^2 \log d_n/d}$$

where $C = \frac{2 \pi \times 10^2}{2.303} = 272.8$,

d_n = outer diameter of the insulation,

and d = diameter of the conductor.

The tests were continued for three or four hours in order to ensure constant conditions of temperature. The stationary condition was, however, attained in about two hours. Seven cables were tested, each with from 2 to 5 different values of the load current. The various values obtained for σ_2 were in each case in good agreement, and the average

* *Elektrotechnische Zeitschrift*, vol. 27, p. 379, 1906.

value for the seven cables was 644, the extreme values being 617 and 755. For all values of the temperature occurring under working conditions (over a range of 50° C.) the thermal resistivity according to Teichmüller and Humann may be regarded as practically constant. The average value of the thermal resistivity of the filling and packing material was found to be 570. The effect of moisture was also investigated. As a good average value of insulation and packing taken together $\sigma_s = 600$ may be adopted.

It had also been suggested that there was a "transition thermal resistance" at the common boundary of two different layers of material. This point had been discussed by Teichmüller in his book on the heating of cables.* To investigate the matter two cables each of 10.5 sq. mm. cross-section and 4 mm. insulation thickness were prepared. Each was exactly alike in every particular except that in one the impregnated paper was applied in two layers, separated by a thin layer of tinfoil, thus introducing two additional "transition boundaries." When tested the difference in the value of the thermal resistivity as determined from these two cases was found to be quite negligible.

In the determination of σ_s , the thermal resistivity of the soil or other substance by which a buried cable may be surrounded, a horizontal iron tube 383 cm. long and 20 cm. in diameter was employed. Through this was passed a brass tube of somewhat greater length, 5.2 cm. in diameter and 1 mm. thick. Clamps on the two projecting ends of this inner tube enabled a current to be passed along it to secure a suitable temperature elevation. The annular space between the two tubes was filled in turn with the various materials under investigation. The temperature of the outer tube was kept constant by a stream of water flowing over it. The materials investigated and the value of the thermal resistivities were as follows:—

Material	Value of σ_s in Electrical Units
Sand 0.4 % wetness (very dry)	320 mean value
" 0.4 % "	324 another determination
" 4.4 % "	81
" 9.9 % "	62
Normal soil 12 % "	117
" 11 % "	102 by different apparatus
Dry gravel	229

Note.—The very dry sand and gravel are extreme conditions which do not apply in practice.

The values thus obtained were higher than had been expected from the results of tests made on cables laid in soils of this description.

Further investigations were made under practical conditions. For this purpose a spiral of constantan wire about 10 m. long was wound on a wooden pole and buried 70 cm. below the surface of the ground. A thermometer was placed at the middle of the pole, and other thermometers at points 30 and 50 cm. above the pole and also at a point 5 cm. below the surface of the ground. It was found that the temperature in the immediate neighbour-

hood of the wire, and even at 30 and 50 cm. away, did not become constant till after the elapse of 60 hours. Further investigations showed that 13 days were required for a really stationary temperature to be attained. Absolute values for σ_s were not obtained, the experiment being directed more to determining the time required for a stationary condition to be reached.

As a result of this investigation Teichmüller and Humann conclude that owing to the heat capacity of the earth and to the fact that the greatest time of loading is only a few hours, one-half of the mean value of the thermal resistivity of soft earth should be taken. Thus they propose for purposes of calculation that $\sigma_s = 40$ to 60.

In 1907 appeared the load tables of the Verband deutscher Elektrotechniker⁵ and "Notes on the New Load Tables for Cables laid direct in the Ground" by Teichmüller.[†] The Commission which drew up the load tables consisted of Uppenborn (President), Passavant, Apt, Humann, Teichmüller, and Klement. Teichmüller in his note states that the new load tables for cables laid in the ground were calculated by the following formula, which holds for all cables:—

$$I = \frac{C}{\sqrt{2\pi}} \sqrt{\frac{\Lambda \theta}{\sigma_s \log \frac{d''}{d'} + \sigma_s \log \frac{1}{d'}}$$

where $C = \sqrt{\frac{2\pi \cdot 10^{-7}}{2.303 \times 10^{-4}}} = 16.52$.

For single cables the term d' would be d , as in the formula on p. 783. d' is derived from a theory given by Mie[‡] by means of which a multicore cable can be reduced to the case of a single cable. The formula given above combines the theories of Teichmüller and Mie, and this applies to single, concentric, and multicore cables. This formula and the tables based upon it are regarded as exact for the stationary conditions. It was noted by several experimenters that the stationary condition was not reached with certainty until after several days. The rise, however, after from 6 to 10 hours was very slow; thus, roughly speaking, after 3 to 10 hours the conditions could be taken as being practically stationary.

It remained to determine from the available material the most probable values for σ_s and σ_c , and the Commission decided on the values $\sigma_s = 550$ and $\sigma_c = 40$.

The only experiments of which the results did not agree with those calculated from the formula were not further considered in view of the fact that one of the observers (Dr. Apt) expressed his agreement with the table founded on the formula. He explained that the difference was due to the fact that in the experiments made by himself and Mauritius the cables were not laid under practical conditions, but were in an iron basin.

The Commission were of opinion that the values chosen for σ_s and σ_c could therefore be regarded with special confidence as the best mean values, being accepted not only by the newer but by the older observers also (Kennelly, Herzog and Feldmann, Teichmüller, and Humann). The last-named observers did indeed find higher values in their

* J. TEICHMÜLLER, "Die Erwärmung der elektrischen Leitungen." Stuttgart, 1905.

⁵ *Elektrotechnische Zeitschrift*, vol. 28, p. 823, 1907.

[†] *Ibid.*, vol. 28, p. 499, 1907.

[‡] *Ibid.*, vol. 26, p. 137, 1905.

Laboratory experiments, getting a figure about double (see p. 785), but in their experiments on cables laid under practical conditions the lower values were also observed, and it is stated that the difference probably depends on the great heat capacity of the earth. In the first case the true stationary condition was reached, and in the last the *quasi* stationary, which corresponds more nearly to the practical conditions.

The temperature rise allowed for in the table is 25° C., as in the old tables. The maximum temperature allowed for cables is 50° C., and therefore the normal maximum temperature of the soil is taken as being 25° C. Teichmüller states that this temperature limit is to be regarded as a compromise between the cable manufacturers and the cable users. The latter regard higher temperatures as possible, the former will undertake no guarantee for such higher demands. The normal depth of laying is 70 cm. (2 ft. 3 in.).

No difference is made between direct and alternating current, it being stated that the losses due to the causes mentioned (hysteresis in the dielectric, eddy currents in the armouring, etc.) are, in general, small.

WIRING RULES ADOPTED BY THE VERBAND DEUTSCHER ELEKTROTECHNIKER.

*Table of Loads for Single-conductor Cables, at 700 Volts, with and without Pilot Wire, laid direct in the Ground.** (A table giving the equivalent cross-section in square inches has been added.)

Cross-section in sq. mm.	Cross-section in sq. in.	Current in Amperes
10	0.00155	24
15	0.00232	31
25	0.00387	41
4	0.0002	55
6	0.0003	70
10	0.00155	95
16	0.00248	130
25	0.00387	170

Tables are also given for cables working up to 10,000 volts. The difference between them and those given above is however less than 10 per cent. These tables hold so long as not more than two cables are laid together in the same trench.

In laying cables in channels or running a number of cables together in the ground or any such unfavourable conditions, it is advisable to reduce the maximum load to three-quarters of the values given in the tables.

Ferguson in a paper on "Underground Electrical Construction" described some tests made with cables drawn into ducts. The tests were made in the laboratory, the ducts being surrounded by 6 in. of sand. The rise of temperature under these conditions was rather larger than

* *Elektrotechnische Zeitschrift*, vol. 28, p. 824, 1907.

* *Transactions of the International Electrical Congress, St. Louis, 1904*, vol. 2, p. 266.

when the cables were supported in air. Since, however, the ducts were not buried in the ground, it would seem that the results are scarcely comparable with what might be expected under practical conditions.

Ferguson emphasizes the importance of making observations of the temperature of cables in actual use, and recommends that where a large number of loaded cables pass through one manhole it is well to have readings taken periodically to determine whether a temperature unsafe for the cable is reached.

The question of proper ventilation is also discussed in the paper. The author considers it to be important that ventilators should be frequently examined and cleared.

Kennelly and Shepard⁶ made a series of determinations of the thermal resistivity of various grades of soil such as sand, and gravel. For this purpose a copper wire was supported at or near the axis of an iron tube, the space around the wire being packed with the different soils. The iron tube was surrounded by a water jacket, the temperature at the outside of the tube being kept constant by a stream of water.

The test wire attained its maximum temperature under these conditions in rather less than 2 hours.

The following are some of the values obtained for the various grades of soil.

Material	Thermal Resistivity
Yellow sand (dry)	351
Fine white-quality sand (dry)	391
" " with 20 % of water	164
" " with 10 % of water	229
Fine sandy soil (dry)	490
" " with 20 % of water	356

Lichtenstein[†] describes the results of some experiments on high-tension cables with the special object of determining to what extent the permissible current was affected by the extra thickness of insulation.

The cables were laid, a number in a trench, direct in the ground at a depth of 75 cm. The distance between the cables was about 7 cm. Some of the cables had conductors of iron wire, and the current in these was reduced in order to have the same loss in watts as in a copper conductor of similar size. Various types of cable, such as plain lead-sheathed, armoured, single, concentric, and three-core, were tested.

Lichtenstein found that the temperature rise in such cables with the currents prescribed by the German tables of 1907 for low-tension cables was in many cases considerably higher than the 25° C. limit allowed. Thus a normal high-tension cable 3 × 44 sq. mm. with 16 to 18 mm. thickness of insulation showed a temperature rise of 40.7° C. These discrepancies are held to indicate the necessity of special tables for high-tension cables, and Lichtenstein accordingly draws up load tables.

For high-tension (up to 30,000 volts) cables.

- (1) For single conductor with 5 mm. thickness of insulation, both armoured and bare.
- (2) For 3-conductor armoured cables with 17 mm. thickness of insulation.

* A. E. KENNELLY and E. R. SHEPARD. The heating of copper wires by electric currents. *Transactions of the American Institute of Electrical Engineers*, vol. 26, p. 960, 1907.

† L. LICHTENSTEIN. Versuche zur Bestimmung der Kabelwärme. *Elektrotechnische Zeitschrift*, vol. 30, p. 389, 1909.

Further experiments were made with two or more cables laid in the same trench loaded together. In the case of two cables separated by a distance of 21 cm. a temperature rise of 43° C. was obtained, as against 38° C. for a single cable under similar conditions of load. The additional 5° C. rise brought about by the presence of the neighbouring active cable was approximately equivalent to the additional temperature rise caused by an increase of 7 per cent in the current.

With three or more cables connected in series the results generally were held to justify the German rule in which it is recommended that in the case of a number of cables laid in one trench the load should be reduced to three-quarters of that for cables laid singly.

Mosman has given an account[‡] of an extensive series of investigations made with an 81-way conduit system arranged 9 × 9. Only a few of the cables had actually been installed and apparently the special object of the investigation was to determine the proper size and current for the remainder. Only one portion of the system was actually underground, and here the depth of the upper surface of the concrete envelope, the section of which was approximately 4 × 4.5 ft., was only 1½ to 2 ft. below the surface of the ground. It does not therefore appear easy to derive any results capable of very general application from these investigations. The type of conduit system here in question is very unusual.

The underground section was about 260 ft. in length. An important test from the point of view of further investigation was in connection with the temperature variation along the cable, as showing the magnitude and extent of the end effect. It appears from Fig. 15 (p. 774) of the original paper that whereas the temperature at one manhole was approximately 25° C. and at the other 20° C., the temperature at a point 20 ft. from the first manhole was within 2 or 3 degrees of the maximum, which was about 42.5° C. At the other manhole the end effect was more marked, the temperature falling from 40° C. to 15° C. over a length of about 50 ft. The considerable diffusion of the heat from the end portions, brought about by convection through the large number of empty ducts by which the active cable was surrounded, was no doubt chiefly responsible for this, and shows how great this effect may become when forced draught is resorted to.

The tests were made with alternating current, and apparently some portion of the heat developed was due to induced currents in the lead sheathing. The conduits were of fibre laid in cement. The effects of ventilation were studied and the possibility of using a forced draught for cooling the cables is discussed.

L. Bloch in a paper read before the Elektrotechnische Verein[§] drew attention to the enormous increase in the watts lost and the temperature rise where alternating-current mains were laid singly in iron pipes. Curves and tables are given, showing the number of watts lost and the temperature rise for cables laid singly in iron pipes to be as much as four times that when the cables are laid direct in the ground.

Melson and Booth[†] gave curves showing the heating of

* C. T. MOSMAN. Notes on underground conduits and cables. *Transactions of the American Institute of Electrical Engineers*, vol. 31, p. 575, 1912.

† (Abstract) *Electrician*, p. 531, 1915.

‡ *Journal I.E.E.*, vol. 47, p. 732, 1911.

a 19/14 S.W.G. cable laid in the ground under different conditions.

The temperature rise in the cable with a current of 160 amperes was:—

- (1) Laid direct in the ground = 8° C.
- (2) Laid solid in bitumen = 14° C.
- (3) Laid in a 3-in. earthenware pipe = 20° C.

Mr. C. Beaver in the discussion of the above paper gave some curves for a 0.5 sq. in. cable running at 1,500 amperes per sq. in. when laid under different conditions.

The temperature rise for some of the conditions of laying after running for ten hours was:—

- (1) Armoured cable laid direct = 48° F.
- (2) Lead-covered in asphalt trough = 53° F.
- (3) " " laid solid = 98° F.
- (4) " " drawn in = 85° F.

CONCLUSION AND REMARKS.

In considering the German tables and the work on which they are based it will be seen that while the mathematical work following on that of Kennelly is, for the case of armoured cables laid direct in the ground, fairly complete, certain of the assumptions which have been made and which materially affect the problem are open to criticism. For instance, the value of the thermal resistivity of the soil ($\sigma_s = 40$) taken for the purpose of the German tables is very different from the later values obtained by Kennelly. It seems clear that the German tables are based on what is assumed to be practical conditions and not on the ultimate stationary conditions, since the value of $\sigma_s = 40$ would under the stationary conditions appear to be more nearly the value obtained by Kennelly in 1907, *i.e.* approximately 200. Particulars are not given by the German experimenters as to the amount of moisture in the soil at the depth of 70 cm. at which their cables were buried. It seems probable that in the case of cables laid at a depth of less than 70 cm., owing to there being less moisture in the soil at this depth, the value for the thermal resistivity σ_s would be much greater than 40 and might approach 200. In the case of a typical cable the use of the value $\sigma_s = 200$ instead of 40 would reduce the permissible current by the order of 30 per cent.

There is apparently practically no information available in regard to the case of cables laid solid in bitumen or drawn into ducts. The preliminary results of Melsom and Booth and the curve given by Beaver show that very large differences can be obtained with different systems of laying. It is fairly obvious that the German rule of reducing the current to three-quarters of that allowed for a cable laid direct in the ground cannot apply to such cases.

The thermal conditions are particularly complicated in the case of a multi-way earthenware duct containing a number of cables. In addition to the mutual effect of neighbouring cables there are other important factors, the effect of which is little known. For instance, the thermal resistance of the layer of air contained in the duct around the cable under conditions where the effect of convection may be very small, is likely to be very high. Again, little is known of the thermal properties of the material of the duct itself, or of earthenware troughing containing bitumen. Moreover, a comparison between the figures published by a British firm of cable makers for cable drawn into 3-in. stoneware ducts, with the German tables for cables laid direct in the ground, shows a large difference, due apparently to the different conditions of laying. The British figures allow of a temperature rise of 50° C., while the German tables allow of a rise of 25° C.

Conductor Area, sq. in.	Permissible Current in Amperes	
	British, for Cables in 3-in. Conduits	German, for Armoured Cables Laid Direct
0.1	233	304
0.5	644	800
0.7	795	975
1.0	993	1,210

If we take, for purposes of comparison, the German recommendation for the case of cables in ducts, and reduce the figures for permissible current in the table to three-quarters, and also reduce the British figures to currents corresponding to a 25° C. rise, we have the following table:—

For Cable in 3-in. Conduits for a Rise of Temperature of 25° C.

Conductor Area, sq. in.	British	German
0.1	165	228
0.5	455	600
0.7	562	730
1.0	702	908

OBITUARY NOTICES.

JAMES HERBERT CAWTHRA died in his 42nd year, as the result of a motor car accident on the 8th October, 1913. After serving his apprenticeship he went as Outside Assistant to Messrs. J. H. Holmes & Co., of Newcastle-upon-Tyne, and superintended the erection of complete electrical installations on board ship and in factories. He was for a short time an assistant in the mains department of the Newcastle-upon-Tyne Electric Supply Company. Following upon this he obtained experience as a sea-going engineer with several firms. He was appointed in 1893 Chief Assistant in the generating station of the Yorkshire House to House Electricity Company at Leeds, serving in the same capacity when the works were taken over by the Leeds Corporation. He left Leeds in 1900 on his appointment as Borough Electrical Engineer at Swansea. After a short tenure of office he was appointed in 1901 Borough Electrical Engineer at South Shields. Subsequently he drew up a complete scheme for the electrification of the tramways. In 1911 he was appointed Superintendent to the Victoria Falls & Transvaal Power Company, in which capacity he was responsible for the operation of all the Company's generating stations. He was elected a Member of the Institution in 1904.

THOMAS CUSHING died in October, 1913, in his 73rd year. After a short period of service with the firm of Messrs. T. Cooke & Sons of York, makers of scientific instruments, he was appointed in 1867 to the post of assistant inspector of scientific instruments to the India Store Depot, ultimately becoming the chief inspector. In this capacity it was his duty to carry out tests in the early days of telegraph instruments; and later when heavy electrical machinery came into common use, the testing of this was also comprised in the duties of his office. He was the inventor of a new form of oil insulator which was patented and proved very successful. He was elected a Member of the Institution in 1881.

STEPHEN D. FIELD died at his residence in Stockbridge, Massachusetts, U.S.A., the 18th May, 1913. He was an inventor in many branches of electrical work, including telegraphy, and in 1879-1880 applied for patents for an electric railway, comprising a stationary generator, a trolley wire, an electric car, an under-running trolley, and bonded rails for the return circuit. In the latter year he constructed an experimental electric line in Stockbridge, and in 1883, in connection with Mr. Edison, operated an electric locomotive by a third-rail at the Chicago Railway Exposition. After his early work he paid little attention to electric railways, except in the later nineties, when, representing American capitalists, he had charge of the electrical equipment of the tramway system at Geneva, Switzerland. He was elected a Member of the Institution in 1877.

CHARLES THOMAS FLEETWOOD died in December, 1913, in his 75th year. He entered the service of the

Electric and International Telegraph Company in 1854 and was connected with the Telegraph Department of the Post Office during the remainder of his professional career. He retired in 1902. In 1875 he contributed to the *Journal* of the Institution a paper on "Underground Telegraphs—the London Street Work," and again in 1887 one on "Underground Telegraphs"—the latter of which was awarded the Fabie Premium. He was elected an Associate of the Institution in December, 1872, and a Member in 1886; and he served on the Council in 1879.

ALFRED S. GILES died on the 22nd October, 1913, in his 48th year. He was for some time a member of the engineering staff of the Edison & Swan Company, leaving that firm in the early nineties when the installation department was given up. After five or six years on the staff of Messrs. Thompson, Ritchie & Co., he went to Blackburn in 1895 as Chief Engineer in the Corporation Electricity Department, and held that position until 1904 when he was appointed Engineer-in-Chief of the Cape Tramways. In 1911 he became Manager and Engineer-in-Chief of the Lisbon Tramways, a position which he occupied until his death. He was elected an Associate of the Institution in 1895, and a Member in 1900. He served on the Committee of the Manchester Local Section from 1901 to 1904, in which latter year he became Vice-Chairman. In 1906-7 he was Chairman of the Cape Town Local Section.

JOHN GOTT, who died at Brighton on the 8th March, 1914, was one of the pioneers in submarine cable engineering. He was born at Kendal, Westmoreland, in 1840, and entered the telegraph service early in life. His first employment was with the Electric and International Telegraph Company. In 1863 he went to Tripoli where he was employed in the operation of the first Mediterranean cable, later going to Malta on this same work. In 1864 he was selected to accompany the steamship *Great Eastern* as one of the electrical staff when that vessel made her first attempt to lay a transatlantic cable. In 1866 he accepted the position of Superintendent and Electrician at St. Pierre, Miquelon, when the cable of the first French Atlantic Cable Company was laid. In 1870 he transmitted wireless signals through a distance of about three miles at St. Pierre, Miquelon, using the earth as a conductor. In the same year he invented his fault-searcher coil. In 1881 he introduced a modification of Lord Kelvin's formula for testing measurements of the electrostatic capacity of condensers and cables; this is now used as a standard test and is known as "Gott's capacity test." In 1884, upon his retirement from the French Cable Company's service, he became Chief Electrician to the Commercial Cable Company, a position which he held until his death. In 1892 he devised the "Gott ratio arm," which made it possible to avoid the necessity for temperature corrections for the resistance of Wheatstone bridge coils by introducing coils of manganin for one of the ratio arms, and also made it possible to obtain measurements in modern units by means of a bridge wound to discarded

standards. Of greatest importance, however, was his recent invention, whereby he made it possible to communicate from the Pacific coast of the United States and Canada direct to Europe without the aid of human retransmission at intermediate station, cables and land lines being linked up and the ordinary Morse method of operation employed. He also latterly invented a new and improved system of quadruplex working. He was elected an Associate of the Institution in 1873, and a Member in 1877.

ROBERT KAYE GRAY, Past President, was born in June, 1851, and died on the 28th April, 1914. He received his early education in Greenock, entered University College School in 1865 and later University College. The son of Matthew Gray, Manager of the India Rubber, Gutta Percha, and Telegraph Works Company, Ltd., he entered the service of that Company in 1869. He later became Chief Electrician and in 1875 Engineer-in-Chief. The submarine-cable industry had by this time come through its initiatory period of romance and uncertainty and had settled down as a technical business involving for its successful accomplishment the combination of high scientific attainments and considerable commercial acumen. This combination Robert Kaye Gray possessed in a remarkable degree. In 1901 he became Managing Director of the Company and was in addition a Director of the following submarine cable companies:—Cuba Submarine Telegraph Co., Ltd., Spanish National Telegraph Co., Ltd. (*Chairman*), West African Telegraph Co., Ltd., and South American Cable Co., Ltd. (*Chairman*). With all the demands upon his attention, which his business pursuits made, he gave ungrudgingly of his time and his ripe experience to learned and other societies. He was a member of the Royal Institution, the Royal Society of Arts, the Institution of Civil Engineers, and the Institute of Metals. In all of these he took a lively interest, and in some he was an active worker, but it was to the Institution of Electrical Engineers that he gave his closest attention. He was elected an Associate in 1874, and a Member in 1877. He was first elected to the Council in 1894, served as Vice-President in 1895 and 1899, and in 1903 was elected President. It was in this year that the International Telegraph Conference was held in London, and the wisdom of the Institution in selecting so prominent a telegraph member as its premier officer was abundantly justified. The principal social function in connection with the Conference was a concert at the Albert Hall to which Mr. Gray invited all the members of the Institution to meet the delegates of the Congress. Excursions to Warwick Castle, Shakespeare's birthplace, and other historic localities, were organized and personally conducted by Mr. Gray, as well as visits to places of technical interest nearer London. The success of these excursions was remarked by all. Everything was foreseen and nothing happened that ought not to have happened. Mr. Gray organized these functions himself. He was the general, each department had its lieutenant, and the visitors, whilst appreciative of the results, were ignorant of the organization and the military precision by which such results were obtained. He was in charge of the foreign visits to Italy and St. Louis, ensuring for the members instructive and enjoyable trips, and for the Institution a representation in harmony with its position and traditions. To the Town Council of Colchester

he presented in 1904 the picture by A. Ackland Hunt of Gilbert showing his experiments to Queen Elizabeth and her Court. As a mark of appreciation of his services his colleagues on the Council and past members presented him in 1905 with his portrait painted by Miss Beatrice Bright, daughter of the late Sir Charles Bright. A replica of the same portrait painted by the same artist was also presented to the Institution. In the year of his presidency the Institution sustained a very serious loss in the death of Mr. McMillan, the Secretary, whose untiring labours and single-minded devotion established a tradition which will long prevail. For some time Mr. Gray practically added the administrative duties of the Secretary to those of the President. He took exceptional care in the appointment of a new Secretary, organized a Committee for the purpose and took a leading part in its deliberations. It was found that the Articles of Association prevented the Institution making a suitable acknowledgment of Mr. McMillan's services by a pension or allowance to his widow and children, and Mr. Gray instituted that subscription from the members which made some amends for the lack of suitable acknowledgment from the Institution's funds. He represented the Institution on the governing bodies of the Imperial College of Science and Technology, and the National Physical Laboratory. For many years past Mr. Gray acted as Chairman of the Finance Committee of the Institution. It was a position for which he was admirably adapted. Sound in judgment, careful in details, he handled small things and great in a manner to attain the best results. He took great interest in the acquisition of the new building and its alteration, considered with much care the financial aspect, and was keenly appreciative of the satisfactory outcome. It has been well said of him that he was "the most beloved man in the broad community that centres upon the electrical and telegraph industry in this country," and it may perhaps with equal truth be said that the Institution of Electrical Engineers was by him the most beloved of the interests which occupied his time and thoughts. He cherished the objects of the Institution, was jealous of its honour and prestige, concerned that its influence should not be invoked for doubtful causes, proud of its progress, and solicitous for its continued welfare. He made no claims to oratory. He spoke with brevity, but with a sincerity and conviction which appealed with effect to every listener. Yet it was not as a speaker in a large gathering but when with "Friends in Council," as Chairman or Member of Committees, that his magnetism was most effective. Sincerity and unselfishness were his dominating characteristics, and thoughtful kindness their constant manifestation. At the Albert Hall and other similar celebrations it was the Institution that was in the forefront and not Robert Gray; at Colchester he presented a picture on behalf of subscribers, but the preponderance (as is probable) of his own subscription was never considered. And it was the same in every action for the Institution. His was the word and the work of a man who sought the end and in the means thought not at all of himself. Esteemed as he was by his colleagues and every member of the staff the universal reflection must be that "take him for all in all we shall not look upon his like again." J. E. K.

JOHN WYKEHAM JACOMB-HOOD was born in 1859 and was educated at Tonbridge School and at the Crystal

Palace School of Engineering. He became a pupil to the then chief engineer to the London & South-Western Railway Company in 1875. From 1878 to 1887 he served in the capacity of assistant engineer to the Company, carrying out the construction of various new works. For the next eight years he was District Engineer in charge of the way and works in the London district, afterwards being transferred in 1895 to the Western district. In 1901 he became Chief Resident Engineer, a position that he held until his death, which took place suddenly at a meet of the Dulverton Hounds on the 6th March, 1914. He was responsible for the carrying out and maintenance of much of the electrical work of the Company, and took great interest in the question of electrification. In recent years his most important work was in connection with the enlargement and reconstruction of Waterloo Station. He was elected a Member of the Institution in 1904.

WALTER AMBROSE PEARSON died at New York on the 25th January, 1914, at the age of 44. After receiving a four years' training he entered the service, in 1890, of the West End Street Railway Company of Boston (Mass.) as Superintendent of Construction. He filled this post for three years, and then took charge of the power station of the Brooklyn Heights Railroad Company. In 1896 he was appointed Electrical Engineer to the Metropolitan Street Railway Company of New York—a post which he held for 10 years, until he became Chief Engineer to the Electrical Development Company which was engaged in constructional work at the Niagara Falls of transmission lines and transformer stations. Four years afterwards he became Assistant General Manager to the Rio de Janeiro Tramways, Light, and Power Company, but had to return to the United States in 1912 owing to ill-health. He was elected a Member of the Institution in 1909.

SIR WILLIAM HENRY PREECE, K.C.B., a Past President of the Institution, passed away on the 6th November, 1913, in his 80th year. He was one of those who had witnessed the entire growth of modern electrical engineering and who had himself all through his life taken the most active share in its development. Educated at King's College, London, of which he afterwards became a Fellow, and commencing his career under the late Mr. Edward Clark, he entered the service of the Electric and International Telegraph Company in 1854, becoming Superintendent of the Southern District in 1856. He also held concurrently the positions of Superintendent of Telegraphs on the London & South-Western Railway and Engineer of the Channel Islands Telegraph Company. He was likewise, prior to the foundation of Cooper's Hill College, selected by the Indian Government as the Telegraph Engineer, under whom entrants to the Indian Telegraph service received their practical training, and some 60 or 70 of these gentlemen passed through his hands. From the earliest days of electrical engineering, and during the whole of his career, he was always in the forefront in all new extensions of the range of the science, and apart from his own inventions, many useful developments were helped materially by his forceful advocacy. During his period of office as Superintendent of Telegraphs on the London & South-Western Railway, he invented

his method of signalling the movements of trains on railways by the introduction of miniature reproductions of the outdoor signals, worked electrically from the distant cabins, together with many other devices to secure the safety of railway working, and he helped largely in the general adoption of the block system for railways in the United Kingdom. When in 1870 the various telegraph companies, about 30 in number, which were engaged in the business of transmitting telegrams in this country were transferred to the State, Mr. Preece, as he then was, became a Divisional Engineer under the Post Office. In 1877 he became the Electrician, and from 1892 to 1899, when he retired, he carried out the duties of Engineer-in-Chief to the Post Office. He was made a C.B. in 1894, and became a K.C.B. five years later. He materially improved the telegraph system in this country, devoting his attention primarily to methods of high speed and multiplex systems of working, whereby he so increased the carrying capacity of existing wires as to provide for the enormous increase of traffic arising from the reduction of rates with only a reasonable increase of external plant. Telephones, electric lighting, traction, and all other modern applications of electricity equally engaged his attention. He was a prolific writer, an admirable lecturer, and he acquired a world-wide reputation as one of the foremost electrical engineers of the age. On his retirement from the Post Office Sir William Preece entered into partnership with two of his sons and Major Philip Cardew as consulting engineers in Westminster. Latterly Sir William had resided at Carnarvon, but he still continued to take the warmest interest in the welfare of the Institution and missed no opportunity of extending its interest and prestige.

Sir William had acted as a member of the Council of the Institution almost from its inception. He served as Vice-President in the years 1877-1879, and was elected President in 1880 and again in 1893. He contributed innumerable papers to the Proceedings of the Institution as he did also to those of the Institution of Civil Engineers, the British Association, the Royal Society of Arts, and the Physical Society. He acted as the representative of the Institution at the opening of the United Engineering Societies' building in New York and at the Franklin bicentenary celebration. He was President of the Institution of Civil Engineers in 1898.

J. G.

ALFRED RICHMOND SILLAR, born on the 22nd April, 1871, was educated at Shrewsbury and at the City and Guilds Technical Institute, Finsbury. He served a two years' apprenticeship with the Electrical Engineering Corporation, and was then employed by Messrs. J. G. Statter & Co., first as an improver, and subsequently as outside foreman. In 1895 he became Outside Manager to Messrs. Foote & Milne, and a year later was appointed Resident Engineer to the Blackpool Winter Garden and Pavilion Company, where he had charge of what was at that time one of the largest private installations in this country. In 1899 he was appointed Resident Electrical Engineer at Colchester, and also supervised the construction of the electric tramways in that town. He left Colchester in 1911 on being appointed Chief Engineer to the Chinese Chartered Electric Lighting Company of Peking, which position he occupied until his death on the

20th May, 1914. He joined the Institution in 1892 as a Student, and was elected an Associate in 1895, an Associate Member in 1901, and a Member in 1904.

SIR JOSEPH WILSON SWAN, a Past President and an Honorary Member of the Institution, died on 27th May, 1914, at the age of 85. Most people identify Swan with the incandescent lamp, and forget what a prolific inventor he was in other directions. Naturally, the Institution is more interested in his electrical work, but his other inventions must not be forgotten. He was essentially a careful and painstaking observer, and an indefatigable worker with infinite resource in tackling the difficulties that came up in the development of new processes. His work in photography includes the perfection of the dry plate. It is true that there were dry plates of a sort before he took the matter up, but we owe the modern rapid gelatino-bromide plate to him. The application of the same emulsion to paper, producing bromide paper, is also his invention. Though not the actual inventor of the carbon, or Autotype, process, he is entitled to the credit for producing the first practicable process. From it was evolved the present-day photogravure process, and this also gave rise to a sort of intaglio printing on power presses, for newspaper work, the ink being thicker where the hollow is deep, with the result that when dry it is darker. By this means all the shades or tones of the original are obtained, so that the impressions are practically duplicates of the original carbon print, showing all the gradations with no visible grain due to any screen. He also applied the screen to reproducing half tones in relief blocks with ordinary ink, and was thus a pioneer in what is generically called process work. Mr. Swan, as he then was, entered into partnership with Mr. Mawson when quite a young man. Mr. Mawson was killed by the explosion of some nitro-glycerine which had been found in Newcastle. This was in the time of the "Fenians," and Mr. Mawson had to superintend the destruction of the nitro-glycerine, which was to be run into the earth on the Town Moor. There was no means of knowing what caused the explosion, as there were no survivors; but it is supposed that some of the nitro-glycerine was frozen, and that a workman tried to help it out with a spade. Mr. Swan thus had the whole responsibility of the firm on his own shoulders. Part became "Mawson, Swan & Morgan" and devoted its attention to books, stationery, and so on; but "Mawson & Swan" became the leading house in the North for chemicals and scientific apparatus, and especially for photographic goods. In wet-plate days "Mawson's Collodion" was in universal demand, and even now, owing to its employment for photo-mechanical processes, it has a very large sale. Then came the Swan dry plates with the ferrous-oxalate developer, and these still enjoy wide popularity. The firm also made ink and yeast.

The incandescent lamp interests us more. There has been much discussion as to whether Swan or Edison invented the incandescent lamp. In fact, invention practically always consists in outstripping competitors; but in this case Edison and Swan were hardly racing, as they were on different roads. In 1878 there was a great exhibition in Paris, and the Jablockhoff and some other arc lights were shown. The great problem of the day was what was

called "The Subdivision of the Electric Light." The only dynamo in common use was the Gramme, which was series wound. Dynamo design was not understood then, and these machines though series wound had drooping characteristics, and worked one arc each. It is very difficult for modern engineers to carry their minds back to those days. The Jablockhoff was one solution of the subdivision problem, as one dynamo worked several lamps. The Brush series system of 1878 was another. Very advanced electrical engineers of those days could see the difference between the series and the parallel arrangement of lamps. Edison fully realized that parallel distribution must be used for lighting a town, and it was possible only with what was then a very high pressure, about 100 volts, and a small current for each lamp. He also realized that carbon is permanent in a vacuum; and he took out the classical patent for a lamp with a carbon filament of high resistance in a vacuum. The Edison invention was really the true solution of the problem of the subdivision of electric light. Edison had been working at a platinum lamp for some years, and though he took out this patent, he apparently went on working at platinum and took up the carbon lamp seriously somewhat later. Swan, on the other hand, does not seem to have concerned himself at first with questions of distribution; he tackled the problem of making a practical carbon incandescent lamp. He began with a low-pressure lamp, having a small rod of carbon, and then when he had found that the material carbon was right, he turned his attention to making it of high enough resistance to be useful for parallel running. It is very hard for us to realize the difficulties of working out such an invention. He was essentially a practical chemist with an extraordinary knowledge of commercial chemistry, but he was not a trained electrician, nor was he a physicist. He found an enthusiastic collaborator in Mr. C. H. Stearn, who had already done work with the Sprengel pump; and while Mr. Swan worked at the preparation of the filaments in Newcastle, Mr. Stearn, and his able assistant, Mr. F. Topham, did the exhausting. In those days there were no good measuring instruments. There were electrodynamos, which were not direct reading, and not very accurate; but these instruments were practically useless for lamp work, as if the current instrument was between the voltmeter terminals the pressure read was too high, and if the current instrument was outside it included the voltmeter current, and people in those days did not think of such things. Moreover, the generator was always a series-wound dynamo driven by a gas-engine with a "hit and miss" governor and a rise of pressure at every explosion. Swan first proved that carbon was suitable, and then set to work to find out a practical way of making fine carbon threads. He worked out the parchementized cotton process, and later a method of squirting nitro-cellulose and reducing the thread with ammonium sulphide. The squirting process is now in universal use for carbon lamps, a solution of cellulose in zinc chloride, or "viscose," being used. In the Inventions Exhibition of 1885 he showed a beautiful lace handkerchief made entirely of squirted cellulose. This was, however, subsequent to Chardonnets' first patents. The method of mounting the filament on the leading-in wires by short-circuiting the joints under some such liquid as benzol, or benzol and aniline, was

another great advance. There was great difficulty in mounting a carbon satisfactorily. He was also one of the pioneers in the development of the secondary battery. About 1880 Planté had called attention to the possibilities of the secondary battery. He used plain lead plates and "formed" them. Faure had brought out a pasted plate, but it was not satisfactory. Swan and J. S. Sellon were early workers on lead plates with large surfaces so that they could be formed, and on plates designed to hold an applied coating and to keep in good contact with it. The last of Swan's important inventions is the addition of small quantities of such bodies as glue or gelatine to a copper deposition bath. This, under proper conditions, enables the deposit to be made very rapidly, and is thus of great commercial importance. Generally speaking, an inventor—even a great inventor—makes only one invention in his life-time. Swan, on the other hand, seems to have been perfecting one invention after another during the greater part of a long life; and it is when all his work is considered that one gets an idea of the real greatness of the man. He was a great judge of character, and in most cases chose his assistants and co-workers well; his great ability, and his kindly character and great natural goodness, attached his subordinates to him with great affection and loyalty. He was elected a Member of the Institution in 1881, was President in

1898-1899, and was made an Honorary Member in 1900. He was also a Fellow of the Royal Society, a Chevalier of the Legion of Honour, the first President of the Faraday Society—apparently being chosen as the most eminent and best example of the combination of the knowledge of science and of its applications—President of the Society of Chemical Industry, and the recipient of the Albert Medal of the Royal Society of Arts. He was knighted in 1904. After a long and extraordinarily useful life he died full of honours, all well deserved.

J. S.

WILLIAM ROWAN WILSON was born at Partick, Glasgow, on the 14th February, 1872, and was educated at Glasgow Academy and at Glasgow University. After taking his B.Sc. degree he assisted Lord Kelvin for some time. He then entered the Glasgow Corporation Electricity Department, and from there went to Messrs. John Fleming & Co., Bombay, the Indian house of Messrs. Thomas Wilson & Co. of London. He subsequently became Manager of the New Edgerton Woollen Mills, Dhariwall, India, and later was fitting up the electric light installation for Simla when he was appointed Director of Industries at Cawnpore. He had to retire owing to ill-health, and he died at Glasgow on the 9th December, 1913, at the age of 41. He was elected an Associate of the Institution in 1896 and a Member in 1898.

INDEX TO VOL. 52.

1914.

EXPLANATION OF ABBREVIATIONS.

- (P) indicates a reference to the general title or subject of a paper or address.
 (p) indicates a reference to a subject dealt with in a paper or address of which the title is not quoted.
 (D) indicates a reference to a discussion upon a paper or address of which the general title or subject is quoted.
 (d) indicates a reference to a subject dealt with in a discussion on a paper or address of which the general title is not quoted.
